Preface (U. Shmueli) .. xiii

Preface to the second edition (U. Shmueli) .. xiii

Preface to the third edition (U. Shmueli) .. xiv

PART 1. GENERAL RELATIONSHIPS AND TECHNIQUES

1.1. Reciprocal space in crystallography (U. Shmueli) .. 2

1.1.1. Introduction .. 2

1.1.2. Reciprocal lattice in crystallography .. 2

1.1.3. Fundamental relationships .. 3

1.1.4. Tensor-algebraic formulation .. 5

1.1.5. Transformations .. 7

1.1.6. Some analytical aspects of the reciprocal space .. 8

1.2. The structure factor (P. Coppens) .. 10

1.2.1. Introduction .. 10

1.2.2. General scattering expression for X-rays .. 10

1.2.3. Scattering by a crystal: definition of a structure factor .. 10

1.2.4. The isolated-atom approximation in X-ray diffraction .. 10

1.2.5. Scattering of thermal neutrons .. 11

1.2.6. Effect of bonding on the atomic electron density within the spherical-atom approximation: the kappa formalism .. 11

1.2.7. Beyond the spherical-atom description: the atom-centred spherical harmonic expansion .. 12

1.2.8. Fourier transform of orbital products .. 15

1.2.9. The atomic temperature factor .. 17

1.2.10. The vibrational probability distribution and its Fourier transform in the harmonic approximation .. 17

1.2.11. Rigid-body analysis .. 18

1.2.12. Treatment of anharmonicity .. 20

1.2.13. The generalized structure factor .. 22

1.2.14. Conclusion .. 22

1.3. Fourier transforms in crystallography: theory, algorithms and applications (G. Bricogne) .. 24

1.3.1. General introduction .. 24

1.3.2. The mathematical theory of the Fourier transformation .. 24

1.3.3. Numerical computation of the discrete Fourier transform .. 52

1.3.4. Crystallographic applications of Fourier transforms .. 62

1.4. Symmetry in reciprocal space (U. Shmueli) .. 114

1.4.1. Introduction .. 114

1.4.2. Effects of symmetry on the Fourier image of the crystal .. 114

1.4.3. Structure-factor tables .. 117

1.4.4. Symmetry in reciprocal space: space-group tables .. 119

Appendix A1.4.1. Comments on the preparation and usage of the tables .. 122

Appendix A1.4.2. Space-group symbols for numeric and symbolic computations (U. Shmueli, S. R. Hall and R. W. Grosse-Kunstleve) .. 122

Appendix A1.4.3. Structure-factor tables .. 135

Appendix A1.4.4. Crystallographic space groups in reciprocal space .. 162

1.5. Crystallographic viewpoints in the classification of space-group representations (M. I. Aroyo and H. Wondratschek) .. 175

1.5.1. List of abbreviations and symbols .. 175

1.5.2. Introduction .. 175

1.5.3. Basic concepts .. 176

1.5.4. Conventions in the classification of space-group irreps .. 179
1.5.5. Examples and discussion .. 182
1.5.6. Conclusions .. 191
Appendix A1.5.1. Reciprocal-space groups $(\mathcal{G})^*$ .. 192

PART 2. RECIPROCAL SPACE IN CRYSTAL-STRUCTURE DETERMINATION

2.1. Statistical properties of the weighted reciprocal lattice (U. Shmueli and A. J. C. Wilson) .. 195
2.1.1. Introduction .. 195
2.1.2. The average intensity of general reflections .. 195
2.1.3. The average intensity of zones and rows .. 196
2.1.4. Probability density distributions – mathematical preliminaries .. 197
2.1.5. Ideal probability density distributions .. 200
2.1.6. Distributions of sums, averages and ratios .. 202
2.1.7. Non-ideal distributions: the correction-factor approach .. 203
2.1.8. Non-ideal distributions: the Fourier method .. 207

2.2. Direct methods (C. Giacovazzo) .. 215
2.2.1. List of symbols and abbreviations .. 215
2.2.2. Introduction .. 215
2.2.3. Origin specification .. 215
2.2.4. Normalized structure factors .. 216
2.2.5. Phase-determining formulae .. 221
2.2.6. Direct methods in real and reciprocal space: Sayre's equation .. 230
2.2.7. Scheme of procedure for phase determination: the small-molecule case .. 231
2.2.8. Other multisolution methods applied to small molecules .. 232
2.2.9. Some references to direct-methods packages: the small-molecule case .. 234
2.2.10. Direct methods in macromolecular crystallography .. 235

2.3. Patterson and molecular replacement techniques, and the use of noncrystallographic symmetry in phasing (L. Tong, M. G. Rossmann and E. Arnold) .. 244
2.3.1. Introduction .. 244
2.3.2. Interpretation of Patterson maps .. 247
2.3.3. Isomorphous replacement difference Pattersons .. 251
2.3.4. Anomalous dispersion .. 255
2.3.5. Noncrystallographic symmetry .. 258
2.3.6. Rotation functions .. 260
2.3.7. Translation functions .. 269
2.3.8. Molecular replacement .. 272
2.3.9. Conclusions .. 275

2.4. Isomorphous replacement and anomalous scattering (M. Vijayan and S. Ramaseshan) .. 282
2.4.1. Introduction .. 282
2.4.2. Isomorphous replacement method .. 282
2.4.3. Anomalous-scattering method .. 284
2.4.4. Isomorphous replacement and anomalous scattering in protein crystallography .. 287
2.4.5. Anomalous scattering of neutrons and synchrotron radiation. The multiwavelength method .. 293

2.5. Electron diffraction and electron microscopy in structure determination (J. M. Cowley, J. C. H. Spence, M. Tanaka, B. K. Vainshtein, B. B. Zvyagin, P. A. Penczek and D. L. Dorset) .. 297
2.5.1. Foreword (J. M. Cowley and J. C. H. Spence) .. 297
2.5.2. Electron diffraction and electron microscopy (J. M. Cowley) .. 299
2.5.3. Point-group and space-group determination by convergent-beam electron diffraction (M. Tanaka) .. 307

2.5.4. Electron-diffraction structure analysis (EDSA) (B. K. Vainshtein and B. B. Zvyagin) .. 356
2.5.5. Image reconstruction (B. K. Vainshtein) .. 361
2.5.6. Three-dimensional reconstruction (B. K. Vainshtein and P. A. Penczek) .. 366
2.5.7. Single-particle reconstruction (P. A. Penczek) .. 375
2.5.8. Direct phase determination in electron crystallography (D. L. Dorset) .. 388

PART 3. DUAL BASES IN CRYSTALLOGRAPHIC COMPUTING

3.1. Distances, angles, and their standard uncertainties (D. E. Sands) .. 404
3.1.1. Introduction .. 404
3.1.2. Scalar product .. 404
3.1.3. Length of a vector .. 404
3.1.4. Angle between two vectors .. 404
3.1.5. Vector product .. 405
3.1.6. Permutation tensors .. 405
3.1.7. Components of vector product .. 405
3.1.8. Some vector relationships .. 405
3.1.9. Planes .. 406
3.1.10. Variance–covariance matrices .. 406
3.1.11. Mean values .. 408
3.1.12. Computation .. 408

3.2. The least-squares plane (R. E. Marsh and V. Schomaker) .. 410
3.2.1. Introduction .. 410
3.2.2. Least-squares plane based on uncorrelated, isotropic weights .. 410
3.2.3. The proper least-squares plane, with Gaussian weights .. 413
Appendix A3.2.1 .. 416

3.3. Molecular modelling and graphics (R. Diamond and L. M. D. Cranswick) .. 418
3.3.1. Graphics (R. Diamond) .. 418
3.3.2. Molecular modelling, problems and approaches (R. Diamond) .. 434
3.3.3. Implementations (R. Diamond) .. 438
3.3.4. Graphics software for the display of small and medium-sized molecules (L. M. D. Cranswick) .. 442

3.4. Accelerated convergence treatment of R^{-n} lattice sums (D. E. Williams) .. 449
3.4.1. Introduction .. 449
3.4.2. Definition and behaviour of the direct-space sum .. 449
3.4.3. Preliminary description of the method .. 449
3.4.4. Preliminary derivation to obtain a formula which accelerates the convergence of an R^{-n} sum over lattice points X(d) .. 450
3.4.5. Extension of the method to a composite lattice .. 452
3.4.6. The case of $n = 1$ (Coulombic lattice energy) .. 453
3.4.7. The cases of $n = 2$ and $n = 3$ .. 454
3.4.8. Derivation of the accelerated convergence formula *via* the Patterson function .. 454
3.4.9. Evaluation of the incomplete gamma function .. 454
3.4.10. Summation over the asymmetric unit and elimination of intramolecular energy terms .. 455
3.4.11. Reference formulae for particular values of n .. 455
3.4.12. Numerical illustrations .. 456

3.5. Extensions of the Ewald method for Coulomb interactions in crystals (T. A. Darden) .. 458
3.5.1. Introduction .. 458
3.5.2. Lattice sums of point charges .. 460
3.5.3. Generalization to Gaussian- and Hermite-based continuous charge distributions .. 471
3.5.4. Computational efficiency .. 474

PART 4. DIFFUSE SCATTERING AND RELATED TOPICS

4.1. Thermal diffuse scattering of X-rays and neutrons (B. T. M. Willis) .. 484
4.1.1. Introduction .. 484
4.1.2. Dynamics of three-dimensional crystals .. 484
4.1.3. Scattering of X-rays by thermal vibrations .. 487
4.1.4. Scattering of neutrons by thermal vibrations .. 488
4.1.5. Phonon dispersion relations .. 489
4.1.6. Measurement of elastic constants .. 490

4.2. Disorder diffuse scattering of X-rays and neutrons (F. Frey, H. Boysen and H. Jagodzinski) .. 492
4.2.1. Introduction .. 492
4.2.2. Basic scattering theory .. 493
4.2.3. Qualitative treatment of structural disorder .. 495
4.2.4. General guidelines for analysing a disorder problem .. 507
4.2.5. Quantitative interpretation .. 509
4.2.6. Disorder diffuse scattering from aperiodic crystals .. 526
4.2.7. Computer simulations and modelling .. 528
4.2.8. Experimental techniques and data evaluation .. 530

4.3. Diffuse scattering in electron diffraction (J. M. Cowley and J. K. Gjønnes) .. 540
4.3.1. Introduction .. 540
4.3.2. Inelastic scattering .. 541
4.3.3. Kinematical and pseudo-kinematical scattering .. 542
4.3.4. Dynamical scattering: Bragg scattering effects .. 542
4.3.5. Multislice calculations for diffraction and imaging .. 544
4.3.6. Qualitative interpretation of diffuse scattering of electrons .. 544

4.4. Scattering from mesomorphic structures (P. S. Pershan) .. 547
4.4.1. Introduction .. 547
4.4.2. The nematic phase .. 549
4.4.3. Smectic-A and smectic-C phases .. 551
4.4.4. Phases with in-plane order .. 554
4.4.5. Discotic phases .. 561
4.4.6. Other phases .. 561

4.5. Polymer crystallography (R. P. Millane and D. L. Dorset) .. 567
4.5.1. Overview (R. P. Millane and D. L. Dorset) .. 567
4.5.2. X-ray fibre diffraction analysis (R. P. Millane) .. 568
4.5.3. Electron crystallography of polymers (D. L. Dorset) .. 583

4.6. Reciprocal-space images of aperiodic crystals (W. Steurer and T. Haibach) .. 590
4.6.1. Introduction .. 590
4.6.2. The *n*-dimensional description of aperiodic crystals .. 591
4.6.3. Reciprocal-space images .. 598
4.6.4. Experimental aspects of the reciprocal-space analysis of aperiodic crystals .. 621

PART 5. DYNAMICAL THEORY AND ITS APPLICATIONS

5.1. Dynamical theory of X-ray diffraction (A. Authier) .. 626
5.1.1. Introduction .. 626
5.1.2. Fundamentals of plane-wave dynamical theory .. 626
5.1.3. Solutions of plane-wave dynamical theory .. 630
5.1.4. Standing waves .. 633
5.1.5. Anomalous absorption .. 633

5.1.6. Intensities of plane waves in transmission geometry .. 634
5.1.7. Intensity of plane waves in reflection geometry .. 638
5.1.8. Real waves .. 640
Appendix A5.1.1. Basic equations .. 642

5.2. Dynamical theory of electron diffraction (A. F. Moodie, J. M. Cowley and P. Goodman) .. 647
5.2.1. Introduction .. 647
5.2.2. The defining equations .. 647
5.2.3. Forward scattering .. 647
5.2.4. Evolution operator .. 648
5.2.5. Projection approximation – real-space solution .. 648
5.2.6. Semi-reciprocal space .. 648
5.2.7. Two-beam approximation .. 649
5.2.8. Eigenvalue approach .. 649
5.2.9. Translational invariance .. 650
5.2.10. Bloch-wave formulations .. 650
5.2.11. Dispersion surfaces .. 650
5.2.12. Multislice .. 651
5.2.13. Born series .. 651
5.2.14. Approximations .. 652

5.3. Dynamical theory of neutron diffraction (M. Schlenker and J.-P. Guigay) .. 654
5.3.1. Introduction .. 654
5.3.2. Comparison between X-rays and neutrons with spin neglected .. 654
5.3.3. Neutron spin, and diffraction by perfect magnetic crystals .. 655
5.3.4. Extinction in neutron diffraction (nonmagnetic case) .. 658
5.3.5. Effect of external fields on neutron scattering by perfect crystals .. 659
5.3.6. Experimental tests of the dynamical theory of neutron scattering .. 659
5.3.7. Applications of the dynamical theory of neutron scattering .. 660

Author index .. 665

Subject index .. 675

Preface

By Uri Shmueli

The purpose of Volume B of *International Tables for Crystallography* is to provide the user or reader with accounts of some well established topics, of importance to the science of crystallography, which are related in one way or another to the concepts of reciprocal lattice and, more generally, reciprocal space. Efforts have been made to extend the treatment of the various topics to include X-ray, electron, and neutron diffraction techniques, and thereby do some justice to the inclusion of the present Volume in the new series of *International Tables for Crystallography*.

An important crystallographic aspect of symmetry in reciprocal space, space-group-dependent expressions of trigonometric structure factors, already appears in Volume I of *International Tables for X-ray Crystallography*, and preliminary plans for incorporating this and other crystallographic aspects of reciprocal space in the new edition of *International Tables* date back to 1972. However, work on a volume of *International Tables for Crystallography*, largely dedicated to the subject of reciprocal space, began over ten years later. The present structure of Volume B, as determined in the years preceding the 1984 Hamburg congress of the International Union of Crystallography (IUCr), is due to (i) computer-controlled production of concise structure-factor tables, (ii) the ability to introduce many more aspects of reciprocal space – as a result of reducing the effort of producing the above tables, as well as their volume, and (iii) suggestions by the National Committees and individual crystallographers of some additional interesting topics. It should be pointed out that the initial plans for the present Volume and Volume C (*Mathematical, Physical and Chemical Tables*, edited by Professor A. J. C. Wilson), were formulated and approved during the same period.

The obviously delayed publication of Volume B is due to several reasons. Some minor delays were caused by a requirement that potential contributors should be approved by the Executive Committee prior to issuing relevant invitations. Much more serious delays were caused by authors who failed to deliver their contributions. In fact, some invited contributions had to be excluded from this first edition of Volume B. Some of the topics here treated are greatly extended, considerably updated or modern versions of similar topics previously treated in the old Volumes I, II, and IV. Most of the subjects treated in Volume B are new to *International Tables*.

I gratefully thank Professor A. J. C. Wilson, for suggesting that I edit this Volume and for sharing with me his rich editorial experience. I am indebted to those authors of Volume B who took my requests and deadlines seriously, and to the Computing Center of Tel Aviv University for computing facilities and time. Special thanks are due to Mrs Z. Stein (Tel Aviv University) for skilful assistance in numeric and symbolic programming, involved in my contributions to this Volume.

I am most grateful to many colleagues–crystallographers for encouragement, advice, and suggestions. In particular, thanks are due to Professors J. M. Cowley, P. Goodman and C. J. Humphreys, who served as Chairmen of the Commission on Electron Diffraction during the preparation of this Volume, for prompt and expert help at all stages of the editing. The kind assistance of Dr J. N. King, the Executive Secretary of the IUCr, is also gratefully acknowledged. Last, but certainly not least, I wish to thank Mr M. H. Dacombe, the Technical Editor of the IUCr, and his staff for the skilful and competent treatment of the variety of drafts and proofs out of which this Volume arose.

Preface to the second edition

By Uri Shmueli

The first edition of Volume B appeared in 1993, and was followed by a corrected reprint in 1996. Although practically all the material for the second edition was available in early 1997, its publication was delayed by the decision to translate all of Volume B, and indeed all the other volumes of *International Tables for Crystallography*, to Standard Generalized Markup Language (SGML) and thus make them available also in an electronic form suitable for modern publishing procedures.

During the preparation of the second edition, most chapters that appeared in the first edition have been corrected and/or revised, some were rather extensively updated, and five new chapters were added. The overall structure of the second edition is outlined below.

After an introductory chapter, Part 1 presents the reader with an account of structure-factor formalisms, an extensive treatment of the theory, algorithms and crystallographic applications of Fourier methods, and treatments of symmetry in reciprocal space. These are here enriched with more advanced aspects of representations of space groups in reciprocal space.

In Part 2, these general accounts are followed by detailed expositions of crystallographic statistics, the theory of direct methods, Patterson techniques, isomorphous replacement and anomalous scattering, and treatments of the role of electron microscopy and diffraction in crystal structure determination. The latter topic is here enhanced by applications of direct methods to electron crystallography.

Part 3, *Dual Bases in Crystallographic Computing*, deals with applications of reciprocal space to molecular geometry and 'best'-plane calculations, and contains a treatment of the principles of molecular graphics and modelling and their applications; it concludes with the presentation of a convergence-acceleration method, of importance in the computation of approximate lattice sums.

Part 4 contains treatments of various diffuse-scattering phenomena arising from crystal dynamics, disorder and low dimensionality (liquid crystals), and an exposition of the underlying theories and/or experimental evidence. The new additions to this part are treatments of polymer crystallography and of reciprocal-space images of aperiodic crystals.

Part 5 contains introductory treatments of the theory of the interaction of radiation with matter, the so-called dynamical theory, as applied to X-ray, electron and neutron diffraction techniques. The chapter on the dynamical theory of neutron diffraction is new.

I am deeply grateful to the authors of the new contributions for making their expertise available to Volume B and for their excellent collaboration. I also take special pleasure in thanking

those authors of the first edition who revised and updated their contributions in view of recent developments. Last but not least, I wish to thank all the authors for their contributions and their patience, and am grateful to those authors who took my requests seriously. I hope that the updating and revision of future editions will be much easier and more expedient, mainly because of the new format of *International Tables*.

Four friends and greatly respected colleagues who contributed to the second edition of Volume B are no longer with us. These are Professors Arthur J. C. Wilson, Peter Goodman, Verner Schomaker and Boris K. Vainshtein. I asked Professors Michiyoshi Tanaka, John Cowley and Douglas Dorset if they were prepared to answer queries related to the contributions of the late Peter Goodman and Boris K. Vainshtein to Chapter 2.5. I am most grateful for their prompt agreement.

This editorial work was carried out at the School of Chemistry and the Computing Center of Tel Aviv University. The facilities they put at my disposal are gratefully acknowledged on my behalf and on behalf of the IUCr. I wish to thank many colleagues for interesting conversations and advice, and in particular Professor Theo Hahn with whom I discussed at length problems regarding Volume B and *International Tables* in general.

Given all these expert contributions, the publication of this volume would not have been possible without the expertise and devotion of the Technical Editors of the IUCr. My thanks go to Mrs Sue King, for her cooperation during the early stages of the work on the second edition of Volume B, while the material was being collected, and to Dr Nicola Ashcroft, for her collaboration during the final stages of the production of the volume, for her most careful and competent treatment of the proofs, and last but not least for her tactful and friendly attitude.

Preface to the third edition

By Uri Shmueli

The second edition of Volume B appeared in 2001. Plans for the third edition included the addition of new chapters and sections, the substantial revision of several chapters that existed in the second edition and minor revisions and updating of existing chapters. The overall structure of Volume B remained unchanged.

In Part 1, Chapter 1.5 on classifications of space-group representations in reciprocal space has been extensively revised.

In Part 2, Chapter 2.2 on direct methods has been considerably extended to include applications of these methods to macromolecular crystallography. Chapter 2.3 on Patterson and molecular replacement techniques has been updated and extended. Section 2.5.3 on convergent-beam electron diffraction has been completely rewritten by a newly invited author, and Section 2.5.6 on three-dimensional reconstruction has been updated and extended by a newly invited author, who has also added Section 2.5.7 on single-particle reconstruction. The Foreword to Chapter 2.5 on electron diffraction and microscopy has also been revised.

In Part 3, Chapter 3.3 on computer graphics and molecular modelling has been enriched by Section 3.3.4 on the implementation of molecular graphics to small and medium-sized molecules, and a comprehensive Chapter 3.5 on modern extensions of Ewald methods has been added, dealing with (i) inclusion of fast Fourier transforms in the computation of sums and (ii) departure from the point-charge model in Ewald summations.

In Part 4, Chapter 4.1 on thermal diffuse scattering of X-rays and neutrons has been updated, and Chapter 4.2 on disorder diffuse scattering of X-rays and neutrons has been extensively revised and updated.

Minor updates and corrections have also been made to several existing chapters and sections in all the parts of the volume.

My gratitude is extended to the authors of new contributions and to the authors of the first and second editions of the volume for significant revisions of their chapters and sections in view of new developments. I wish to thank all the authors for their excellent collaboration and for sharing with the *International Tables for Crystallography* their expertise. I hope that the tradition of keeping the contributions up to date will also persist in future editions of Volume B. This will be aided by significant improvements in various aspects of technical editing which were already apparent in the preparation of this edition.

Three greatly respected friends and colleagues who contributed to this and previous editions of Volume B passed away after the second edition of Volume B was published. These are Professors John Cowley, Boris Zvyagin and Donald Williams. I asked Professors John Spence, Douglas Dorset and Pawel Penczek to take care of any questions about the articles of the late John Cowley, Boris Zvyagin and Boris Vainshtein in Chapter 2.5, and Dr Bill Smith to answer any questions about Chapter 3.4 by the late Donald Williams. They all agreed promptly and I am most grateful for this.

My editorial work was carried out at the School of Chemistry of Tel Aviv University and I wish to acknowledge gratefully the facilities that were put at my disposal. I am grateful to many friends and colleagues for interesting conversations and exchanges related to this volume. Thanks are also due to my friends from the IUCr office in Chester for their helpful interest.

Finally, I think that the publication of the third edition of Volume B would not have been possible without the competent, tactful and friendly collaboration of Dr Nicola Ashcroft, the Technical Editor of this project during all the stages of the preparation of this edition.

International Tables for Crystallography (2010). Vol. B, Chapter 1.1, pp. 2–9.

1.1. Reciprocal space in crystallography

By U. Shmueli

1.1.1. Introduction

The purpose of this chapter is to provide an introduction to several aspects of reciprocal space, which are of general importance in crystallography and which appear in the various chapters and sections to follow. We first summarize the basic definitions and briefly inspect some fundamental aspects of crystallography, while recalling that they can be usefully and simply discussed in terms of the concept of the reciprocal lattice. This introductory section is followed by a summary of the basic relationships between the direct and associated reciprocal lattices. We then introduce the elements of tensor-algebraic formulation of such dual relationships, with emphasis on those that are important in many applications of reciprocal space to crystallographic algorithms. We proceed with a section that demonstrates the role of mutually reciprocal bases in transformations of coordinates and conclude with a brief outline of some important analytical aspects of reciprocal space, most of which are further developed in other parts of this volume.

1.1.2. Reciprocal lattice in crystallography

The notion of mutually reciprocal triads of vectors dates back to the introduction of vector calculus by J. Willard Gibbs in the 1880s (*e.g.* Wilson, 1901). This concept appeared to be useful in the early interpretations of diffraction from single crystals (Ewald, 1913; Laue, 1914) and its first detailed exposition and the recognition of its importance in crystallography can be found in Ewald's (1921) article. The following free translation of Ewald's (1921) introduction, presented in a somewhat different notation, may serve the purpose of this section:

> To the set of $\mathbf{a}_i$, there corresponds in the vector calculus a set of 'reciprocal vectors' $\mathbf{b}_i$, which are defined (by Gibbs) by the following properties:
>
> $$\mathbf{a}_i \cdot \mathbf{b}_k = 0 \quad (\text{for } i \neq k) \tag{1.1.2.1}$$
>
> and
>
> $$\mathbf{a}_i \cdot \mathbf{b}_i = 1, \tag{1.1.2.2}$$
>
> where i and k may each equal 1, 2 or 3. The first equation, (1.1.2.1), says that each vector $\mathbf{b}_k$ is perpendicular to two vectors $\mathbf{a}_i$, as follows from the vanishing scalar products. Equation (1.1.2.2) provides the norm of the vector $\mathbf{b}_i$: the length of this vector must be chosen such that the projection of $\mathbf{b}_i$ on the direction of $\mathbf{a}_i$ has the length $1/a_i$, where a_i is the magnitude of the vector $\mathbf{a}_i$ ....

The consequences of equations (1.1.2.1) and (1.1.2.2) were elaborated by Ewald (1921) and are very well documented in the subsequent literature, crystallographic as well as other.

As is well known, the reciprocal lattice occupies a rather prominent position in crystallography and there are nearly as many accounts of its importance as there are crystallographic texts. It is not intended to review its applications, in any detail, in the present section; this is done in the remaining chapters and sections of the present volume. It seems desirable, however, to mention by way of an introduction some fundamental geometrical, physical and mathematical aspects of crystallography, and try to give a unified demonstration of the usefulness of mutually reciprocal bases as an interpretive tool.

Let us assume that the coordinates of all the (direct) lattice points are integers. This can only be true for *P*-type lattices. Consider the equation of a lattice plane in the direct lattice. It can be shown (*e.g.* Buerger, 1941; also Shmueli, 2007) that this equation is given by

$$hx + ky + lz = n, \tag{1.1.2.3}$$

where h, k and l, known as Miller indices of the (hkl) lattice plane, are (under the above assumption) relatively prime integers (*i.e.* do not have a common factor other than $+1$ or -1). In this equation, x, y and z are the coordinates of any point lying in the plane and are expressed as fractions of the magnitudes of the basis vectors $\mathbf{a}$, $\mathbf{b}$ and $\mathbf{c}$ of the direct lattice, and n is an integer denoting the serial number of the lattice plane within the family of parallel and equidistant (hkl) planes. The interplanar spacing is denoted by d_{hkl}, the value $n = 0$ corresponding to the (hkl) plane passing through the origin.

Let $\mathbf{r} = x\mathbf{a} + y\mathbf{b} + z\mathbf{c}$ and $\mathbf{r}_\mathrm{L} = u\mathbf{a} + v\mathbf{b} + w\mathbf{c}$, where u, v, w are any integers, denote the position vectors of the point xyz and a lattice point uvw lying in the plane (1.1.2.3), respectively, and assume that $\mathbf{r}$ and $\mathbf{r}_\mathrm{L}$ are different vectors. If the plane normal is denoted by $\mathbf{N}$, where $\mathbf{N}$ is proportional to the vector product of two in-plane lattice vectors, the vector form of the equation of the lattice plane becomes

$$\mathbf{N} \cdot (\mathbf{r} - \mathbf{r}_\mathrm{L}) = 0 \quad \text{or} \quad \mathbf{N} \cdot \mathbf{r} = \mathbf{N} \cdot \mathbf{r}_\mathrm{L}. \tag{1.1.2.4}$$

For equations (1.1.2.3) and (1.1.2.4) to be identical, the plane normal $\mathbf{N}$ must satisfy the requirement that $\mathbf{N} \cdot \mathbf{r}_\mathrm{L} = n$, where n is an (unrestricted) integer.

While the Miller indices of lattice planes in *P*-type lattices must be relatively prime, if the direct lattice is based on a non-primitive unit cell (any centring type) the Miller indices of some lattice planes are no longer relatively prime (*e.g.* Nespolo, 2015).

Let us now consider the basic diffraction relations (*e.g.* Lipson & Cochran, 1966). Suppose a parallel beam of monochromatic radiation, of wavelength λ, falls on a lattice of identical point scatterers. If it is assumed that the scattering is elastic, *i.e.* there is no change of the wavelength during this process, the wavevectors of the incident and scattered radiation have the same magnitude, which can conveniently be taken as $1/\lambda$. A consideration of path and phase differences between the waves outgoing from two point scatterers separated by the lattice vector $\mathbf{r}_\mathrm{L}$ (defined as above) shows that the condition for their maximum constructive interference is given by

$$(\mathbf{s} - \mathbf{s}_0) \cdot \mathbf{r}_\mathrm{L} = n, \tag{1.1.2.5}$$

where $\mathbf{s}_0$ and $\mathbf{s}$ are the wavevectors of the incident and scattered beams, respectively, and n is an arbitrary integer.

Since $\mathbf{r}_\mathrm{L} = u\mathbf{a} + v\mathbf{b} + w\mathbf{c}$, where u, v and w are unrestricted integers, equation (1.1.2.5) is equivalent to the equations of Laue:

$$\mathbf{h} \cdot \mathbf{a} = h, \quad \mathbf{h} \cdot \mathbf{b} = k, \quad \mathbf{h} \cdot \mathbf{c} = l, \tag{1.1.2.6}$$

where $\mathbf{h} = \mathbf{s} - \mathbf{s}_0$ is the diffraction vector, and h, k and l are integers corresponding to orders of diffraction from the three-dimensional lattice (Lipson & Cochran, 1966). The diffraction vector thus has to satisfy a condition that is analogous to that imposed on the normal to a lattice plane.

The next relevant aspect to be commented on is the Fourier expansion of a function having the periodicity of the crystal lattice. Such functions are *e.g.* the electron density, the density of nuclear matter and the electrostatic potential in the crystal, which are the operative definitions of crystal structure in X-ray, neutron and electron-diffraction methods of crystal structure determination. A Fourier expansion of such a periodic function may be

Copyright © 2010 International Union of Crystallography

thought of as a superposition of waves (*e.g.* Buerger, 1959), with wavevectors related to the interplanar spacings d_{hkl}, in the crystal lattice. Denoting the wavevector of a Fourier wave by $\mathbf{g}$ (a function of hkl), the phase of the Fourier wave at the point $\mathbf{r}$ in the crystal is given by $2\pi\mathbf{g}\cdot\mathbf{r}$, and the triple Fourier series corresponding to the expansion of the periodic function, say $G(\mathbf{r})$, can be written as

$$G(\mathbf{r}) = \sum_{\mathbf{g}} C(\mathbf{g}) \exp(-2\pi i \mathbf{g}\cdot\mathbf{r}), \tag{1.1.2.7}$$

where $C(\mathbf{g})$ are the amplitudes of the Fourier waves, or Fourier coefficients, which are related to the experimental data. Numerous examples of such expansions appear throughout this volume.

The permissible wavevectors in the above expansion are restricted by the periodicity of the function $G(\mathbf{r})$. Since, by definition, $G(\mathbf{r}) = G(\mathbf{r}+\mathbf{r}_{\rm L})$, where $\mathbf{r}_{\rm L}$ is a direct-lattice vector, the right-hand side of (1.1.2.7) must remain unchanged when $\mathbf{r}$ is replaced by $\mathbf{r}+\mathbf{r}_{\rm L}$. This, however, can be true only if the scalar product $\mathbf{g}\cdot\mathbf{r}_{\rm L}$ is an integer.

Each of the above three aspects of crystallography may lead, independently, to a useful introduction of the reciprocal vectors, and there are many examples of this in the literature. It is interesting, however, to consider the representation of the equation

$$\mathbf{v}\cdot\mathbf{r}_{\rm L} = n, \tag{1.1.2.8}$$

which is common to all three, in its most convenient form. Obviously, the vector $\mathbf{v}$ which stands for the plane normal, the diffraction vector, and the wavevector in a Fourier expansion, may still be referred to any permissible basis and so may $\mathbf{r}_{\rm L}$, by an appropriate transformation.

Let $\mathbf{v} = U\mathbf{A} + V\mathbf{B} + W\mathbf{C}$, where $\mathbf{A}$, $\mathbf{B}$ and $\mathbf{C}$ are linearly independent vectors. Equation (1.1.2.8) can then be written as

$$(U\mathbf{A} + V\mathbf{B} + W\mathbf{C})\cdot(u\mathbf{a} + v\mathbf{b} + w\mathbf{c}) = n, \tag{1.1.2.9}$$

or, in matrix notation,

$$(UVW)\begin{pmatrix}\mathbf{A}\\ \mathbf{B}\\ \mathbf{C}\end{pmatrix}\cdot(\mathbf{abc})\begin{pmatrix}u\\ v\\ w\end{pmatrix} = n, \tag{1.1.2.10}$$

or

$$(UVW)\begin{pmatrix}\mathbf{A}\cdot\mathbf{a} & \mathbf{A}\cdot\mathbf{b} & \mathbf{A}\cdot\mathbf{c}\\ \mathbf{B}\cdot\mathbf{a} & \mathbf{B}\cdot\mathbf{b} & \mathbf{B}\cdot\mathbf{c}\\ \mathbf{C}\cdot\mathbf{a} & \mathbf{C}\cdot\mathbf{b} & \mathbf{C}\cdot\mathbf{c}\end{pmatrix}\begin{pmatrix}u\\ v\\ w\end{pmatrix} = n. \tag{1.1.2.11}$$

The simplest representation of equation (1.1.2.8) results when the matrix of scalar products in (1.1.2.11) reduces to a unit matrix. This can be achieved (i) by choosing the basis vectors **ABC** to be orthonormal to the basis vectors **abc**, while requiring that the components of $\mathbf{r}_{\rm L}$ be integers, or (ii) by requiring that the bases **ABC** and **abc** coincide with the same orthonormal basis, *i.e.* expressing both $\mathbf{v}$ and $\mathbf{r}_{\rm L}$, in (1.1.2.8), in the same Cartesian system. If we choose the first alternative, it is seen that:

(1) The components of the vector $\mathbf{v}$, and hence those of $\mathbf{N}$, $\mathbf{h}$ and $\mathbf{g}$, are of necessity integers, since u, v and w are already integral. The components of $\mathbf{v}$ include Miller indices in the case of the lattice plane, they coincide with the orders of diffraction from a three-dimensional lattice of scatterers, and correspond to the summation indices in the triple Fourier series (1.1.2.7).

(2) The basis vectors $\mathbf{A}$, $\mathbf{B}$ and $\mathbf{C}$ are reciprocal to $\mathbf{a}$, $\mathbf{b}$ and $\mathbf{c}$, as can be seen by comparing the scalar products in (1.1.2.11) with those in (1.1.2.1) and (1.1.2.2). In fact, the bases **ABC** and **abc** are mutually reciprocal. Since there are no restrictions on the integers U, V and W, the vector $\mathbf{v}$ belongs to a lattice which, on account of its basis, is called the reciprocal lattice.

It follows that, at least in the present case, algebraic simplicity goes together with ease of interpretation, which certainly accounts for much of the importance of the reciprocal lattice in crystallography. The second alternative of reducing the matrix in (1.1.2.11) to a unit matrix, a transformation of (1.1.2.8) to a Cartesian system, leads to non-integral components of the vectors, which makes any interpretation of $\mathbf{v}$ or $\mathbf{r}_{\rm L}$ much less transparent. However, transformations to Cartesian systems are often very useful in crystallographic computing and will be discussed below (see also Chapters 2.3 and 3.3 in this volume).

We shall, in what follows, abandon all the temporary notation used above and write the reciprocal-lattice vector as

$$\mathbf{h} = h\mathbf{a}^* + k\mathbf{b}^* + l\mathbf{c}^* \tag{1.1.2.12}$$

or

$$\mathbf{h} = h_1\mathbf{a}^1 + h_2\mathbf{a}^2 + h_3\mathbf{a}^3 = \sum_{i=1}^{3} h_i\mathbf{a}^i, \tag{1.1.2.13}$$

and denote the direct-lattice vectors by $\mathbf{r}_{\rm L} = u\mathbf{a} + v\mathbf{b} + w\mathbf{c}$, as above, or by

$$\mathbf{r}_{\rm L} = u^1\mathbf{a}_1 + u^2\mathbf{a}_2 + u^3\mathbf{a}_3 = \sum_{i=1}^{3} u^i\mathbf{a}_i. \tag{1.1.2.14}$$

The representations (1.1.2.13) and (1.1.2.14) are used in the tensor-algebraic formulation of the relationships between mutually reciprocal bases (see Section 1.1.4 below).

1.1.3. Fundamental relationships

We now present a brief derivation and a summary of the most important relationships between the direct and the reciprocal bases. The usual conventions of vector algebra are observed and the results are presented in the conventional crystallographic notation. Equations (1.1.2.1) and (1.1.2.2) now become

$$\mathbf{a}\cdot\mathbf{b}^* = \mathbf{a}\cdot\mathbf{c}^* = \mathbf{b}\cdot\mathbf{a}^* = \mathbf{b}\cdot\mathbf{c}^* = \mathbf{c}\cdot\mathbf{a}^* = \mathbf{c}\cdot\mathbf{b}^* = 0 \tag{1.1.3.1}$$

and

$$\mathbf{a}\cdot\mathbf{a}^* = \mathbf{b}\cdot\mathbf{b}^* = \mathbf{c}\cdot\mathbf{c}^* = 1, \tag{1.1.3.2}$$

respectively, and the relationships are obtained as follows.

1.1.3.1. Basis vectors

It is seen from (1.1.3.1) that $\mathbf{a}^*$ must be proportional to the vector product of $\mathbf{b}$ and $\mathbf{c}$,

$$\mathbf{a}^* = K(\mathbf{b}\times\mathbf{c}),$$

and, since $\mathbf{a}\cdot\mathbf{a}^* = 1$, the proportionality constant K equals $1/[\mathbf{a}\cdot(\mathbf{b}\times\mathbf{c})]$. The mixed product $\mathbf{a}\cdot(\mathbf{b}\times\mathbf{c})$ can be interpreted as the positive volume of the unit cell in the direct lattice only if $\mathbf{a}$, $\mathbf{b}$ and $\mathbf{c}$ form a *right-handed* set. If the above condition is fulfilled, we obtain

$$\mathbf{a}^* = \frac{\mathbf{b}\times\mathbf{c}}{V}, \quad \mathbf{b}^* = \frac{\mathbf{c}\times\mathbf{a}}{V}, \quad \mathbf{c}^* = \frac{\mathbf{a}\times\mathbf{b}}{V} \tag{1.1.3.3}$$

and analogously

$$\mathbf{a} = \frac{\mathbf{b}^*\times\mathbf{c}^*}{V^*}, \quad \mathbf{b} = \frac{\mathbf{c}^*\times\mathbf{a}^*}{V^*}, \quad \mathbf{c} = \frac{\mathbf{a}^*\times\mathbf{b}^*}{V^*}, \tag{1.1.3.4}$$

where V and V^* are the volumes of the unit cells in the associated direct and reciprocal lattices, respectively. Use has been made of the fact that the mixed product, say $\mathbf{a}\cdot(\mathbf{b}\times\mathbf{c})$, remains unchanged under cyclic rearrangement of the vectors that appear in it.

1.1.3.2. Volumes

The reciprocal relationship of V and V^* follows readily. We have from equations (1.1.3.2), (1.1.3.3) and (1.1.3.4)

$$\mathbf{c}\cdot\mathbf{c}^* = \frac{(\mathbf{a}\times\mathbf{b})\cdot(\mathbf{a}^*\times\mathbf{b}^*)}{VV^*} = 1.$$

If we make use of the vector identity

$$(\mathbf{A}\times\mathbf{B})\cdot(\mathbf{C}\times\mathbf{D}) = (\mathbf{A}\cdot\mathbf{C})(\mathbf{B}\cdot\mathbf{D}) - (\mathbf{A}\cdot\mathbf{D})(\mathbf{B}\cdot\mathbf{C}), \quad (1.1.3.5)$$

and equations (1.1.3.1) and (1.1.3.2), it is seen that $V^* = 1/V$.

1.1.3.3. Angular relationships

The relationships of the angles α, β, γ between the pairs of vectors (**b**, **c**), (**c**, **a**) and (**a**, **b**), respectively, and the angles $\alpha^*, \beta^*, \gamma^*$ between the corresponding pairs of reciprocal basis vectors, can be obtained by simple vector algebra. For example, we have from (1.1.3.3):

(i) $\mathbf{b}^*\cdot\mathbf{c}^* = b^*c^*\cos\alpha^*$, with

$$b^* = \frac{ca\sin\beta}{V} \quad \text{and} \quad c^* = \frac{ab\sin\gamma}{V}$$

and (ii)

$$\mathbf{b}^*\cdot\mathbf{c}^* = \frac{(\mathbf{c}\times\mathbf{a})\cdot(\mathbf{a}\times\mathbf{b})}{V^2}.$$

If we make use of the identity (1.1.3.5), and compare the two expressions for $\mathbf{b}^*\cdot\mathbf{c}^*$, we readily obtain

$$\cos\alpha^* = \frac{\cos\beta\cos\gamma - \cos\alpha}{\sin\beta\sin\gamma}. \quad (1.1.3.6)$$

Similarly,

$$\cos\beta^* = \frac{\cos\gamma\cos\alpha - \cos\beta}{\sin\gamma\sin\alpha} \quad (1.1.3.7)$$

and

$$\cos\gamma^* = \frac{\cos\alpha\cos\beta - \cos\gamma}{\sin\alpha\sin\beta}. \quad (1.1.3.8)$$

The expressions for the cosines of the direct angles in terms of those of the reciprocal ones are analogous to (1.1.3.6)–(1.1.3.8). For example,

$$\cos\alpha = \frac{\cos\beta^*\cos\gamma^* - \cos\alpha^*}{\sin\beta^*\sin\gamma^*}.$$

1.1.3.4. Matrices of metric tensors

Various computational and algebraic aspects of mutually reciprocal bases are most conveniently expressed in terms of the metric tensors of these bases. The tensors will be treated in some detail in the next section, and only the definitions of their matrices are given and interpreted below.

Consider the length of the vector $\mathbf{r} = x\mathbf{a} + y\mathbf{b} + z\mathbf{c}$. This is given by

$$|\mathbf{r}| = [(x\mathbf{a} + y\mathbf{b} + z\mathbf{c})\cdot(x\mathbf{a} + y\mathbf{b} + z\mathbf{c})]^{1/2} \quad (1.1.3.9)$$

and can be written in matrix form as

$$|\mathbf{r}| = [\boldsymbol{x}^T\boldsymbol{G}\boldsymbol{x}]^{1/2}, \quad (1.1.3.10)$$

where

$$\boldsymbol{x} = \begin{pmatrix} x \\ y \\ z \end{pmatrix}, \quad \boldsymbol{x}^T = (xyz)$$

and

$$\boldsymbol{G} = \begin{pmatrix} \mathbf{a}\cdot\mathbf{a} & \mathbf{a}\cdot\mathbf{b} & \mathbf{a}\cdot\mathbf{c} \\ \mathbf{b}\cdot\mathbf{a} & \mathbf{b}\cdot\mathbf{b} & \mathbf{b}\cdot\mathbf{c} \\ \mathbf{c}\cdot\mathbf{a} & \mathbf{c}\cdot\mathbf{b} & \mathbf{c}\cdot\mathbf{c} \end{pmatrix} \quad (1.1.3.11)$$

$$= \begin{pmatrix} a^2 & ab\cos\gamma & ac\cos\beta \\ ba\cos\gamma & b^2 & bc\cos\alpha \\ ca\cos\beta & cb\cos\alpha & c^2 \end{pmatrix}. \quad (1.1.3.12)$$

This is the matrix of the metric tensor of the direct basis, or briefly the direct metric. The corresponding reciprocal metric is given by

$$\boldsymbol{G}^* = \begin{pmatrix} \mathbf{a}^*\cdot\mathbf{a}^* & \mathbf{a}^*\cdot\mathbf{b}^* & \mathbf{a}^*\cdot\mathbf{c}^* \\ \mathbf{b}^*\cdot\mathbf{a}^* & \mathbf{b}^*\cdot\mathbf{b}^* & \mathbf{b}^*\cdot\mathbf{c}^* \\ \mathbf{c}^*\cdot\mathbf{a}^* & \mathbf{c}^*\cdot\mathbf{b}^* & \mathbf{c}^*\cdot\mathbf{c}^* \end{pmatrix} \quad (1.1.3.13)$$

$$= \begin{pmatrix} a^{*2} & a^*b^*\cos\gamma^* & a^*c^*\cos\beta^* \\ b^*a^*\cos\gamma^* & b^{*2} & b^*c^*\cos\alpha^* \\ c^*a^*\cos\beta^* & c^*b^*\cos\alpha^* & c^{*2} \end{pmatrix}. \quad (1.1.3.14)$$

The matrices $\boldsymbol{G}$ and $\boldsymbol{G}^*$ are of fundamental importance in crystallographic computations and transformations of basis vectors and coordinates from direct to reciprocal space and *vice versa.* Examples of applications are presented in Part 3 of this volume and in the remaining sections of this chapter.

It can be shown (*e.g.* Buerger, 1941) that the determinants of $\boldsymbol{G}$ and $\boldsymbol{G}^*$ equal the squared volumes of the direct and reciprocal unit cells, respectively. Thus,

$$\det(\boldsymbol{G}) = [\mathbf{a}\cdot(\mathbf{b}\times\mathbf{c})]^2 = V^2 \quad (1.1.3.15)$$

and

$$\det(\boldsymbol{G}^*) = [\mathbf{a}^*\cdot(\mathbf{b}^*\times\mathbf{c}^*)]^2 = V^{*2}, \quad (1.1.3.16)$$

and a direct expansion of the determinants, from (1.1.3.12) and (1.1.3.14), leads to

$$V = abc(1 - \cos^2\alpha - \cos^2\beta - \cos^2\gamma + 2\cos\alpha\cos\beta\cos\gamma)^{1/2} \quad (1.1.3.17)$$

and

$$V^* = a^*b^*c^*(1 - \cos^2\alpha^* - \cos^2\beta^* - \cos^2\gamma^* + 2\cos\alpha^*\cos\beta^*\cos\gamma^*)^{1/2}. \quad (1.1.3.18)$$

The following algorithm has been found useful in computational applications of the above relationships to calculations in reciprocal space (*e.g.* data reduction) and in direct space (*e.g.* crystal geometry).

(1) Input the direct unit-cell parameters and construct the matrix of the metric tensor [*cf.* equation (1.1.3.12)].

(2) Compute the determinant of the matrix $\boldsymbol{G}$ and find the inverse matrix, $\boldsymbol{G}^{-1}$; this inverse matrix is just $\boldsymbol{G}^*$, the matrix of the metric tensor of the reciprocal basis (see also Section 1.1.4 below).

(3) Use the elements of $\boldsymbol{G}^*$, and equation (1.1.3.14), to obtain the parameters of the reciprocal unit cell.

The direct and reciprocal sets of unit-cell parameters, as well as the corresponding metric tensors, are now available for further calculations.

Explicit relations between direct- and reciprocal-lattice parameters, valid for the various crystal systems, are given in most

textbooks on crystallography [see also Chapters 1.1 and 1.2 of Volume C (Koch, 2004)].

1.1.4. Tensor-algebraic formulation

The present section summarizes the tensor-algebraic properties of mutually reciprocal sets of basis vectors, which are of importance in the various aspects of crystallography. This is not intended to be a systematic treatment of tensor algebra; for more thorough expositions of the subject the reader is referred to relevant crystallographic texts (*e.g.* Patterson, 1967; Sands, 1982), and other texts in the physical and mathematical literature that deal with tensor algebra and analysis.

Let us first recall that symbolic vector and matrix notations, in which basis vectors and coordinates do not appear explicitly, are often helpful in qualitative considerations. If, however, an expression has to be evaluated, the various quantities appearing in it must be presented in component form. One of the best ways to achieve a concise presentation of geometrical expressions in component form, while retaining much of their 'transparent' symbolic character, is their tensor-algebraic formulation.

1.1.4.1. Conventions

We shall adhere to the following conventions:

(i) Notation for direct and reciprocal basis vectors:

$$\mathbf{a} = \mathbf{a}_1, \mathbf{b} = \mathbf{a}_2, \mathbf{c} = \mathbf{a}_3$$
$$\mathbf{a}^* = \mathbf{a}^1, \mathbf{b}^* = \mathbf{a}^2, \mathbf{c}^* = \mathbf{a}^3.$$

Subscripted quantities are associated in tensor algebra with *covariant*, and superscripted with *contravariant* transformation properties. Thus the basis vectors of the direct lattice are represented as covariant quantities and those of the reciprocal lattice as contravariant ones.

(ii) Summation convention: if an index appears twice in an expression, once as subscript and once as superscript, a summation over this index is thereby implied and the summation sign is omitted. For example,

$$\sum_i \sum_j x^i T_{ij} x^j \text{ will be written } x^i T_{ij} x^j$$

since both i and j conform to the convention. Such repeating indices are often called *dummy* indices. The implied summation over repeating indices is also often used even when the indices are at the same level and the coordinate system is Cartesian; there is no distinction between contravariant and covariant quantities in Cartesian frames of reference (see Chapter 3.3).

(iii) Components (coordinates) of vectors referred to the covariant basis are written as contravariant quantities, and *vice versa.* For example,

$$\mathbf{r} = x\mathbf{a} + y\mathbf{b} + z\mathbf{c} = x^1\mathbf{a}_1 + x^2\mathbf{a}_2 + x^3\mathbf{a}_3 = x^i\mathbf{a}_i$$
$$\mathbf{h} = h\mathbf{a}^* + k\mathbf{b}^* + l\mathbf{c}^* = h_1\mathbf{a}^1 + h_2\mathbf{a}^2 + h_3\mathbf{a}^3 = h_i\mathbf{a}^i.$$

1.1.4.2. Transformations

A familiar concept but a fundamental one in tensor algebra is the transformation of coordinates. For example, suppose that an atomic position vector is referred to two unit-cell settings as follows:

$$\mathbf{r} = x^k\mathbf{a}_k \tag{1.1.4.1}$$

and

$$\mathbf{r} = x'^k\mathbf{a}'_k. \tag{1.1.4.2}$$

Let us multiply both sides of (1.1.4.1) and (1.1.4.2), on the right, by the vectors $\mathbf{a}^m$, m = 1, 2, or 3, *i.e.* by the reciprocal vectors to the basis $\mathbf{a}_1\mathbf{a}_2\mathbf{a}_3$. We obtain from (1.1.4.1)

$$x^k\mathbf{a}_k \cdot \mathbf{a}^m = x^k\delta^m_k = x^m,$$

where δ^m_k is the Kronecker symbol which equals 1 when $k = m$ and equals zero if $k \neq m$, and by comparison with (1.1.4.2) we have

$$x^m = x'^k T^m_k, \tag{1.1.4.3}$$

where $T^m_k = \mathbf{a}'_k \cdot \mathbf{a}^m$ is an element of the required transformation matrix. Of course, the same transformation could have been written as

$$x^m = T^m_k x'^k, \tag{1.1.4.4}$$

where $T^m_k = \mathbf{a}^m \cdot \mathbf{a}'_k$.

A *tensor* is a quantity that transforms as the product of coordinates, and the *rank* of a tensor is the number of transformations involved (Patterson, 1967; Sands, 1982). *E.g.* the product of two coordinates, as in the above example, transforms from the $\mathbf{a}'$ basis to the $\mathbf{a}$ basis as

$$x^m x^n = T^m_p T^n_q x'^p x'^q; \tag{1.1.4.5}$$

the same transformation law applies to the components of a contravariant tensor of rank two, the components of which are referred to the primed basis and are to be transformed to the unprimed one:

$$Q^{mn} = T^m_p T^n_q Q'^{pq}. \tag{1.1.4.6}$$

1.1.4.3. Scalar products

The expression for the scalar product of two vectors, say $\mathbf{u}$ and $\mathbf{v}$, depends on the bases to which the vectors are referred. If we admit only the covariant and contravariant bases defined above, we have four possible types of expression:

(I) $\mathbf{u} = u^i\mathbf{a}_i, \mathbf{v} = v^i\mathbf{a}_i$

$$\mathbf{u} \cdot \mathbf{v} = u^i v^j(\mathbf{a}_i \cdot \mathbf{a}_j) \equiv u^i v^j g_{ij}, \tag{1.1.4.7}$$

(II) $\mathbf{u} = \mathbf{u}_i\mathbf{a}^i, \mathbf{v} = v_i\mathbf{a}^i$

$$\mathbf{u} \cdot \mathbf{v} = u_i v_j(\mathbf{a}^i \cdot \mathbf{a}^j) \equiv u_i v_j g^{ij}, \tag{1.1.4.8}$$

(III) $\mathbf{u} = u^i\mathbf{a}_i, \mathbf{v} = v_i\mathbf{a}^i$

$$\mathbf{u} \cdot \mathbf{v} = u^i v_j(\mathbf{a}_i \cdot \mathbf{a}^j) \equiv u^i v_j \delta^j_i = u^i v_i, \tag{1.1.4.9}$$

(IV) $\mathbf{u} = u_i\mathbf{a}^i, \mathbf{v} = v^i\mathbf{a}_i$

$$\mathbf{u} \cdot \mathbf{v} = u_i v^j(\mathbf{a}^i \cdot \mathbf{a}_j) \equiv u_i v^j \delta^i_j = u_i v^i. \tag{1.1.4.10}$$

(i) The sets of scalar products $g_{ij} = \mathbf{a}_i \cdot \mathbf{a}_j$ (1.1.4.7) and $g^{ij} = \mathbf{a}^i \cdot \mathbf{a}^j$ (1.1.4.8) are known as the *metric* tensors of the covariant (direct) and contravariant (reciprocal) bases, respectively; the corresponding matrices are presented in conventional notation in equations (1.1.3.11) and (1.1.3.13). Numerous applications of these tensors to the computation of distances and angles in crystals are given in Chapter 3.1.

(ii) Equations (1.1.4.7) to (1.1.4.10) furnish the relationships between the covariant and contravariant *components* of the same vector. Thus, comparing (1.1.4.7) and (1.1.4.9), we have

$$v_i = v^j g_{ij}. \tag{1.1.4.11}$$

Similarly, using (1.1.4.8) and (1.1.4.10) we obtain the inverse relationship

$$v^i = v_j g^{ij}. \tag{1.1.4.12}$$

The corresponding relationships between covariant and contravariant *bases* can now be obtained if we refer a vector, say **v**, to each of the bases

$$\mathbf{v} = v^i \mathbf{a}_i = v_k \mathbf{a}^k,$$

and make use of (1.1.4.11) and (1.1.4.12). Thus, *e.g.*,

$$v^i \mathbf{a}_i = (v_k g^{ik}) \mathbf{a}_i = v_k \mathbf{a}^k.$$

Hence

$$\mathbf{a}^k = g^{ik} \mathbf{a}_i \tag{1.1.4.13}$$

and, similarly,

$$\mathbf{a}_k = g_{ik} \mathbf{a}^i. \tag{1.1.4.14}$$

(iii) The tensors g_{ij} and g^{ij} are symmetric, by definition.

(iv) It follows from (1.1.4.11) and (1.1.4.12) or (1.1.4.13) and (1.1.4.14) that the matrices of the direct and reciprocal metric tensors are mutually inverse, *i.e.*

$$\begin{pmatrix} g_{11} & g_{12} & g_{13} \\ g_{21} & g_{22} & g_{23} \\ g_{31} & g_{32} & g_{33} \end{pmatrix}^{-1} = \begin{pmatrix} g^{11} & g^{12} & g^{13} \\ g^{21} & g^{22} & g^{23} \\ g^{31} & g^{32} & g^{33} \end{pmatrix}, \tag{1.1.4.15}$$

and their determinants are mutually reciprocal.

1.1.4.4. Examples

There are numerous applications of tensor notation in crystallographic calculations, and many of them appear in the various chapters of this volume. We shall therefore present only a few examples.

(i) The (squared) magnitude of the diffraction vector $\mathbf{h} = h_i \mathbf{a}^i$ is given by

$$|h|^2 = \frac{4 \sin^2 \theta}{\lambda^2} = h_i h_j g^{ij}. \tag{1.1.4.16}$$

This concise relationship is a starting point in a derivation of unit-cell parameters from experimental data.

(ii) The structure factor, including explicitly anisotropic displacement tensors, can be written in symbolic matrix notation as

$$F(\boldsymbol{h}) = \sum_{j=1}^{N} f_{(j)} \exp(-\boldsymbol{h}^T \boldsymbol{\beta}_{(j)} \boldsymbol{h}) \exp(2\pi i \boldsymbol{h}^T \boldsymbol{r}_{(j)}), \tag{1.1.4.17}$$

where $\boldsymbol{\beta}_{(j)}$ is the matrix of the anisotropic displacement tensor of the jth atom. In tensor notation, with the quantities referred to their natural bases, the structure factor can be written as

$$F(h_1 h_2 h_3) = \sum_{j=1}^{N} f_{(j)} \exp(-h_i h_k \beta^{ik}_{(j)}) \exp(2\pi i h_i x^i_{(j)}), \tag{1.1.4.18}$$

and similarly concise expressions can be written for the derivatives of the structure factor with respect to the positional and displacement parameters. The summation convention applies only to indices denoting components of vectors and tensors; the atom subscript j in (1.1.4.18) clearly does not qualify, and to indicate this it has been surrounded by parentheses.

(iii) Geometrical calculations, such as those described in the chapters of Part 3, may be carried out in any convenient basis but there are often some definite advantages to computations that are referred to the natural, non-Cartesian bases (see Chapter 3.1). Usually, the output positional parameters from structure refinement are available as contravariant components of the atomic position vectors. If we transform them by (1.1.4.11) to their covariant form, and store these covariant components of the atomic position vectors, the computation of scalar products using equations (1.1.4.9) or (1.1.4.10) is *almost as efficient as it would be if the coordinates were referred to a Cartesian system.* For example, the right-hand side of the vector identity (1.1.3.5), which is employed in the computation of dihedral angles, can be written as

$$(A_i C^i)(B_j D^j) - (A_k D^k)(B_l C^l).$$

This is a typical application of reciprocal space to ordinary direct-space computations.

(iv) We wish to derive a tensor formulation of the vector product, along similar lines to those of Chapter 3.1. As with the scalar product, there are several such formulations and we choose that which has both vectors, say **u** and **v**, and the resulting product, $\mathbf{u} \times \mathbf{v}$, referred to a covariant basis. We have

$$\begin{aligned} \mathbf{u} \times \mathbf{v} &= u^i \mathbf{a}_i \times v^j \mathbf{a}_j \\ &= u^i v^j (\mathbf{a}_i \times \mathbf{a}_j). \end{aligned} \tag{1.1.4.19}$$

If we make use of the relationships (1.1.3.3) between the direct and reciprocal basis vectors, it can be verified that

$$\mathbf{a}_i \times \mathbf{a}_j = V e_{kij} \mathbf{a}^k, \tag{1.1.4.20}$$

where V is the volume of the unit cell and the antisymmetric tensor e_{kij} equals $+1$, -1, or 0 according as kij is an even permutation of 123, an odd permutation of 123 or any two of the indices kij have the same value, respectively. We thus have

$$\begin{aligned} \mathbf{u} \times \mathbf{v} &= V e_{kij} u^i v^j \mathbf{a}^k \\ &= V g^{lk} e_{kij} u^i v^j \mathbf{a}_l, \end{aligned} \tag{1.1.4.21}$$

since by (1.1.4.13), $\mathbf{a}^k = g^{lk} \mathbf{a}_l$.

(v) *The rotation operator.* The general formulation of an expression for the rotation operator is of interest in crystal structure determination by Patterson techniques (see Chapter 2.3) and in molecular modelling (see Chapter 3.3), and another well known crystallographic application of this device is the derivation of the translation, libration and screw-motion tensors by the method of Schomaker & Trueblood (1968), discussed in Part 8 of Volume C (*IT* C, 2004) and in Chapter 1.2 of this volume. A digression on an elementary derivation of the above seems to be worthwhile.

Suppose we wish to rotate the vector **r**, about an axis coinciding with the unit vector **k**, through the angle θ and in the positive sense, *i.e.* an observer looking in the direction of $+\mathbf{k}$ will see **r** rotating in the clockwise sense. The vectors **r**, **k** and the rotated (target) vector $\mathbf{r}'$ are referred to an origin on the axis of rotation (see Fig. 1.1.4.1). Our purpose is to express $\mathbf{r}'$ in terms of **r**, **k** and θ by a general vector formula, and represent the components of the rotated vectors in coordinate systems that might be of interest.

Let us decompose the vector **r** and the (target) vector $\mathbf{r}'$ into their components which are parallel ($\parallel$) and perpendicular ($\perp$) to the axis of rotation:

$$\mathbf{r} = \mathbf{r}_\parallel + \mathbf{r}_\perp \tag{1.1.4.22}$$

and

$$\mathbf{r}' = \mathbf{r}'_\parallel + \mathbf{r}'_\perp. \tag{1.1.4.23}$$

It can be seen from Fig. 1.1.4.1 that the parallel components of **r** and $\mathbf{r}'$ are

$$\mathbf{r}_\parallel = \mathbf{r}'_\parallel = \mathbf{k}(\mathbf{k} \cdot \mathbf{r}) \tag{1.1.4.24}$$

and thus

$$\mathbf{r}_\perp = \mathbf{r} - \mathbf{k}(\mathbf{k} \cdot \mathbf{r}). \tag{1.1.4.25}$$

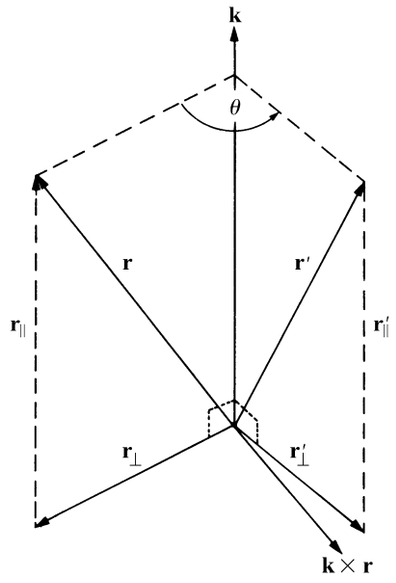

Fig. 1.1.4.1. Derivation of the general expression for the rotation operator. The figure illustrates schematically the decompositions and other simple geometrical considerations required for the derivation outlined in equations (1.1.4.22)–(1.1.4.28).

Only a suitable expression for $\mathbf{r}'_\perp$ is missing. We can find this by decomposing $\mathbf{r}'_\perp$ into its components (i) parallel to $\mathbf{r}_\perp$ and (ii) parallel to $\mathbf{k}\times\mathbf{r}_\perp$. We have, as in (1.1.4.24),

$$\mathbf{r}'_\perp = \frac{\mathbf{r}_\perp}{|\mathbf{r}_\perp|}\left(\frac{\mathbf{r}_\perp}{|\mathbf{r}_\perp|}\cdot\mathbf{r}'_\perp\right) + \frac{\mathbf{k}\times\mathbf{r}_\perp}{|\mathbf{k}\times\mathbf{r}_\perp|}\left(\frac{\mathbf{k}\times\mathbf{r}_\perp}{|\mathbf{k}\times\mathbf{r}_\perp|}\cdot\mathbf{r}'_\perp\right). \quad (1.1.4.26)$$

We observe, using Fig. 1.1.4.1, that

$$|\mathbf{r}'_\perp| = |\mathbf{r}_\perp| = |\mathbf{k}\times\mathbf{r}_\perp|$$

and

$$\mathbf{k}\times\mathbf{r}_\perp = \mathbf{k}\times\mathbf{r},$$

and, further,

$$\mathbf{r}'_\perp\cdot\mathbf{r}_\perp = |\mathbf{r}_\perp|^2\cos\theta$$

and

$$\mathbf{r}'_\perp\cdot(\mathbf{k}\times\mathbf{r}_\perp) = \mathbf{k}\cdot(\mathbf{r}'_\perp\times\mathbf{r}_\perp) = |\mathbf{r}_\perp|^2\sin\theta,$$

since the unit vector $\mathbf{k}$ is perpendicular to the plane containing the vectors $\mathbf{r}_\perp$ and $\mathbf{r}'_\perp$. Equation (1.1.4.26) now reduces to

$$\mathbf{r}'_\perp = \mathbf{r}_\perp\cos\theta + (\mathbf{k}\times\mathbf{r})\sin\theta \quad (1.1.4.27)$$

and equations (1.1.4.23), (1.1.4.25) and (1.1.4.27) lead to the required result

$$\mathbf{r}' = \mathbf{k}(\mathbf{k}\cdot\mathbf{r})(1-\cos\theta) + \mathbf{r}\cos\theta + (\mathbf{k}\times\mathbf{r})\sin\theta. \quad (1.1.4.28)$$

The above general expression can be written as a linear transformation by referring the vectors to an appropriate basis or bases. We choose here $\mathbf{r} = x^j\mathbf{a}_j$, $\mathbf{r}' = x'^i\mathbf{a}_i$ and assume that the components of $\mathbf{k}$ are available in the direct and reciprocal bases.

If we make use of equations (1.1.4.9) and (1.1.4.21), (1.1.4.28) can be written as

$$x'^i = k^i(k_j x^j)(1-\cos\theta) + \delta^i_j x^j\cos\theta + Vg^{im}e_{mpj}k^p x^j\sin\theta, \quad (1.1.4.29)$$

or briefly

$$x'^i = R^i_j x^j, \quad (1.1.4.30)$$

where

$$R^i_j = k^i k_j(1-\cos\theta) + \delta^i_j\cos\theta + Vg^{im}e_{mpj}k^p\sin\theta \quad (1.1.4.31)$$

is a matrix element of the rotation operator $\mathbf{R}$ which carries the vector $\mathbf{r}$ into the vector $\mathbf{r}'$. Of course, the representation (1.1.4.31) of $\mathbf{R}$ depends on our choice of reference bases.

If all the vectors are referred to a Cartesian basis, that is three orthogonal unit vectors, the direct and reciprocal metric tensors reduce to a unit tensor, there is no difference between covariant and contravariant quantities, and equation (1.1.4.31) reduces to

$$R_{ij} = k_i k_j(1-\cos\theta) + \delta_{ij}\cos\theta + e_{ipj}k_p\sin\theta, \quad (1.1.4.32)$$

where all the indices have been taken as subscripts, but the summation convention is still observed. The relative simplicity of (1.1.4.32), as compared to (1.1.4.31), often justifies the transformation of all the vector quantities to a Cartesian basis. This is certainly the case for any extensive calculation in which covariances of the structural parameters are not considered.

1.1.5. Transformations

1.1.5.1. Transformations of coordinates

It happens rather frequently that a vector referred to a given basis has to be re-expressed in terms of another basis, and it is then required to find the relationship between the components (coordinates) of the vector in the two bases. Such situations have already been indicated in the previous section. The purpose of the present section is to give a general method of finding such relationships (transformations), and discuss some simplifications brought about by the use of mutually reciprocal and Cartesian bases. We do not assume anything about the bases, in the general treatment, and hence the tensor formulation of Section 1.1.4 is not appropriate at this stage.

Let

$$\mathbf{r} = \sum_{j=1}^{3} u_j(1)\mathbf{c}_j(1) \quad (1.1.5.1)$$

and

$$\mathbf{r} = \sum_{j=1}^{3} u_j(2)\mathbf{c}_j(2) \quad (1.1.5.2)$$

be the *given* and *required* representations of the vector $\mathbf{r}$, respectively. Upon the formation of scalar products of equations (1.1.5.1) and (1.1.5.2) with the vectors of the second basis, and employing again the summation convention, we obtain

$$u_k(1)[\mathbf{c}_k(1)\cdot\mathbf{c}_l(2)] = u_k(2)[\mathbf{c}_k(2)\cdot\mathbf{c}_l(2)], \quad l = 1, 2, 3 \quad (1.1.5.3)$$

or

$$u_k(1)G_{kl}(12) = u_k(2)G_{kl}(22), \quad l = 1, 2, 3, \quad (1.1.5.4)$$

where $G_{kl}(12) = \mathbf{c}_k(1)\cdot\mathbf{c}_l(2)$ and $G_{kl}(22) = \mathbf{c}_k(2)\cdot\mathbf{c}_l(2)$. Similarly, if we choose the basis vectors $\mathbf{c}_l(1)$, $l = 1, 2, 3$, as the multipliers of (1.1.5.1) and (1.1.5.2), we obtain

$$u_k(1)G_{kl}(11) = u_k(2)G_{kl}(21), \quad l = 1, 2, 3, \quad (1.1.5.5)$$

where $G_{kl}(11) = \mathbf{c}_k(1)\cdot\mathbf{c}_l(1)$ and $G_{kl}(21) = \mathbf{c}_k(2)\cdot\mathbf{c}_l(1)$. Rewriting (1.1.5.4) and (1.1.5.5) in symbolic matrix notation, we have

$$\boldsymbol{u}^T(1)\boldsymbol{G}(12) = \boldsymbol{u}^T(2)\boldsymbol{G}(22), \quad (1.1.5.6)$$

leading to

$$\boldsymbol{u}^T(1) = \boldsymbol{u}^T(2)\{\boldsymbol{G}(22)[\boldsymbol{G}(12)]^{-1}\}$$

and

$$\boldsymbol{u}^T(2) = \boldsymbol{u}^T(1)\{\boldsymbol{G}(12)[\boldsymbol{G}(22)]^{-1}\}, \tag{1.1.5.7}$$

and

$$\boldsymbol{u}^T(1)\boldsymbol{G}(11) = \boldsymbol{u}^T(2)\boldsymbol{G}(21), \tag{1.1.5.8}$$

leading to

$$\boldsymbol{u}^T(1) = \boldsymbol{u}^T(2)\{\boldsymbol{G}(21)[\boldsymbol{G}(11)]^{-1}\}$$

and

$$\boldsymbol{u}^T(2) = \boldsymbol{u}^T(1)\{\boldsymbol{G}(11)[\boldsymbol{G}(21)]^{-1}\}. \tag{1.1.5.9}$$

Equations (1.1.5.7) and (1.1.5.9) are symbolic general expressions for the transformation of the coordinates of **r** from one representation to the other.

In the general case, therefore, we require the matrices of scalar products of the basis vectors, $\boldsymbol{G}(12)$ and $\boldsymbol{G}(22)$ *or* $\boldsymbol{G}(11)$ and $\boldsymbol{G}(21)$ – depending on whether the basis $\mathbf{c}_k(2)$ or $\mathbf{c}_k(1)$, $k = 1, 2, 3$, was chosen to multiply scalarly equations (1.1.5.1) and (1.1.5.2). Note, however, the following simplifications.

(i) If the bases $\mathbf{c}_k(1)$ and $\mathbf{c}_k(2)$ are mutually reciprocal, each of the matrices of mixed scalar products, $\boldsymbol{G}(12)$ and $\boldsymbol{G}(21)$, reduces to a unit matrix. In this important special case, the transformation is effected by the matrices of the metric tensors of the bases in question. This can be readily seen from equations (1.1.5.7) and (1.1.5.9), which then reduce to the relationships between the covariant and contravariant components of the same vector [see equations (1.1.4.11) and (1.1.4.12) above].

(ii) If one of the bases, say $\mathbf{c}_k(2)$, is Cartesian, its metric tensor is by definition a unit tensor, and the transformations in (1.1.5.7) reduce to

$$\boldsymbol{u}^T(1) = \boldsymbol{u}^T(2)[\boldsymbol{G}(12)]^{-1}$$

and

$$\boldsymbol{u}^T(2) = \boldsymbol{u}^T(1)\boldsymbol{G}(12). \tag{1.1.5.10}$$

The transformation matrix is now the mixed matrix of the scalar products, whether or not the basis $\mathbf{c}_k(1)$, $k = 1, 2, 3$, is also Cartesian. If, however, both bases are Cartesian, the transformation can also be interpreted as a rigid rotation of the coordinate axes (see Chapter 3.3).

It should be noted that the above transformations do not involve any shift of the origin. Transformations involving such shifts, notably the symmetry transformations of the space group, are treated rather extensively in Volume A of *International Tables for Crystallography* (2005) [see *e.g.* Part 5 there (Arnold, 2005)].

1.1.5.2. Example

This example deals with the construction of a Cartesian system in a crystal with given basis vectors of its direct lattice. We shall also require that the Cartesian system bear a clear relationship to at least one direction in each of the direct and reciprocal lattices of the crystal; this may be useful in interpreting a physical property which has been measured along a given lattice vector or which is associated with a given lattice plane. For a better consistency of notation, the Cartesian components will be denoted as contravariant.

The appropriate version of equations (1.1.5.1) and (1.1.5.2) is now

$$\mathbf{r} = x^i\mathbf{a}_i \tag{1.1.5.11}$$

and

$$\mathbf{r} = X^k\mathbf{e}_k, \tag{1.1.5.12}$$

where the Cartesian basis vectors are: $\mathbf{e}_1 = \mathbf{r}_\mathrm{L}/|\mathbf{r}_\mathrm{L}|$, $\mathbf{e}_2 = \mathbf{r}^*/|\mathbf{r}^*|$ and $\mathbf{e}_3 = \mathbf{e}_1 \times \mathbf{e}_2$, and the vectors $\mathbf{r}_\mathrm{L}$ and $\mathbf{r}^*$ are given by

$$\mathbf{r}_\mathrm{L} = u^i\mathbf{a}_i \text{ and } \mathbf{r}^* = h_k\mathbf{a}^k,$$

where u^i and h_k, $i, k = 1, 2, 3$, are arbitrary integers. The vectors $\mathbf{r}_\mathrm{L}$ and $\mathbf{r}^*$ must of course be chosen to be mutually perpendicular, $\mathbf{r}_\mathrm{L} \cdot \mathbf{r}^* = u^ih_i = 0$. The $X^1(X)$ axis of the Cartesian system thus coincides with a direct-lattice vector, and the $X^2(Y)$ axis is parallel to a vector in the reciprocal lattice.

Since the basis in (1.1.5.12) is a Cartesian one, the required transformations are given by equations (1.1.5.10) as

$$x^i = X^k(T^{-1})^i_k \text{ and } X^i = x^kT^i_k, \tag{1.1.5.13}$$

where $T^i_k = \mathbf{a}_k \cdot \mathbf{e}_i$, k, $i = 1, 2, 3$, form the matrix of the scalar products. If we make use of the relationships between covariant and contravariant basis vectors, and the tensor formulation of the vector product, given in Section 1.1.4 above (see also Chapter 3.1), we obtain

$$\begin{aligned} T^1_k &= \frac{1}{|\mathbf{r}_\mathrm{L}|}g_{ki}u^i \\ T^2_k &= \frac{1}{|\mathbf{r}^*|}h_k \\ T^3_k &= \frac{V}{|\mathbf{r}_\mathrm{L}||\mathbf{r}^*|}e_{kip}u^ig^{pl}h_l. \end{aligned} \tag{1.1.5.14}$$

Note that the other convenient choice, $\mathbf{e}_1 \propto \mathbf{r}^*$ and $\mathbf{e}_2 \propto \mathbf{r}_\mathrm{L}$, interchanges the first two columns of the matrix $\boldsymbol{T}$ in (1.1.5.14) and leads to a change of the signs of the elements in the third column. This can be done by writing e_{kpi} instead of e_{kip}, while leaving the rest of T^3_k unchanged.

1.1.6. Some analytical aspects of the reciprocal space

1.1.6.1. Continuous Fourier transform

Of great interest in crystallographic analyses are Fourier transforms and these are closely associated with the dual bases examined in this chapter. Thus, *e.g.*, the inverse Fourier transform of the electron-density function of the crystal

$$F(\mathbf{h}) = \int_\text{cell} \rho(\mathbf{r}) \exp(2\pi i\mathbf{h} \cdot \mathbf{r})\, \mathrm{d}^3\mathbf{r}, \tag{1.1.6.1}$$

where $\rho(\mathbf{r})$ is the electron-density function at the point **r** and the integration extends over the volume of a unit cell, is the fundamental model of the contribution of the distribution of crystalline matter to the intensity of the scattered radiation. For the conventional Bragg scattering, the function given by (1.1.6.1), and known as the *structure factor*, may assume nonzero values *only* if **h** can be represented as a reciprocal-lattice vector. Chapter 1.2 is devoted to a discussion of the structure factor of the Bragg reflection, while Chapters 4.1, 4.2 and 4.3 discuss circumstances under which the scattering need not be confined to the points of the reciprocal lattice only, and may be represented by reciprocal-space vectors with non-integral components.

1.1.6.2. Discrete Fourier transform

The electron density $\rho(\mathbf{r})$ in (1.1.6.1) is one of the most common examples of a function which has the periodicity of the crystal. Thus, for an ideal (infinite) crystal the electron density $\rho(\mathbf{r})$ can be written as

$$\rho(\mathbf{r}) = \rho(\mathbf{r} + u\mathbf{a} + v\mathbf{b} + w\mathbf{c}), \tag{1.1.6.2}$$

and, as such, it can be represented by a three-dimensional Fourier series of the form

$$\rho(\mathbf{r}) = \sum_{\mathbf{g}} C(\mathbf{g}) \exp(-2\pi i \mathbf{g} \cdot \mathbf{r}), \qquad (1.1.6.3)$$

where the periodicity requirement (1.1.6.2) enables one to represent all the **g** vectors in (1.1.6.3) as vectors in the reciprocal lattice (see also Section 1.1.2 above). If we insert the series (1.1.6.3) in the integrand of (1.1.6.1), interchange the order of summation and integration and make use of the fact that an integral of a periodic function taken over the entire period must vanish unless the integrand is a constant, equation (1.1.6.3) reduces to the conventional form

$$\rho(\mathbf{r}) = \frac{1}{V} \sum_{\mathbf{h}} F(\mathbf{h}) \exp(-2\pi i \mathbf{h} \cdot \mathbf{r}), \qquad (1.1.6.4)$$

where V is the volume of the unit cell in the direct lattice and the summation ranges over all the reciprocal lattice.

Fourier transforms, discrete as well as continuous, are among the most important mathematical tools of crystallography. The discussion of their mathematical principles, the modern algorithms for their computation and their numerous applications in crystallography form the subject matter of Chapter 1.3. Many more examples of applications of Fourier methods in crystallography are scattered throughout this volume and the crystallographic literature in general.

1.1.6.3. Bloch's theorem

It is in order to mention briefly the important role of reciprocal space and the reciprocal lattice in the field of the theory of solids. At the basis of these applications is the periodicity of the crystal structure and the effect it has on the dynamics (*cf.* Chapter 4.1) and electronic structure of the crystal. One of the earliest, and still most important, theorems of solid-state physics is due to Bloch (1928) and deals with the representation of the wavefunction of an electron which moves in a periodic potential. Bloch's theorem states that:

> *The eigenstates ψ of the one-electron Hamiltonian $\mathcal{H} = (-\hbar^2/2m)\nabla^2 + U(\mathbf{r})$, where $U(\mathbf{r})$ is the crystal potential and $\mathbf{U}(\mathbf{r} + \mathbf{r}_\mathrm{L}) = U(\mathbf{r})$ for all $\mathbf{r}_\mathrm{L}$ in the Bravais lattice, can be chosen to have the form of a plane wave times a function with the periodicity of the Bravais lattice.*

Thus

$$\psi(\mathbf{r}) = \exp(i\mathbf{k} \cdot \mathbf{r}) u(\mathbf{r}), \qquad (1.1.6.5)$$

where

$$u(\mathbf{r} + \mathbf{r}_\mathrm{L}) = u(\mathbf{r}) \qquad (1.1.6.6)$$

and **k** is the wavevector. The proof of Bloch's theorem can be found in most modern texts on solid-state physics (*e.g.* Ashcroft & Mermin, 1975). If we combine (1.1.6.5) with (1.1.6.6), an alternative form of the Bloch theorem results:

$$\psi(\mathbf{r} + \mathbf{r}_\mathrm{L}) = \exp(i\mathbf{k} \cdot \mathbf{r}_\mathrm{L}) \psi(\mathbf{r}). \qquad (1.1.6.7)$$

In the important case where the wavefunction ψ is itself periodic, *i.e.*

$$\psi(\mathbf{r} + \mathbf{r}_\mathrm{L}) = \psi(\mathbf{r}),$$

we must have $\exp(i\mathbf{k} \cdot \mathbf{r}_\mathrm{L}) = 1$. Of course, this can be so only if the wavevector **k** equals 2π times a vector in the reciprocal lattice. It is also seen from equation (1.1.6.7) that the wavevector appearing in the phase factor can be reduced to a unit cell in the reciprocal lattice (the basis vectors of which contain the 2π factor), or to the equivalent polyhedron known as the *Brillouin zone* (*e.g.* Ziman, 1969). This periodicity in reciprocal space is of prime importance in the theory of solids. Some Brillouin zones are discussed in detail in Chapter 1.5.

I wish to thank Professor D. W. J. Cruickshank for bringing to my attention the contribution of M. von Laue (Laue, 1914), who was the first to introduce general reciprocal bases to crystallography.

1.2. The structure factor

By P. Coppens

1.2.1. Introduction

The *structure factor* is the central concept in structure analysis by diffraction methods. Its modulus is called the *structure amplitude*. The structure amplitude is a function of the indices of the set of scattering planes h, k and l, and is defined as the amplitude of scattering by the contents of the crystallographic unit cell, expressed in units of scattering. For X-ray scattering, that unit is the scattering by a single electron (2.82×10^{-15} m), while for neutron scattering by atomic nuclei, the unit of scattering length of 10^{-14} m is commonly used. The complex form of the structure factor means that the phase of the scattered wave is not simply related to that of the incident wave. However, the observable, which is the scattered intensity, must be real. It is proportional to the square of the scattering amplitude (see, *e.g.*, Lipson & Cochran, 1966).

The structure factor is directly related to the distribution of scattering matter in the unit cell which, in the X-ray case, is the electron distribution, time-averaged over the vibrational modes of the solid.

In this chapter we will discuss structure-factor expressions for X-ray and neutron scattering, and, in particular, the modelling that is required to obtain an analytical description in terms of the features of the electron distribution and the vibrational displacement parameters of individual atoms. We concentrate on the most basic developments; for further details the reader is referred to the cited literature.

1.2.2. General scattering expression for X-rays

The total scattering of X-rays contains both elastic and inelastic components. Within the first-order Born approximation (Born, 1926) it has been treated by several authors (*e.g.* Waller & Hartree, 1929; Feil, 1977) and is given by the expression

$$I_{\rm total}(\mathbf{S}) = I_{\rm classical} \sum_n \left| \int \psi_n^* \exp(2\pi i \mathbf{S}\cdot\mathbf{r}_j)\psi_0 \, {\rm d}\mathbf{r} \right|^2, \qquad (1.2.2.1)$$

where $I_{\rm classical}$ is the classical Thomson scattering of an X-ray beam by a free electron, which is equal to $(e^2/mc^2)^2(1+\cos^2 2\theta)/2$ for an unpolarized beam of unit intensity, ψ is the n-electron space-wavefunction expressed in the $3n$ coordinates of the electrons located at $\mathbf{r}_j$ and the integration is over the coordinates of all electrons. $\mathbf{S}$ is the scattering vector of length $2\sin\theta/\lambda$.

The coherent elastic component of the scattering, in units of the scattering of a free electron, is given by

$$I_{\rm coherent,\ elastic}(\mathbf{S}) = \left| \int \psi_0^* \right| \sum_j \exp(2\pi i \mathbf{S}\cdot\mathbf{r}_j) |\psi_0 \, {\rm d}\mathbf{r}|^2. \qquad (1.2.2.2)$$

If integration is performed over all coordinates but those of the jth electron, one obtains after summation over all electrons

$$I_{\rm coherent,\ elastic}(\mathbf{S}) = |\int \rho(\mathbf{r}) \exp(2\pi i \mathbf{S}\cdot\mathbf{r}) \, {\rm d}\mathbf{r}|^2, \qquad (1.2.2.3)$$

where $\rho(\mathbf{r})$ is the electron distribution. The scattering amplitude $A(\mathbf{S})$ is then given by

$$A(\mathbf{S}) = \int \rho(\mathbf{r}) \exp(2\pi i \mathbf{S}\cdot\mathbf{r}) \, {\rm d}\mathbf{r} \qquad (1.2.2.4a)$$

or

$$A(\mathbf{S}) = \hat{F}\{\rho(\mathbf{r})\}, \qquad (1.2.2.4b)$$

where $\hat{F}$ is the Fourier transform operator.

1.2.3. Scattering by a crystal: definition of a structure factor

In a crystal of infinite size, $\rho(\mathbf{r})$ is a three-dimensional periodic function, as expressed by the convolution

$$\rho_{\rm crystal}(\mathbf{r}) = \sum_n \sum_m \sum_p \rho_{\rm unit\ cell}(\mathbf{r}) * \delta(\mathbf{r} - n\mathbf{a} - m\mathbf{b} - p\mathbf{c}), \qquad (1.2.3.1)$$

where n, m and p are integers, and δ is the Dirac delta function.

Thus, according to the Fourier convolution theorem,

$$A(\mathbf{S}) = \hat{F}\{\rho(\mathbf{r})\} = \sum_n \sum_m \sum_p \hat{F}\{\rho_{\rm unit\ cell}(\mathbf{r})\} \hat{F}\{\delta(\mathbf{r} - n\mathbf{a} - m\mathbf{b} - p\mathbf{c})\}, \qquad (1.2.3.2)$$

which gives

$$A(\mathbf{S}) = \hat{F}\{\rho_{\rm unit\ cell}(\mathbf{r})\} \sum_h \sum_k \sum_l \delta(\mathbf{S} - h\mathbf{a}^* - k\mathbf{b}^* - l\mathbf{c}^*). \qquad (1.2.3.3)$$

Expression (1.2.3.3) is valid for a crystal with a very large number of unit cells, in which particle-size broadening is negligible. Furthermore, it does not account for multiple scattering of the beam within the crystal. Because of the appearance of the delta function, (1.2.3.3) implies that $\mathbf{S} = \mathbf{H}$ with $\mathbf{H} = h\mathbf{a}^* + k\mathbf{b}^* + l\mathbf{c}^*$.

The first factor in (1.2.3.3), the scattering amplitude of one unit cell, is defined as the structure factor F:

$$F(\mathbf{H}) = \hat{F}\{\rho_{\rm unit\ cell}(\mathbf{r})\} = \int_{\rm unit\ cell} \rho(\mathbf{r}) \exp(2\pi i \mathbf{H}\cdot\mathbf{r}) \, {\rm d}\mathbf{r}. \qquad (1.2.3.4)$$

1.2.4. The isolated-atom approximation in X-ray diffraction

To a reasonable approximation, the unit-cell density can be described as a superposition of isolated, spherical atoms located at $\mathbf{r}_j$.

$$\rho_{\rm unit\ cell}(\mathbf{r}) = \sum_j \rho_{{\rm atom},j}(\mathbf{r}) * \delta(\mathbf{r} - \mathbf{r}_j). \qquad (1.2.4.1)$$

Substitution in (1.2.3.4) gives

$$F(\mathbf{H}) = \sum_j \hat{F}\{\rho_{{\rm atom},j}\} \hat{F}\{\delta(\mathbf{r} - \mathbf{r}_j)\} = \sum_j f_j \exp(2\pi i \mathbf{H}\cdot\mathbf{r}_j) \qquad (1.2.4.2a)$$

or

$$\begin{aligned} F(h,k,l) &= \sum_j f_j \exp 2\pi i(hx_j + ky_j + lz_j) \\ &= \sum_j f_j \{\cos 2\pi(hx_j + ky_j + lz_j) \\ &\quad + i \sin 2\pi(hx_j + ky_j + lz_j)\}. \end{aligned} \qquad (1.2.4.2b)$$

$f_j(S)$, the spherical atomic scattering factor, or form factor, is the Fourier transform of the spherically averaged atomic density $\rho_j(r)$, in which the polar coordinate r is relative to the nuclear position. $f_j(S)$ can be written as (James, 1982)

Copyright © 2010 International Union of Crystallography

$$f_j(S) = \int_{\text{atom}} \rho_j(r) \exp(2\pi i \mathbf{S}\cdot\mathbf{r})\,\mathrm{d}\mathbf{r}$$
$$= \int_{\upsilon=0}^{\pi}\int_{\varphi=0}^{2\pi}\int_{r=0}^{\infty} \rho_j(r)\exp(2\pi i S r\cos\vartheta) r^2 \sin\vartheta\,\mathrm{d}r\,\mathrm{d}\vartheta\,\mathrm{d}\varphi$$
$$= \int_0^\infty 4\pi r^2 \rho_j(r)\frac{\sin 2\pi S r}{2\pi S r}\,\mathrm{d}r \equiv \int_0^\infty 4\pi r^2\rho_j(r) j_0(2\pi S r)\,\mathrm{d}r$$
$$\equiv \langle j_0\rangle, \qquad (1.2.4.3)$$

where $j_0(2\pi Sr)$ is the zero-order spherical Bessel function.

$\rho_j(r)$ represents either the static or the dynamic density of atom j. In the former case, the effect of thermal motion, treated in Section 1.2.9 and following, is not included in the expression.

When scattering is treated in the second-order Born approximation, additional terms occur which are in particular of importance for X-ray wavelengths with energies close to absorption edges of atoms, where the participation of free and bound excited states in the scattering process becomes very important, leading to *resonance scattering*. [Resonance scattering is referred to as anomalous scattering in the older literature, but this misnomer is avoided in the current chapter.] Inclusion of such contributions leads to two extra terms, which are both wavelength- and scattering-angle-dependent:

$$f_j(S,\lambda) = f_j^0(S) + f_j'(S,\lambda) + i f_j''(S,\lambda). \qquad (1.2.4.4)$$

The treatment of resonance effects is beyond the scope of this chapter. We note however (*a*) that to a reasonable approximation the S-dependence of f_j' and f_j'' can be neglected, (*b*) that f_j' and f_j'' are not independent, but related through the Kramers–Kronig transformation, and (*c*) that in an anisotropic environment the atomic scattering factor becomes anisotropic, and accordingly is described as a tensor property. Detailed descriptions and appropriate references can be found in Materlick *et al.* (1994) and in Section 4.2.6 of *IT* C (2004).

The structure-factor expressions (1.2.4.2) can be simplified when the crystal class contains nontrivial symmetry elements. For example, when the origin of the unit cell coincides with a centre of symmetry ($x, y, z \rightarrow -x, -y, -z$) the sine term in (1.2.4.2*b*) cancels when the contributions from the symmetry-related atoms are added, leading to the expression

$$F(\mathbf{H}) = 2\sum_{j=1}^{N/2} f_j \cos 2\pi(hx_j + ky_j + lz_j), \qquad (1.2.4.2c)$$

where the summation is over the unique half of the unit cell only.

Further simplifications occur when other symmetry elements are present. They are treated in Chapter 1.4, which also contains a complete list of symmetry-specific structure-factor expresions valid in the spherical-atom isotropic-temperature-factor approximation.

1.2.5. Scattering of thermal neutrons

1.2.5.1. Nuclear scattering

The scattering of neutrons by atomic nuclei is described by the atomic scattering length b, related to the total cross section σ_{total} by the expression $\sigma_{\text{total}} = 4\pi b^2$. At present, there is no theory of nuclear forces which allows calculation of the scattering length, so that experimental values are to be used. Two types of nuclei can be distinguished (Squires, 1978). In the first type, the scattering is a resonance phenomenon and is associated with the formation of a compound nucleus (consisting of the original nucleus plus a neutron) with an energy close to that of an excited state. In the second type, the compound nucleus is not near an excited state and the scattering length is essentially real and independent of the energy of the incoming neutron. In either case, b is independent of the Bragg angle θ, unlike the X-ray form factor, since the nuclear dimensions are very small relative to the wavelength of thermal neutrons.

The scattering length is not the same for different isotopes of an element. A random distribution of isotopes over the sites occupied by that element leads to an incoherent contribution, such that effectively $\sigma_{\text{total}} = \sigma_{\text{coherent}} + \sigma_{\text{incoherent}}$. Similarly for nuclei with nonzero spin, a spin incoherent scattering occurs as the spin states are, in general, randomly distributed over the sites of the nuclei.

For free or loosely bound nuclei, the scattering length is modified by $b_{\text{free}} = [M/(m+M)]b$, where M is the mass of the nucleus and m is the mass of the neutron. This effect is of consequence only for the lightest elements. It can, in particular, be of significance for hydrogen atoms. With this in mind, the structure-factor expression for elastic scattering can be written as

$$F(\mathbf{H}) = \sum_j b_{j,\,\text{coherent}} \exp 2\pi i(hx_j + ky_j + lz_j) \qquad (1.2.4.2d)$$

by analogy to (1.2.4.2*b*).

1.2.5.2. Magnetic scattering

The interaction between the magnetic moments of the neutron and the unpaired electrons in solids leads to magnetic scattering. The total elastic scattering including both the nuclear and magnetic contributions is given by

$$|F(\mathbf{H})|^2_{\text{total}} = |F_N(\mathbf{H}) + \mathbf{Q}(\mathbf{H})\cdot\hat{\boldsymbol{\lambda}}|^2, \qquad (1.2.5.1a)$$

where the unit vector $\hat{\boldsymbol{\lambda}}$ describes the polarization vector for the neutron spin, $F_N(\mathbf{H})$ is given by (1.2.4.2*b*) and $\mathbf{Q}$ is defined by

$$\mathbf{Q} = \frac{mc}{eh}\int \widehat{\mathbf{H}} \times [\mathbf{M}(\mathbf{r}) \times \widehat{\mathbf{H}}] \exp(2\pi i \mathbf{H}\cdot\mathbf{r})\,\mathrm{d}\mathbf{r}. \qquad (1.2.5.2a)$$

$\mathbf{M}(\mathbf{r})$ is the vector field describing the electron-magnetization distribution and $\widehat{\mathbf{H}}$ is a unit vector parallel to $\mathbf{H}$.

$\mathbf{Q}$ is thus proportional to the projection of $\mathbf{M}$ onto a direction orthogonal to $\mathbf{H}$ in the plane containing $\mathbf{M}$ and $\mathbf{H}$. The magnitude of this projection depends on $\sin\alpha$, where α is the angle between $\mathbf{Q}$ and $\mathbf{H}$, which prevents magnetic scattering from being a truly three-dimensional probe. If all moments $\mathbf{M}(\mathbf{r})$ are collinear, as may be achieved in paramagnetic materials by applying an external field, and for the maximum signal ($\mathbf{H}$ orthogonal to $\mathbf{M}$), (1.2.5.2*a*) becomes

$$\mathbf{Q} = \mathbf{M}(\mathbf{H}) = \frac{mc}{eh}\int \mathbf{M}(\mathbf{r}) \exp(2\pi i \mathbf{H}\cdot\mathbf{r})\,\mathrm{d}\mathbf{r} \qquad (1.2.5.2b)$$

and (1.2.5.1*a*) gives

$$|F|^2_{\text{total}} = |F_N(\mathbf{H}) - M(\mathbf{H})|^2 \qquad (1.2.5.1b)$$

and

$$|F|^2_{\text{total}} = |F_N(\mathbf{H}) + M(\mathbf{H})|^2$$

for neutrons parallel and antiparallel to $\mathbf{M}(\mathbf{H})$, respectively.

1.2.6. Effect of bonding on the atomic electron density within the spherical-atom approximation: the kappa formalism

A first improvement beyond the isolated-atom formalism is to allow for changes in the radial dependence of the atomic electron distribution.

Such changes may be due to electronegativity differences which lead to the transfer of electrons between the valence shells of different atoms. The electron transfer introduces a change in

the screening of the nuclear charge by the electrons and therefore affects the radial dependence of the atomic electron distribution (Coulson, 1961). A change in radial dependence of the density may also occur in a purely covalent bond, as, for example, in the H_2 molecule (Ruedenberg, 1962). It can be expressed as

$$\rho'_{\rm valence}(r) = \kappa^3 \rho_{\rm valence}(\kappa r) \tag{1.2.6.1}$$

(Coppens *et al.*, 1979), where ρ' is the modified density and κ is an expansion/contraction parameter, which is > 1 for valence-shell contraction and < 1 for expansion. The κ^3 factor results from the normalization requirement.

The valence density is usually defined as the outer electron shell from which charge transfer occurs. The inner or core electrons are much less affected by the change in occupancy of the outer shell and, in a reasonable approximation, retain their radial dependence.

The corresponding structure-factor expression is

$$F(\mathbf{H}) = \sum_j [\{P_{j,\,\rm core} f_{j,\,\rm core}(H) + P_{j,\,\rm valence} f_{j,\,\rm valence}(H/\kappa)\} \times \exp(2\pi i \mathbf{H}\cdot\mathbf{r}_j)], \tag{1.2.6.2}$$

where $P_{j,\,\rm core}$ and $P_{j,\,\rm valence}$ are the number of electrons (not necessarily integral) in the core and valence shell, respectively, and the atomic scattering factors $f_{j,\,\rm core}$ and $f_{j,\,\rm valence}$ are normalized to one electron. Here and in the following sections, the resonant-scattering contributions are incorporated in the core scattering.

1.2.7. Beyond the spherical-atom description: the atom-centred spherical harmonic expansion

1.2.7.1. Direct-space description of aspherical atoms

Even though the spherical-atom approximation is often adequate, atoms in a crystal are in a nonspherical environment; therefore, an accurate description of the atomic electron density requires nonspherical density functions. In general, such density functions can be written in terms of the three polar coordinates r, θ and φ. Under the assumption that the radial and angular parts can be separated, one obtains for the density function:

$$\Phi(r,\theta,\varphi) = R(r)\Theta(\theta,\varphi). \tag{1.2.7.1}$$

The angular functions Θ are based on the spherical harmonic functions Y_{lm} defined by

$$Y_{lm}(\theta,\varphi) = (-1)^m \left[\left(\frac{2l+1}{4\pi}\right)\frac{(l-|m|)!}{(l+|m|)!}\right]^{1/2} P_l^m(\cos\theta)\exp(im\varphi), \tag{1.2.7.2a}$$

with $-l \le m \le l$, where $P_l^m(\cos\theta)$ are the associated Legendre polynomials (see Arfken, 1970).

$$P_l^m(x) = (1-x^2)^{|m|/2}\frac{{\rm d}^{|m|}P_l(x)}{{\rm d}x^{|m|}},$$

$$P_l(x) = \frac{1}{l!2^l}\frac{{\rm d}^l}{{\rm d}x^l}\left[(x^2-1)^l\right].$$

The real spherical harmonic functions y_{lmp}, $0 \le m \le l$, $p = +$ or $-$ are obtained as a linear combination of Y_{lm}:

$$y_{lm+}(\theta,\psi) = \left[\frac{(2l+1)(l-|m|)!}{2\pi(1+\delta_{m0})(l+|m|)!}\right]^{1/2} P_l^m(\cos\theta)\cos m\varphi = N_{lm}P_l^m(\cos\theta)\cos m\varphi = (-1)^m(Y_{lm}+Y_{l,\,-m}) \tag{1.2.7.2b}$$

and

$$y_{lm-}(\theta,\psi) = N_{lm}P_l^m(\cos\theta)\sin m\varphi = (-1)^m(Y_{lm}-Y_{l,\,-m})/(2i). \tag{1.2.7.2c}$$

The normalization constants N_{lm} are defined by the conditions

$$\int y_{lmp}^2\ {\rm d}\Omega = 1, \tag{1.2.7.3a}$$

which are appropriate for normalization of wavefunctions. An alternative definition is used for charge-density basis functions:

$$\int |d_{lmp}|\ {\rm d}\Omega = 2 \text{ for } l>0 \text{ and } \int |d_{lmp}|\ {\rm d}\Omega = 1 \text{ for } l = 0. \tag{1.2.7.3b}$$

The functions y_{lmp} and d_{lmp} differ only in the normalization constants. For the spherically symmetric function d_{00}, a population parameter equal to one corresponds to the function being populated by one electron. For the nonspherical functions with $l > 0$, a population parameter equal to one implies that one electron has shifted from the negative to the positive lobes of the function.

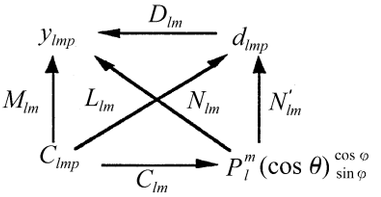
The functions y_{lmp} and d_{lmp} can be expressed in Cartesian coordinates, such that

$$y_{lmp} = M_{lm}c_{lmp} \tag{1.2.7.4a}$$

and

$$d_{lmp} = L_{lm}c_{lmp}, \tag{1.2.7.4b}$$

where the c_{lmp} are Cartesian functions. The relations between the various definitions of the real spherical harmonic functions are summarized by



in which the direction of the arrows and the corresponding conversion factors X_{lm} define expressions of the type (1.2.7.4). The expressions for c_{lmp} with $l \le 4$ are listed in Table 1.2.7.1, together with the normalization factors M_{lm} and L_{lm}.

The spherical harmonic functions are mutually orthogonal and form a complete set, which, if taken to sufficiently high order, can be used to describe any arbitrary angular function.

The spherical harmonic functions are often referred to as multipoles since each represents the components of the charge distribution $\rho(\mathbf{r})$, which gives nonzero contribution to the integral $\Theta_{lmp} = \int \rho(\mathbf{r}) c_{lmp} r^l\ {\rm d}\mathbf{r}$, where Θ_{lmp} is an electrostatic multipole moment. Terms with increasing l are referred to as *monopolar* ($l = 0$), *dipolar* ($l = 1$), *quadrupolar* ($l = 2$), *octapolar* ($l = 3$), *hexadecapolar* ($l = 4$), *triacontadipolar* ($l = 5$) and *hexacontatetrapolar* ($l = 6$).

Site-symmetry restrictions for the real spherical harmonics as given by Kara & Kurki-Suonio (1981) are summarized in Table 1.2.7.2.

In cubic space groups, the spherical harmonic functions as defined by equations (1.2.7.2) are no longer linearly independent. The appropriate basis set for this symmetry consists of the '*Kubic harmonics*' of Von der Lage & Bethe (1947). Some low-order terms are listed in Table 1.2.7.3. Both wavefunction and density-function normalization factors are specified in Table 1.2.7.3.

A related basis set of angular functions has been proposed by Hirshfeld (1977). They are of the form $\cos^n\theta_k$, where θ_k is the angle with a specified set of $(n+1)(n+2)/2$ polar axes. The Hirshfeld functions are identical to a sum of spherical harmonics

Table 1.2.7.1. *Real spherical harmonic functions (x, y, z are direction cosines)*

with $l = n, n-2, n-4, \ldots (0, 1)$ for $n > 1$, as shown elsewhere (Hirshfeld, 1977).

The radial functions $R(r)$ can be selected in different manners. Several choices may be made, such as

$$R_l(r) = \frac{\zeta^{n_l+3}}{(n_l+2)!} r^{n(l)} \exp(-\zeta_l r) \qquad \text{(Slater type function)}, \tag{1.2.7.5a}$$

where the coefficient n_l may be selected by examination of products of hydrogenic orbitals which give rise to a particular multipole (Hansen & Coppens, 1978). Values for the exponential coefficient ζ_l may be taken from energy-optimized coefficients for isolated atoms available in the literature (Clementi & Raimondi, 1963). A standard set has been proposed by Hehre *et al.* (1969). In the bonded atom, such values are affected by changes in nuclear screening due to migrations of charge, as described in part by equation (1.2.6.1).

Other alternatives are:

$$R_l(r) = \frac{\alpha^{n+1}}{n!} r^n \exp(-\alpha r^2) \qquad \text{(Gaussian function)} \tag{1.2.7.5b}$$

† Common factor such that $C_{lm}c_{lmp} = P_l^m(\cos\theta)^{\cos m\varphi}_{\sin m\varphi}$. ‡ $x = \sin\theta\cos\varphi$, $y = \sin\theta\sin\varphi$, $z = \cos\theta$. § As defined by $y_{lmp} = M_{lmp}c_{lmp}$ where c_{lmp} are Cartesian functions. ¶ Paturle & Coppens (1988), as defined by $d_{lmp} = L_{lmp}c_{lmp}$ where c_{lmp} are Cartesian functions. †† ar = arctan (2). ‡‡ $N_{\rm ang} = \{(14A_-^5 - 14A_+^5 + 20A_+^3 - 20A_-^3 + 6A_- - 6A_+)2\pi\}^{-1}$ where $A_\pm = [(30 \pm \sqrt{480})/70]^{1/2}$.

or

$$R_l(r) = r^l L_n^{2l+2}(\gamma r)\exp\left(-\frac{\gamma r}{2}\right) \quad \text{(Laguerre function)}, \tag{1.2.7.5c}$$

where L is a Laguerre polynomial of order n and degree $(2l + 2)$.

In summary, in the multipole formalism the atomic density is described by

$$\rho_{\rm atomic}(\mathbf{r}) = P_c\rho_{\rm core} + P_v\kappa^3\rho_{\rm valence}(\kappa r) + \sum_{l=0}^{l_{\max}}\kappa'^3 R_l(\kappa' r)\sum_{m=0}^{l}\sum_p P_{lmp}d_{lmp}(\mathbf{r}/r), \tag{1.2.7.6}$$

in which the leading terms are those of the kappa formalism [expressions (1.2.6.1), (1.2.6.2)]; the subscript p is either + or −.

The expansion in (1.2.7.6) is frequently truncated at the hexadecapolar ($l = 4$) level. For atoms at positions of high site symmetry the first allowed functions may occur at higher l values. For trigonally bonded atoms in organic molecules the $l = 3$ terms are often found to be the most significantly populated deformation functions.

1.2.7.2. Reciprocal-space description of aspherical atoms

The aspherical-atom form factor is obtained by substitution of (1.2.7.6) in expression (1.2.4.3*a*):

$$f_j(\mathbf{S}) = \int \rho_j(\mathbf{r})\exp(2\pi i\mathbf{S}\cdot\mathbf{r})\,\mathrm{d}\mathbf{r}. \tag{1.2.4.3a}$$

In order to evaluate the integral, the scattering operator $\exp(2\pi i\mathbf{S}\cdot\mathbf{r})$ must be written as an expansion of products of spherical harmonic functions. In terms of the complex spherical harmonic functions, the appropriate expression is (Weiss & Freeman, 1959; Cohen-Tannoudji *et al.*, 1977)

$$\exp(2\pi i\mathbf{S}\cdot\mathbf{r}) = 4\pi\sum_{l=0}^{\infty}\sum_{m=-l}^{l} i^l j_l(2\pi Sr)Y_{lm}(\theta,\varphi)Y_{lm}^*(\beta,\gamma). \tag{1.2.7.7a}$$

Table 1.2.7.2. *Index-picking rules of site-symmetric spherical harmonics (Kara & Kurki-Suonio, 1981)*

λ, μ and j are integers.

	$m \perp x$	$(2\lambda, 6\mu, +)$, $(2\lambda+1, 6\mu+3, -)$
$6/mmm$	$6 \parallel z, m \perp z, m \perp y$	$(2\lambda, 6\mu, +)$

The Fourier transform of the product of a complex spherical harmonic function with normalization $\int |Y_{lm}|^2 \, \mathrm{d}\Omega = 1$ and an arbitrary radial function $R_l(r)$ follows from the orthonormality properties of the spherical harmonic functions, and is given by

$$\int Y_{lm} R_l(r) \exp(2\pi i \mathbf{S} \cdot \mathbf{r}) \, \mathrm{d}\tau = 4\pi i^l \int j_l(2\pi S r) R_l(r) r^2 \, \mathrm{d}r Y_{lm}(\beta, \gamma), \tag{1.2.7.8a}$$

where j_l is the lth-order spherical Bessel function (Arfken, 1970), and θ and φ, β and γ are the angular coordinates of $\mathbf{r}$ and $\mathbf{S}$, respectively.

For the Fourier transform of the real spherical harmonic functions, the scattering operator is expressed in terms of the real spherical harmonics:

$$\exp(2\pi i \mathbf{S} \cdot \mathbf{r}) = \sum_{l=0}^{\infty} i^l j_l(2\pi S r)(2 - \delta_{m0})(2l+1) \sum_{m=0}^{l} \frac{(l-m)!}{(l+m)!} \times P_l^m(\cos\theta) P_l^m(\cos\beta) \cos[m(\phi - \gamma)], \tag{1.2.7.7b}$$

which leads to

$$\int y_{lmp}(\theta, \varphi) R_l(r) \exp(2\pi i \mathbf{S} \cdot \mathbf{r}) \, \mathrm{d}\tau = 4\pi i^l \langle j_l \rangle y_{lmp}(\beta, \gamma). \tag{1.2.7.8b}$$

Since y_{lmp} occurs on both sides, the expression is independent of the normalization selected. Therefore, for the Fourier transform of the density functions d_{lmp}

$$\int d_{lmp}(\theta, \varphi) R_l(r) \exp(2\pi i \mathbf{S} \cdot \mathbf{r}) \, \mathrm{d}\tau = 4\pi i^l \langle j_l \rangle d_{lmp}(\beta, \gamma). \tag{1.2.7.8c}$$

In (1.2.7.8*b*) and (1.2.7.8*c*), $\langle j_l \rangle$, the *Fourier–Bessel transform*, is the radial integral defined as

$$\langle j_l \rangle = \int j_l(2\pi S r) R_l(r) r^2 \, \mathrm{d}r \tag{1.2.7.9}$$

of which $\langle j_0 \rangle$ in expression (1.2.4.3) is a special case. The functions $\langle j_l \rangle$ for Hartree–Fock valence shells of the atoms are tabulated in scattering-factor tables (*IT* IV, 1974). Expressions for the evaluation of $\langle j_l \rangle$ using the radial function (1.2.7.5*a–c*) have been given by Stewart (1980) and in closed form for (1.2.7.5*a*) by Avery & Watson (1977) and Su & Coppens (1990). The closed-form expressions are listed in Table 1.2.7.4.

Expressions (1.2.7.8) show that the Fourier transform of a direct-space spherical harmonic function is a reciprocal-space spherical harmonic function with the same l, m, or, in other words, the spherical harmonic functions are Fourier-transform invariant.

The scattering factors $f_{lmp}(\mathbf{S})$ of the aspherical density functions $R_l(r) d_{lmp}(\theta, \phi)$ in the multipole expansion (1.2.7.6) are thus given by

$$f_{lmp}(\mathbf{S}) = 4\pi i^l \langle j_l \rangle d_{lmp}(\beta, \gamma). \tag{1.2.7.8d}$$

The reciprocal-space spherical harmonic functions in this expression are identical to the functions given in Table 1.2.7.1, except for the replacement of the direction cosines x, y and z by the direction cosines of the scattering vector $\mathbf{S}$.

1.2.8. Fourier transform of orbital products

If the wavefunction is written as a sum over normalized Slater determinants, each representing an antisymmetrized combination of occupied molecular orbitals χ_i expressed as linear combinations of atomic orbitals φ_ν, *i.e.* $\chi_i = \sum_\nu c_{i\nu} \varphi_\nu$, the electron density is given by (Stewart, 1969*a*)

$$\rho(\mathbf{r}) = \sum_i n_i \chi_i^2 = \sum_\mu \sum_\nu P_{\mu\nu} \varphi_\mu(\mathbf{r}) \varphi_\nu(\mathbf{r}), \tag{1.2.8.1}$$

with $n_i = 1$ or 2. The coefficients $P_{\mu\nu}$ are the populations of the orbital product density functions $\phi_\mu(\mathbf{r})\varphi_\nu(\mathbf{r})$ and are given by

$$P_{\mu\nu} = \sum_i n_i c_{i\mu} c_{i\nu}. \tag{1.2.8.2}$$

For a multi-Slater determinant wavefunction the electron density is expressed in terms of the occupied natural spin orbitals, leading again to (1.2.8.2) but with noninteger values for the coefficients n_i.

The summation (1.2.8.1) consists of one- and two-centre terms for which φ_μ and φ_ν are centred on the same or on different nuclei, respectively. The latter represent the overlap density, which is only significant if $\varphi_\mu(\mathbf{r})$ and $\varphi_\nu(\mathbf{r})$ have an appreciable value in the same region of space.

1.2.8.1. One-centre orbital products

If the atomic basis consists of hydrogenic type s, p, d, f, ... orbitals, the basis functions may be written as

$$\varphi(r, \theta, \varphi) = R_l(r) Y_{lm}(\theta, \varphi) \tag{1.2.8.3a}$$

or

$$\varphi(r, \theta, \varphi) = R_l(r) y_{lmp}(\theta, \varphi), \tag{1.2.8.3b}$$

which gives for corresponding values of the orbital products

$$\varphi_\mu(\mathbf{r}) \varphi_\nu(\mathbf{r}) = R_l(r) R_{l'}(r) Y_{lm}(\theta, \varphi) Y_{l'm'}(\theta, \varphi) \tag{1.2.8.4a}$$

and

$$\varphi_\mu(\mathbf{r}) \varphi_\nu(\mathbf{r}) = R_l(r) R_{l'}(r) y_{lmp}(\theta, \varphi) y_{l'm'p'}(\theta, \varphi), \tag{1.2.8.4b}$$

respectively, where it has been assumed that the radial function depends only on l.

Because the spherical harmonic functions form a complete set, their products can be expressed as a linear combination of spherical harmonics. The coefficients in this expansion are the *Clebsch–Gordan coefficients* (Condon & Shortley, 1957), defined by

$$Y_{lm}(\theta,\varphi)Y_{l'm'}(\theta,\varphi)=\sum_L\sum_M C_{Ll l'}^{Mmm'}\,Y_{LM}(\theta,\varphi) \qquad (1.2.8.5a)$$

or the equivalent definition

$$C_{Ll l'}^{Mmm'}=\int_0^{\pi}\sin\theta\,\mathrm{d}\theta\int_0^{2\pi}\mathrm{d}\varphi Y_{LM}^{*}(\theta,\varphi)Y_{lm}(\theta,\varphi)Y_{l'm'}(\theta,\varphi). \quad (1.2.8.5b)$$

The $C_{Ll l'}^{Mmm'}$ vanish, unless $L+l+l'$ is even, $|l-l'|<L<l+l'$ and $M=m+m'$.

The corresponding expression for y_{lmp} is

$$y_{lmp}(\theta,\varphi)y_{l'm'p'}(\theta,\varphi)=\sum_L\sum_M C'^{\,Mmm'}_{\substack{Ll l'\\ P}}\,y_{LMP}(\theta,\varphi), \qquad (1.2.8.5c)$$

with $M=|m+m'|$ and $|m-m'|$ for $p=p'$, and $M=-|m+m'|$ and $-|m-m'|$ for $p=-p'$ and $P=p\times p'$.

Values of C and C' for $l\le 2$ are given in Tables 1.2.8.1 and 1.2.8.2. They are valid for the functions Y_{lm} and y_{lmp} with normalization $\int|Y_{lm}|^2\,\mathrm{d}\Omega=1$ and $\int y_{lmp}^2\,\mathrm{d}\Omega=1$.

By using (1.2.8.5*a*) or (1.2.8.5*c*), the one-centre orbital products are expressed as a sum of spherical harmonic functions. It follows that the one-centre orbital product density basis set is formally equivalent to the multipole description, both in real and in reciprocal space. To obtain the relation between orbital products and the charge-density functions, the right-hand side of (1.2.8.5*c*) has to be multiplied by the ratio of the normalization constants, as the wavefunctions y_{lmp} and charge-density functions d_{lmp} are normalized in a different way as described by (1.2.7.3*a*) and (1.2.7.3*b*). Thus

$$y_{lmp}(\theta,\varphi)y_{l'm'p'}(\theta,\varphi)=\sum_L\sum_M R_{LMP}C'^{\,Mmm'}_{\substack{Ll l'\\ P}}\,d_{LMP}(\theta,\varphi), \quad (1.2.8.6)$$

where $R_{LMP}=M_{LMP}$ (wavefunction)$/L_{LMP}$ (density function). The normalization constants M_{lmp} and L_{lmp} are given in Table 1.2.7.1, while the coefficients in the expressions (1.2.8.6) are listed in Table 1.2.8.3.

1.2.8.2. Two-centre orbital products

Fourier transform of the electron density as described by (1.2.8.1) requires explicit expressions for the two-centre orbital product scattering. Such expressions are described in the literature for both Gaussian (Stewart, 1969*b*) and Slater-type (Bentley & Stewart, 1973; Avery & Ørmen, 1979) atomic orbitals. The expressions can also be used for Hartree–Fock atomic functions, as expansions in terms of Gaussian- (Stewart, 1969*b*, 1970; Stewart & Hehre, 1970; Hehre *et al.*, 1970) and Slater-type (Clementi & Roetti, 1974) functions are available for many atoms.

1.2.9. The atomic temperature factor

Since the crystal is subject to vibrational oscillations, the observed elastic scattering intensity is an average over all normal modes of the crystal. Within the Born–Oppenheimer approximation, the theoretical electron density should be calculated for each set of nuclear coordinates. An average can be obtained by taking into account the statistical weight of each nuclear configuration, which may be expressed by the probability distribution function $P(\mathbf{u}_1,\ldots,\mathbf{u}_N)$ for a set of displacement coordinates $\mathbf{u}_1,\ldots,\mathbf{u}_N$.

In general, if $\rho(\mathbf{r},\mathbf{u}_1,\ldots,\mathbf{u}_N)$ is the electron density corresponding to the geometry defined by $\mathbf{u}_1,\ldots,\mathbf{u}_N$, the time-averaged electron density is given by

$$\langle\rho(\mathbf{r})\rangle=\int\rho(\mathbf{r},\mathbf{u}_1,\ldots,\mathbf{u}_N)P(\mathbf{u}_1,\ldots,\mathbf{u}_N)\,\mathrm{d}\mathbf{u}_1\ldots\mathrm{d}\mathbf{u}_N. \quad (1.2.9.1)$$

When the crystal can be considered as consisting of perfectly following rigid entities, which may be molecules or atoms, expression (1.2.9.1) simplifies:

$$\langle\rho_{\text{rigid group}}(\mathbf{r})\rangle=\int\rho_{\text{r.g., static}}(\mathbf{r}-\mathbf{u})P(\mathbf{u})\,\mathrm{d}\mathbf{u}=\rho_{\text{r.g., static}}*P(\mathbf{u}). \quad (1.2.9.2)$$

In the approximation that the atomic electrons perfectly follow the nuclear motion, one obtains

$$\langle\rho_{\text{atom}}(\mathbf{r})\rangle=\rho_{\text{atom, static}}(\mathbf{r})*P(\mathbf{u}). \quad (1.2.9.3)$$

The Fourier transform of this convolution is the product of the Fourier transforms of the individual functions:

$$\langle f(\mathbf{H})\rangle=f(\mathbf{H})T(\mathbf{H}). \quad (1.2.9.4)$$

Thus $T(\mathbf{H})$, the atomic temperature factor, is the Fourier transform of the probability distribution $P(\mathbf{u})$.

1.2.10. The vibrational probability distribution and its Fourier transform in the harmonic approximation

For a harmonic oscillator, the probability distribution averaged over all populated energy levels is a Gaussian, centred at the equilibrium position. For the three-dimensional isotropic harmonic oscillator, the distribution is

Table 1.2.7.4. *Closed-form expressions for Fourier transform of Slater-type functions (Avery & Watson, 1977; Su & Coppens, 1990)*

$\langle j_k \rangle \equiv \int_0^\infty r^N \exp(-Zr) j_k(Kr)\,\mathrm{d}r$, $K = 4\pi \sin\theta/\lambda$.

$$P(u) = (2\pi\langle u^2\rangle)^{-3/2} \exp\{-|u|^2/2\langle u^2\rangle\}, \tag{1.2.10.1}$$

where $\langle u^2\rangle$ is the mean-square displacement in any direction.

The corresponding trivariate normal distribution to be used for anisotropic harmonic motion is, in tensor notation,

$$P(\mathbf{u}) = \frac{|\boldsymbol{\sigma}^{-1}|^{1/2}}{(2\pi)^{3/2}} \exp\{-\tfrac{1}{2}\boldsymbol{\sigma}^{-1}_{jk}(u^j u^k)\}. \tag{1.2.10.2a}$$

Here $\boldsymbol{\sigma}$ is the variance–covariance matrix, with covariant components, and $|\boldsymbol{\sigma}^{-1}|$ is the determinant of the inverse of $\boldsymbol{\sigma}$. Summation over repeated indices has been assumed. The corresponding equation in matrix notation is

$$P(\mathbf{u}) = \frac{|\boldsymbol{\sigma}^{-1}|^{1/2}}{(2\pi)^{3/2}} \exp\{-\tfrac{1}{2}(\mathbf{u})^T \boldsymbol{\sigma}^{-1}(\mathbf{u})\}, \tag{1.2.10.2b}$$

where the superscript T indicates the transpose.

The characteristic function, or Fourier transform, of $P(\mathbf{u})$ is

$$T(\mathbf{H}) = \exp\{-2\pi^2 \sigma^{jk} h_j h_k\} \tag{1.2.10.3a}$$

or

$$T(\mathbf{H}) = \exp\{-2\pi^2 \mathbf{H}^T \boldsymbol{\sigma} \mathbf{H}\}. \tag{1.2.10.3b}$$

With the change of variable $b^{jk} = 2\pi^2\sigma^{jk}$, (1.2.10.3*a*) becomes

$$T(\mathbf{H}) = \exp\{-b^{jk} h_j h_k\}.$$

1.2.11. Rigid-body analysis

The treatment of rigid-body motion of molecules or molecular fragments was developed by Cruickshank (1956) and expanded into a general theory by Schomaker & Trueblood (1968). The theory has been described by Johnson (1970*b*) and by Dunitz (1979). The latter reference forms the basis for the following treatment.

The most general motions of a rigid body consist of rotations about three axes, coupled with translations parallel to each of the axes. Such motions correspond to screw rotations. A libration around a vector $\boldsymbol{\lambda}$ (λ_1, λ_2, λ_3), with length corresponding to the magnitude of the rotation, results in a displacement $\delta\mathbf{r}$, such that

$$\delta\mathbf{r} = (\boldsymbol{\lambda} \times \mathbf{r}) = \mathbf{D}\mathbf{r} \tag{1.2.11.1}$$

with

$$\mathbf{D} = \begin{bmatrix} 0 & -\lambda_3 & \lambda_2 \\ \lambda_3 & 0 & -\lambda_1 \\ -\lambda_2 & \lambda_1 & 0 \end{bmatrix}, \tag{1.2.11.2}$$

or in Cartesian tensor notation, assuming summation over repeated indices,

$$\delta r_i = D_{ij} r_j = -\varepsilon_{ijk} \lambda_k r_j \tag{1.2.11.3}$$

where the permutation operator ε_{ijk} equals +1 for i, j, k a cyclic permutation of the indices 1, 2, 3, or −1 for a noncyclic permutation, and zero if two or more indices are equal. For i = 1, for example, only the ε_{123} and ε_{132} terms occur. Addition of a translational displacement gives

$$\delta r_i = D_{ij} r_j + t_i. \tag{1.2.11.4}$$

When a rigid body undergoes vibrations the displacements vary with time, so suitable averages must be taken to derive the mean-square displacements. If the librational and translational motions are independent, the cross products between the two terms in (1.2.11.4) average to zero and the elements of the mean-square displacement tensor of atom n, U^n_{ij}, are given by

$$\begin{aligned}
U^n_{11} &= +L_{22}r_3^2 + L_{33}r_2^2 - 2L_{23}r_2r_3 + T_{11} \\
U^n_{22} &= +L_{33}r_1^2 + L_{11}r_3^2 - 2L_{13}r_1r_3 + T_{22} \\
U^n_{33} &= +L_{11}r_2^2 + L_{22}r_1^2 - 2L_{12}r_1r_2 + T_{33} \\
U^n_{12} &= -L_{33}r_1r_2 - L_{12}r_3^2 + L_{13}r_2r_3 + L_{23}r_1r_3 + T_{12} \\
U^n_{13} &= -L_{22}r_1r_3 + L_{12}r_2r_3 - L_{13}r_2^2 + L_{23}r_1r_2 + T_{13} \\
U^n_{23} &= -L_{11}r_2r_3 + L_{12}r_1r_3 - L_{13}r_1r_2 - L_{23}r_1^2 + T_{23},
\end{aligned} \tag{1.2.11.5}$$

where the coefficients $L_{ij} = \langle\lambda_i\lambda_j\rangle$ and $T_{ij} = \langle t_i t_j\rangle$ are the elements of the 3 × 3 libration tensor $\mathbf{L}$ and the 3 × 3 translation tensor $\mathbf{T}$, respectively. Since pairs of terms such as $\langle t_i t_j\rangle$ and $\langle t_j t_i\rangle$

\end{aligned}
$$

correspond to averages over the same two scalar quantities, the **T** and **L** tensors are symmetrical.

If a rotation axis is correctly oriented, but incorrectly positioned, an additional translation component perpendicular to the rotation axes is introduced. The rotation angle and the parallel component of the translation are invariant to the position of the axis, but the perpendicular component is not. This implies that the **L** tensor is unaffected by any assumptions about the position of the libration axes, whereas the **T** tensor depends on the assumptions made concerning the location of the axes.

The quadratic correlation between librational and translational motions can be allowed for by including in (1.2.11.5) cross terms of the type $\langle D_{ik}t_j\rangle$, or, with (1.2.11.3),

$$
\begin{aligned}
U_{ij} &= \langle D_{ik}D_{jl}\rangle r_k r_l + \langle D_{ik}t_j + D_{jk}t_i\rangle r_k + \langle t_i t_j\rangle\\
&= A_{ijkl}r_k r_l + B_{ijk}r_k + \langle t_i t_j\rangle,
\end{aligned}
\tag{1.2.11.6}
$$

which leads to the explicit expressions such as

$$
\begin{aligned}
U_{11} = \langle \delta r_1\rangle^2 &= \langle\lambda_3^2\rangle r_2^2 + \langle\lambda_2^2\rangle r_3^2 - 2\langle\lambda_2\lambda_3\rangle r_2 r_3\\
&\quad - 2\langle\lambda_3 t_1\rangle r_2 - 2\langle\lambda_2 t_1\rangle r_3 + \langle t_1^2\rangle,\\
U_{12} = \langle \delta r_1 \delta r_2\rangle &= -\langle\lambda_3^2\rangle r_1 r_2 + \langle\lambda_1\lambda_3\rangle r_2 r_3 + \langle\lambda_2\lambda_3\rangle r_1 r_3\\
&\quad - \langle\lambda_1\lambda_2\rangle r_3^2 + \langle\lambda_3 t_1\rangle r_1 - \langle\lambda_1 t_1\rangle r_3\\
&\quad - \langle\lambda_3 t_2\rangle r_2 + \langle\lambda_2 t_2\rangle r_3 + \langle t_1 t_2\rangle.
\end{aligned}
\tag{1.2.11.7}
$$

The products of the type $\langle\lambda_i t_j\rangle$ are the components of an additional tensor, **S**, which unlike the tensors **T** and **L** is unsymmetrical, since $\langle\lambda_i t_j\rangle$ is different from $\langle\lambda_j t_i\rangle$. The terms involving elements of **S** may be grouped as

$$
\langle\lambda_3 t_1\rangle r_1 - \langle\lambda_3 t_2\rangle r_2 + (\langle\lambda_2 t_2\rangle - \langle\lambda_1 t_1\rangle) r_3 \tag{1.2.11.8}
$$

or

$$
S_{31}r_1 - S_{32}r_2 + (S_{22} - S_{11})r_3.
$$

As the diagonal elements occur as differences in this expression, a constant may be added to each of the diagonal terms without changing the observational equations. In other words, the trace of **S** is indeterminate.

In terms of the **L**, **T** and **S** tensors, the observational equations are

$$
U_{ij} = G_{ijkl}L_{kl} + H_{ijkl}S_{kl} + T_{ij}. \tag{1.2.11.9}
$$

The arrays G_{ijkl} and H_{ijkl} involve the atomic coordinates $(x,\ y,\ z) = (r_1,\ r_2,\ r_3)$, and are listed in Table 1.2.11.1. Equations (1.2.11.9) for each of the atoms in the rigid body form the observational equations, from which the elements of **T**, **L** and **S** can be derived by a linear least-squares procedure. One of the diagonal elements of **S** must be fixed in advance or some other suitable constraint applied because of the indeterminacy of Tr(**S**). It is common practice to set Tr(**S**) equal to zero. There are thus eight elements of **S** to be determined, as well as the six each of **L** and **T**, for a total of 20 variables. A shift of origin leaves **L** invariant, but it intermixes **T** and **S**.

If the origin is located at a centre of symmetry, for each atom at **r** with vibration tensor $\mathbf{U}^n$ there will be an equivalent atom at $-\mathbf{r}$ with the same vibration tensor. When the observational equations for these two atoms are added, the terms involving elements of **S** disappear since they are linear in the components of **r**. The other terms, involving elements of the **T** and **L** tensors, are simply doubled, like the $\mathbf{U}^n$ components.

The physical meaning of the **T** and **L** tensor elements is as follows. $T_{ij}l_i l_j$ is the mean-square amplitude of translational vibration in the direction of the unit vector **l** with components $l_1,\ l_2,\ l_3$ along the Cartesian axes and $L_{ij}l_i l_j$ is the mean-square amplitude of libration about an axis in this direction. The quantity $S_{ij}l_i l_j$ represents the mean correlation between libration

Table 1.2.8.3. *Products of two real spherical harmonic functions y_{lmp} in terms of the density functions d_{lmp} defined by equation (1.2.7.3b)*

$$
\begin{aligned}

y_{22\pm}\, y_{22\pm} &= \pm 0.31831 d_{44+} + 0.061413 d_{40} - 0.27493 d_{20} + 1.0 d_{00}\\
y_{22+}\, y_{22-} &= 0.31831 d_{44-}
\end{aligned}
$$

about the axis l and translation parallel to this axis. This quantity, like $T_{ij}l_il_j$, depends on the choice of origin, although the sum of the two quantities is independent of the origin.

The nonsymmetrical tensor **S** can be written as the sum of a symmetric tensor with elements $S^S_{ij} = (S_{ij} + S_{ji})/2$ and a skew-symmetric tensor with elements $S^A_{ij} = (S_{ij} - S_{ji})/2$. Expressed in terms of principal axes, $\mathbf{S}^S$ consists of three principal screw correlations $\langle \lambda_l t_l \rangle$. Positive and negative screw correlations correspond to opposite senses of helicity. Since an arbitrary constant may be added to all three correlation terms, only the differences between them can be determined from the data.

The skew-symmetric part $\mathbf{S}^A$ is equivalent to a vector $(\boldsymbol{\lambda} \times \mathbf{t})/2$ with components $(\boldsymbol{\lambda} \times \mathbf{t})_i/2 = (\lambda_j t_k - \lambda_k t_j)/2$, involving correlations between a libration and a perpendicular translation. The components of $\mathbf{S}^A$ can be reduced to zero, and **S** made symmetric, by a change of origin. It can be shown that the origin shift that symmetrizes **S** also minimizes the trace of **T**. In terms of the coordinate system based on the principal axes of **L**, the required origin shifts $\widehat{\rho}_i$ are

$$\widehat{\rho}_1 = \frac{\widehat{S}_{23} - \widehat{S}_{32}}{\widehat{L}_{22} + \widehat{L}_{33}} \quad \widehat{\rho}_2 = \frac{\widehat{S}_{31} - \widehat{S}_{13}}{\widehat{L}_{11} + \widehat{L}_{33}} \quad \widehat{\rho}_3 = \frac{\widehat{S}_{12} - \widehat{S}_{21}}{\widehat{L}_{11} + \widehat{L}_{22}}, \tag{1.2.11.10}$$

in which the carets indicate quantities referred to the principal axis system.

The description of the averaged motion can be simplified further by shifting to three generally nonintersecting libration axes, one each for each principal axis of **L**. Shifts of the $\mathbf{L}_1$ axis in the $\mathbf{L}_2$ and $\mathbf{L}_3$ directions by

$${}^1\widehat{\rho}_2 = -\widehat{S}_{13}/\widehat{L}_{11} \text{ and } {}^1\widehat{\rho}_3 = \widehat{S}_{12}/\widehat{L}_{11}, \tag{1.2.11.11}$$

respectively, annihilate the S_{12} and S_{13} terms of the symmetrized **S** tensor and simultaneously effect a further reduction in Tr(**T**) (the presuperscript denotes the axis that is shifted, the subscript the direction of the shift component). Analogous equations for displacements of the $\mathbf{L}_2$ and $\mathbf{L}_3$ axes are obtained by permutation of the indices. If all three axes are appropriately displaced, only the diagonal terms of **S** remain. Referred to the principal axes of **L**, they represent screw correlations along these axes and are independent of origin shifts.

Table 1.2.11.1. *The arrays G_{ijkl} and H_{ijkl} to be used in the observational equations $U_{ij} = G_{ijkl}L_{kl} + H_{ijkl}S_{kl} + T_{ij}$ [equation (1.2.11.9)]*

G_{ijkl}

	kl					
ij	11	22	33	23	31	12
11	0	z^2	y^2	$-2yz$	0	0
22	z^2	0	x^2	0	$-2xz$	0
33	y^2	x^2	0	0	0	$-2xy$
23	$-yz$	0	0	$-x^2$	xy	xz
31	0	$-xz$	0	xy	$-y^2$	yz
12	0	0	$-xy$	xz	yz	$-z^2$

H_{ijkl}

	kl								
ij	11	22	33	23	31	12	32	13	21
11	0	0	0	0	$-2y$	0	0	0	$2z$
22	0	0	0	0	0	$-2z$	$2x$	0	0
33	0	0	0	$-2x$	0	0	0	$2y$	0
23	0	$-x$	x	0	0	y	0	$-z$	0
31	y	0	$-y$	z	0	0	0	0	$-x$
12	$-z$	z	0	0	x	0	$-y$	0	0

The elements of the reduced **T** are

$$\begin{aligned} {}^rT_{II} &= \widehat{T}_{II} - \sum_{K \neq I} (\widehat{S}_{KI})^2/\widehat{L}_{KK} \\ {}^rT_{IJ} &= \widehat{T}_{IJ} - \sum_K \widehat{S}_{KI}\widehat{S}_{KJ}/\widehat{L}_{KK}, \quad J \neq I. \end{aligned} \tag{1.2.11.12}$$

The resulting description of the average rigid-body motion is in terms of six independently distributed instantaneous motions – three screw librations about nonintersecting axes (with screw pitches given by $\widehat{S}_{11}/\widehat{L}_{11}$ *etc.*) and three translations. The parameter set consists of three libration and three translation amplitudes, six angles of orientation for the principal axes of **L** and **T**, six coordinates of axis displacement, and three screw pitches, one of which has to be chosen arbitrarily, again for a total of 20 variables.

Since diagonal elements of **S** enter into the expression for ${}^rT_{IJ}$, the indeterminacy of Tr(**S**) introduces a corresponding indeterminacy in ${}^r\mathbf{T}$. The constraint Tr(**S**) = 0 is unaffected by the various rotations and translations of the coordinate systems used in the course of the analysis.

1.2.12. Treatment of anharmonicity

The probability distribution (1.2.10.2) is valid in the case of rectilinear harmonic motion. If the deviations from Gaussian shape are not too large, distributions may be used which are expansions with the Gaussian distribution as the leading term. Three such distributions are discussed in the following sections.

1.2.12.1. The Gram–Charlier expansion

The three-dimensional Gram–Charlier expansion, introduced into thermal-motion treatment by Johnson & Levy (1974), is an expansion of a function in terms of the zero and higher derivatives of a normal distribution (Kendall & Stuart, 1958). If D_j is the operator $\mathrm{d}/\mathrm{d}u^j$,

Table 1.2.12.1. *Some Hermite polynomials (Johnson & Levy, 1974; Zucker & Schulz, 1982)*

$$
\begin{aligned}
H(\mathbf{u}) &= 1\\
H_j(\mathbf{u}) &= w_j\\
H_{jk}(\mathbf{u}) &= w_jw_k - p_{jk}\\
H_{jkl}(\mathbf{u}) &= w_jw_kw_l - (w_jp_{kl} + w_kp_{lj} + w_lp_{jk}) = w_jw_kw_l - 3w_{(j}p_{kl)}\\
H_{jklm}(\mathbf{u}) &= w_jw_kw_lw_m - 6w_{(j}w_kp_{lm)} + 3p_{(j}p_{lm)}\\
H_{jklmn}(\mathbf{u}) &= w_jw_kw_lw_mw_n - 10w_{(i}w_mw_np_{jk)} + 15w_{(n}p_{jk}p_{lm)}\\
H_{jklmnp}(\mathbf{u}) &= w_jw_kw_lw_mw_nw_p - 15w_{(j}w_kw_lw_mp_{jk)} + 45w_{(j}w_kp_{lm}p_{np)}\\
&\quad - 15p_{(j}p_{lm}p_{np)}
\end{aligned}
$$

where $w_j \equiv p_{jk}u^k$ and p_{jk} are the elements of σ^{-1}, defined in expression (1.2.10.2). Indices between brackets indicate that the term is to be averaged over all permutations which produce distinct terms, keeping in mind that $p_{jk} = p_{kj}$ and $w_jw_k = w_kw_j$ as illustrated for H_{jkl}.

$$P(\mathbf{u}) = [1 - c^jD_j + \frac{1}{2!}c^{jk}D_jD_k - \frac{1}{3!}c^{jkl}D_jD_kD_l + \ldots + (-1)^r\frac{c^{\alpha_1}\ldots c^{\alpha_r}}{r!}D_{\alpha_1}D_{\alpha_r}]P_0(\mathbf{u}), \quad (1.2.12.1)$$

where $P_0(\mathbf{u})$ is the harmonic distribution, $\alpha_i = 1, 2$ or 3, and the operator $D_{\alpha_1}\ldots D_{\alpha_r}$ is the rth partial derivative $\partial^r/(\partial u^{\alpha 1}\ldots\partial u^{\alpha r})$. Summation is again implied over repeated indices.

The differential operators D may be eliminated by the use of three-dimensional Hermite polynomials $H_{\alpha_1\ldots\alpha_r}$ defined, by analogy with the one-dimensional Hermite polynomials, by the expression

$$D_{\alpha_1}\ldots D_{\alpha_r}\exp(-\tfrac{1}{2}\sigma^{-1}_{jk}u^ju^k) = (-1)^rH_{\alpha_1\ldots\alpha_r}(\mathbf{u})\exp(-\tfrac{1}{2}\sigma^{-1}_{jk}u^ju^k), \quad (1.2.12.2)$$

which gives

$$P(\mathbf{u}) = \left[1 + \frac{1}{3!}c^{jkl}H_{jkl}(\mathbf{u}) + \frac{1}{4!}c^{jklm}H_{jklm}(\mathbf{u}) + \frac{1}{5!}c^{jklmn}H_{jklmn}(\mathbf{u}) + \frac{1}{6!}c^{jklmnp}H_{jklmnp}(\mathbf{u}) + \ldots\right]P_0(\mathbf{u}), \quad (1.2.12.3)$$

where the first and second terms have been omitted since they are equivalent to a shift of the mean and a modification of the harmonic term only. The permutations of $j, k, l\ldots$ here, and in the following sections, include all combinations which produce different terms.

The coefficients c, defined by (1.2.12.1) and (1.2.12.2), are known as the *quasimoments* of the frequency function $P(\mathbf{u})$ (Kutznetsov *et al.*, 1960). They are related in a simple manner to the moments of the function (Kendall & Stuart, 1958) and are invariant to permutation of indices. There are 10, 15, 21 and 28 components of c for orders 3, 4, 5 and 6, respectively. The multivariate Hermite polynomials are functions of the elements of σ^{-1}_{jk} and of u^k, and are given in Table 1.2.12.1 for orders ≤ 6 (*IT* IV, 1974; Zucker & Schulz, 1982).

The Fourier transform of (1.2.12.3) is given by

$$T(\mathbf{H}) = \left[1 - \frac{4}{3}\pi^3ic^{jkl}h_jh_kh_l + \frac{2}{3}\pi^4c^{jklm}h_jh_kh_lh_m + \frac{4}{15}\pi^5ic^{jklmn}h_jh_kh_lh_mh_n - \frac{4}{45}\pi^6c^{jklmnp}h_jh_kh_lh_mh_nh_p + \ldots\right]T_0(\mathbf{H}), \quad (1.2.12.4)$$

where $T_0(\mathbf{H})$ is the harmonic temperature factor. $T(\mathbf{H})$ is a power-series expansion about the harmonic temperature factor, with even and odd terms, respectively, real and imaginary.

1.2.12.2. The cumulant expansion

A second statistical expansion which has been used to describe the atomic probability distribution is that of Edgeworth (Kendall & Stuart, 1958; Johnson, 1969). It expresses the function $P(\mathbf{u})$ as

$$P(\mathbf{u}) = \exp\left(\kappa^jD_j + \frac{1}{2!}\kappa^{jk}D_jD_k - \frac{1}{3!}\kappa^{jkl}D_jD_kD_l + \frac{1}{4!}\kappa^{jklm}D_jD_kD_lD_m - \ldots\right)P_0(\mathbf{u}). \quad (1.2.12.5a)$$

Like the moments μ of a distribution, the cumulants κ are descriptive constants. They are related to each other (in the one-dimensional case) by the identity

$$\exp\left\{\kappa_1t + \frac{\kappa_2t^2}{2!} + \ldots\frac{\kappa_rt^r}{r!} + \ldots\right\} = 1 + \mu_1t + \frac{\mu_2t^2}{2!} + \ldots + \frac{\mu_rt^r}{r!}. \quad (1.2.12.5b)$$

When it is substituted for t, (1.2.12.5b) is the characteristic function, or Fourier transform of $P(t)$ (Kendall & Stuart, 1958).

The first two terms in the exponent of (1.2.12.5a) can be omitted if the expansion is around the equilibrium position and the harmonic term is properly described by $P_0(\mathbf{u})$.

The Fourier transform of (1.2.12.5a) is, by analogy with the left-hand part of (1.2.12.5b) (with t replaced by $2\pi ih$),

$$T(\mathbf{H}) = \exp\left[\frac{(2\pi i)^3}{3!}\kappa^{jkl}h_jh_kh_l + \frac{(2\pi i)^4}{4!}\kappa^{jklm}h_jh_kh_lh_m + \ldots\right]T_0(\mathbf{H}) = \exp\left[-\frac{4}{3}\pi^3i\kappa^{jkl}h_jh_kh_l + \frac{2}{3}\pi^4\kappa^{jklm}h_jh_kh_lh_m + \ldots\right]T_0(\mathbf{H}), \quad (1.2.12.6)$$

where the first two terms have been omitted. Expression (1.2.12.6) is similar to (1.2.12.4) except that the entire series is in the exponent. Following Schwarzenbach (1986), (1.2.12.6) can be developed in a Taylor series, which gives

$$T(\mathbf{H}) = \left\{1 + \frac{(2\pi i)^3}{3!}\kappa^{jkl}h_jh_kh_l + \frac{(2\pi i)^4}{4!}\kappa^{jklm}h_jh_kh_lh_m + \ldots + \frac{(2\pi i)^6}{6!}\left[\kappa^{jklmp} + \frac{6!}{2!(3!)^2}\kappa^{jkl}\kappa^{mnp}\right]h_jh_kh_lh_mh_nh_p + \text{higher-order terms}\right\}T_0(\mathbf{H}). \quad (1.2.12.7)$$

This formulation, which is sometimes called the Edgeworth approximation (Zucker & Schulz, 1982), clearly shows the relation to the Gram–Charlier expansion (1.2.12.4), and corresponds to the probability distribution [analogous to (1.2.12.3)]

$$P(\mathbf{u}) = P_0(\mathbf{u})\left\{1 + \frac{1}{3!}\kappa^{jkl}H_{jkl}(\mathbf{u}) + \frac{1}{4!}\kappa^{jklm}H_{jklm}(\mathbf{u}) + \ldots + \frac{1}{6!}\left[\kappa^{jklmnp} + 10\kappa^{jkl}\kappa^{mnp}\right]H_{jklmnp} + \text{higher-order terms}\right\}. \quad (1.2.12.8)$$

The relation between the cumulants κ^{jkl} and the quasimoments c^{jkl} are apparent from comparison of (1.2.12.8) and (1.2.12.4):

$$\begin{aligned}
c^{jkl} &= \kappa^{jkl}\\
c^{jklm} &= \kappa^{jklm}\\
c^{jklmn} &= \kappa^{jklmn}\\
c^{jklmnp} &= \kappa^{jklmnp} + 10\kappa^{jkl}\kappa^{mnp}.
\end{aligned} \quad (1.2.12.9)$$

The sixth- and higher-order cumulants and quasimoments differ. Thus the third-order cumulant κ^{jkl} contributes not only to the coefficient of H_{jkl}, but also to higher-order terms of the probability distribution function. This is also the case for cumulants of higher orders. It implies that for a finite truncation of (1.2.12.6), the probability distribution cannot be represented by a finite number of terms. This is a serious difficulty when a probability distribution is to be derived from an experimental temperature factor of the cumulant type.

1.2.12.3. The one-particle potential (OPP) model

When an atom is considered as an independent oscillator vibrating in a potential well $V(\mathbf{u})$, its distribution may be described by Boltzmann statistics.

$$P(\mathbf{u}) = N \exp\{-V(\mathbf{u})/kT\}, \tag{1.2.12.10}$$

with N, the normalization constant, defined by $\int P(\mathbf{u})\ \mathrm{d}\mathbf{u} = 1$. The classical expression (1.2.12.10) is valid in the high-temperature limit for which $kT \gg V(\mathbf{u})$.

Following Dawson (1967) and Willis (1969), the potential function may be expanded in terms of increasing order of products of the contravariant displacement coordinates:

$$V = V_0 + \alpha_j u^j + \beta_{jk} u^j u^k + \gamma_{jkl} u^j u^k u^l + \delta_{jklm} u^j u^k u^l u^m + \ldots. \tag{1.2.12.11}$$

The equilibrium condition gives $\alpha_j = 0$. Substitution into (1.2.12.10) leads to an expression which may be simplified by the assumption that the leading term is the harmonic component represented by β_{jk}:

$$P(\mathbf{u}) = N \exp\{-\beta'_{jk} u^j u^k\} \times \{1 - \gamma'_{jkl} u^j u^k u^l - \delta'_{jklm} u^j u^k u^l u^m - \ldots\}, \tag{1.2.12.12}$$

in which $\beta' = \beta/kT$ *etc.* and the normalization factor N depends on the level of truncation.

The probability distribution is related to the spherical harmonic expansion. The ten products of the displacement parameters $u^j u^k u^l$, for example, are linear combinations of the seven octapoles ($l = 3$) and three dipoles ($l = 1$) (Coppens, 1980). The thermal probability distribution and the aspherical atom description can be separated only because the latter is essentially confined to the valence shell, while the former applies to all electrons which follow the nuclear motion in the atomic scattering model.

The Fourier transform of the OPP distribution, in a general coordinate system, is (Johnson, 1970*a*; Scheringer, 1985*a*)

$$T(\mathbf{H}) = T_0(\mathbf{H})\left[1 - \frac{4}{3}\pi^3 i\gamma'_{jkl} G^{jkl}(\mathbf{H}) + \frac{2}{3}\pi^4 \delta'_{jklm} G^{jklm}(\mathbf{H}) + \frac{4}{15}\pi^5 i\varepsilon'_{jklmn} G^{jklmn}(\mathbf{H}) - \frac{4}{45}\pi^6 i\varphi'_{jklmnp} G^{jklmnp}(\mathbf{H}) \ldots\right], \tag{1.2.12.13}$$

where T_0 is the harmonic temperature factor and G represents the Hermite polynomials in reciprocal space.

If the OPP temperature factor is expanded in the coordinate system which diagonalizes β_{jk}, simpler expressions are obtained in which the Hermite polynomials are replaced by products of the displacement coordinates u^j (Dawson *et al.*, 1967; Coppens, 1980; Tanaka & Marumo, 1983).

1.2.12.4. Relative merits of the three expansions

The relative merits of the Gram–Charlier and Edgeworth expansions have been discussed by Zucker & Schulz (1982), Kuhs (1983), and by Scheringer (1985*b*). In general, the Gram–Charlier expression is found to be preferable because it gives a better fit in the cases tested, and because its truncation is equivalent in real and reciprocal space. The latter is also true for the one-particle potential model, which is mathematically related to the Gram–Charlier expansion by the interchange of the real- and reciprocal-space expressions. The terms of the OPP model have a specific physical meaning. The model allows prediction of the temperature dependence of the temperature factor (Willis, 1969; Coppens, 1980), provided the potential function itself can be assumed to be temperature independent.

It has recently been shown that the Edgeworth expansion (1.2.12.5*a*) always has negative regions (Scheringer, 1985*b*). This implies that it is not a realistic description of a vibrating atom.

1.2.13. The generalized structure factor

In the generalized structure-factor formalism developed by Dawson (1975), the complex nature of both the atomic scattering factor and the generalized temperature factor are taken into account. We write for the atomic scattering factor:

$$f_j(\mathbf{H}) = f_{j,\mathrm{c}}(\mathbf{H}) + if_{j,\mathrm{a}}(\mathbf{H}) + f'_j + if''_j \tag{1.2.13.1a}$$

$$T_j(\mathbf{H}) = T_{j,\mathrm{c}}(\mathbf{H}) + iT_{j,\mathrm{a}}(\mathbf{H}) \tag{1.2.13.1b}$$

and

$$F(\mathbf{H}) = A(\mathbf{H}) + iB(\mathbf{H}), \tag{1.2.13.2}$$

where the subscripts c and a refer to the centrosymmetric and noncentrosymmetric components of the underlying electron distribution, respectively. Substitution in (1.2.4.2) gives for the real and imaginary components A and B of $F(\mathbf{H})$

$$A(\mathbf{H}) = \sum_j (f_{j,\mathrm{c}} + f'_j)[\cos(2\pi\mathbf{H}\cdot\mathbf{r}_j)T_\mathrm{c} - \sin(2\pi\mathbf{H}\cdot\mathbf{r}_j)T_\mathrm{a}] - (f_{j,\mathrm{a}} + f''_j)[\cos(2\pi\mathbf{H}\cdot\mathbf{r}_j)T_\mathrm{a} + \sin(2\pi\mathbf{H}\cdot\mathbf{r}_j)T_\mathrm{c}] \tag{1.2.13.3a}$$

and

$$B(\mathbf{H}) = \sum_j (f_{j,\mathrm{c}} + f'_j)[\cos(2\pi\mathbf{H}\cdot\mathbf{r}_j)T_\mathrm{a} + \sin(2\pi\mathbf{H}\cdot\mathbf{r}_j)T_\mathrm{c}] + (f_{j,\mathrm{a}} + f''_j)[\cos(2\pi\mathbf{H}\cdot\mathbf{r}_j)T_\mathrm{c} - \sin(2\pi\mathbf{H}\cdot\mathbf{r}_j)T_\mathrm{a}] \tag{1.2.13.3b}$$

Expressions (1.2.13.3) illustrate the relation between valence-density anisotropy and anisotropy of thermal motion.

1.2.14. Conclusion

This chapter summarizes mathematical developments of the structure-factor formalism. The introduction of atomic asphericity into the formalism and the treatment of thermal motion are interlinked. It is important that the complexities of the thermal probability distribution function can often be reduced by very low temperature experimentation. Results obtained with the multipole formalism for atomic asphericity can be used to derive physical properties and *d*-orbital populations of transition-metal atoms (*IT* C, 2004). In such applications, the deconvolution of the charge density and the thermal vibrations is essential. This deconvolution is dependent on the adequacy of the models summarized here.

The author would like to thank several of his colleagues who gave invaluable criticism of earlier versions of this manuscript. Corrections and additions were made following comments by P. J. Becker, D. Feil, N. K. Hansen, G. McIntyre, E. N. Maslen, S. Ohba, C. Scheringer and D. Schwarzenbach. Z. Su contributed to the revised version of the manuscript. Support of this work by the US

National Science Foundation (CHE8711736 and CHE9317770) is gratefully acknowledged.

1.3. Fourier transforms in crystallography: theory, algorithms and applications

By G. Bricogne

1.3.1. General introduction

Since the publication of Volume II of *International Tables*, most aspects of the theory, computation and applications of Fourier transforms have undergone considerable development, often to the point of being hardly recognizable.

The mathematical analysis of the Fourier transformation has been extensively reformulated within the framework of distribution theory, following Schwartz's work in the early 1950s.

The computation of Fourier transforms has been revolutionized by the advent of digital computers and of the Cooley–Tukey algorithm, and progress has been made at an ever-accelerating pace in the design of new types of algorithms and in optimizing their interplay with machine architecture.

These advances have transformed both theory and practice in several fields which rely heavily on Fourier methods; much of electrical engineering, for instance, has become digital signal processing.

By contrast, crystallography has remained relatively unaffected by these developments. From the conceptual point of view, old-fashioned Fourier series are still adequate for the quantitative description of X-ray diffraction, as this rarely entails consideration of molecular transforms between reciprocal-lattice points. From the practical point of view, three-dimensional Fourier transforms have mostly been used as a tool for visualizing electron-density maps, so that only moderate urgency was given to trying to achieve ultimate efficiency in these relatively infrequent calculations.

Recent advances in phasing and refinement methods, however, have placed renewed emphasis on concepts and techniques long used in digital signal processing, *e.g.* flexible sampling, Shannon interpolation, linear filtering, and interchange between convolution and multiplication. These methods are iterative in nature, and thus generate a strong incentive to design new crystallographic Fourier transform algorithms making the fullest possible use of all available symmetry to save both storage and computation.

As a result, need has arisen for a modern and coherent account of Fourier transform methods in crystallography which would provide:

(i) a simple and foolproof means of switching between the three different guises in which the Fourier transformation is encountered (Fourier transforms, Fourier series and discrete Fourier transforms), both formally and computationally;

(ii) an up-to-date presentation of the most important algorithms for the efficient numerical calculation of discrete Fourier transforms;

(iii) a systematic study of the incorporation of symmetry into the calculation of crystallographic discrete Fourier transforms;

(iv) a survey of the main types of crystallographic computations based on the Fourier transformation.

The rapid pace of progress in these fields implies that such an account would be struck by quasi-immediate obsolescence if it were written solely for the purpose of compiling a catalogue of results and formulae 'customized' for crystallographic use. Instead, the emphasis has been placed on a mode of presentation in which most results and formulae are *derived* rather than listed. This does entail a substantial mathematical overhead, but has the advantage of preserving in its 'native' form the context within which these results are obtained. It is this context, rather than any particular set of results, which constitutes the most fertile source of new ideas and new applications, and as such can have any hope at all of remaining useful in the long run.

These conditions have led to the following choices:

(i) the mathematical theory of the Fourier transformation has been cast in the language of Schwartz's theory of distributions which has long been adopted in several applied fields, in particular electrical engineering, with considerable success; the extra work involved handsomely pays for itself by allowing the three different types of Fourier transformations to be treated together, and by making all properties of the Fourier transform consequences of a single property (the convolution theorem). This is particularly useful in all questions related to the sampling theorem;

(ii) the various numerical algorithms have been presented as the consequences of basic algebraic phenomena involving Abelian groups, rings and finite fields; this degree of formalization greatly helps the subsequent incorporation of symmetry;

(iii) the algebraic nature of space groups has been re-emphasized so as to build up a framework which can accommodate both the phenomena used to factor the discrete Fourier transform and those which underlie the existence (and lead to the classification) of space groups; this common ground is found in the notion of *module over a group ring* (*i.e.* integral representation theory), which is then applied to the formulation of a large number of algorithms, many of which are new;

(iv) the survey of the main types of crystallographic computations has tried to highlight the roles played by various properties of the Fourier transformation, and the ways in which a better exploitation of these properties has been the driving force behind the discovery of more powerful methods.

In keeping with this philosophy, the theory is presented first, followed by the crystallographic applications. There are 'forward references' from mathematical results to the applications which later invoke them (thus giving 'real-life' examples rather than artificial ones), and 'backward references' as usual. In this way, the internal logic of the mathematical developments – the surest guide to future innovations – can be preserved, whereas the alternative solution of relegating these to appendices tends on the contrary to obscure that logic by subordinating it to that of the applications.

It is hoped that this attempt at an overall presentation of the main features of Fourier transforms and of their ubiquitous role in crystallography will be found useful by scientists both within and outside the field.

1.3.2. The mathematical theory of the Fourier transformation

1.3.2.1. Introduction

The Fourier transformation and the practical applications to which it gives rise occur in three different forms which, although they display a similar range of phenomena, normally require distinct formulations and different proof techniques:

(i) *Fourier transforms*, in which both function and transform depend on continuous variables;

(ii) *Fourier series*, which relate a periodic function to a discrete set of coefficients indexed by n-tuples of integers;

(iii) *discrete Fourier transforms*, which relate finite-dimensional vectors by linear operations representable by matrices.

Copyright © 2010 International Union of Crystallography

At the same time, the most useful property of the Fourier transformation – the exchange between multiplication and convolution – is mathematically the most elusive and the one which requires the greatest caution in order to avoid writing down meaningless expressions.

It is the unique merit of Schwartz's theory of distributions (Schwartz, 1966) that it affords complete control over all the troublesome phenomena which had previously forced mathematicians to settle for a piecemeal, fragmented theory of the Fourier transformation. By its ability to handle rigorously highly 'singular' objects (especially δ-functions, their derivatives, their tensor products, their products with smooth functions, their translates and lattices of these translates), distribution theory can deal with all the major properties of the Fourier transformation as particular instances of a single basic result (the exchange between multiplication and convolution), *and* can at the same time accommodate the three previously distinct types of Fourier theories within a unique framework. This brings great simplification to matters of central importance in crystallography, such as the relations between

(*a*) periodization, and sampling or decimation;

(*b*) Shannon interpolation, and masking by an indicator function;

(*c*) section, and projection;

(*d*) differentiation, and multiplication by a monomial;

(*e*) translation, and phase shift.

All these properties become subsumed under the same theorem.

This striking synthesis comes at a slight price, which is the relative complexity of the notion of distribution. It is first necessary to establish the notion of topological vector space and to gain sufficient control (or, at least, understanding) over convergence behaviour in certain of these spaces. The key notion of *metrizability* cannot be circumvented, as it underlies most of the constructs and many of the proof techniques used in distribution theory. Most of Section 1.3.2.2 builds up to the fundamental result at the end of Section 1.3.2.2.6.2, which is basic to the definition of a distribution in Section 1.3.2.3.4 and to all subsequent developments.

The reader mostly interested in applications will probably want to reach this section by starting with his or her favourite topic in Section 1.3.4, and following the backward references to the relevant properties of the Fourier transformation, then to the proof of these properties, and finally to the definitions of the objects involved. Hopefully, he or she will then feel inclined to follow the forward references and thus explore the subject from the abstract to the practical. The books by Dieudonné (1969) and Lang (1965) are particularly recommended as general references for all aspects of analysis and algebra.

1.3.2.2. Preliminary notions and notation

Throughout this text, $\mathbb{R}$ will denote the set of real numbers, $\mathbb{Z}$ the set of rational (signed) integers and $\mathbb{N}$ the set of natural (unsigned) integers. The symbol $\mathbb{R}^n$ will denote the Cartesian product of n copies of $\mathbb{R}$:

$$\mathbb{R}^n = \mathbb{R} \times \ldots \times \mathbb{R} \quad (n \text{ times}, n \geq 1),$$

so that an element $\mathbf{x}$ of $\mathbb{R}^n$ is an n-tuple of real numbers:

$$\mathbf{x} = (x_1, \ldots, x_n).$$

Similar meanings will be attached to $\mathbb{Z}^n$ and $\mathbb{N}^n$.

The symbol $\mathbb{C}$ will denote the set of complex numbers. If $z \in \mathbb{C}$, its modulus will be denoted by $|z|$, its conjugate by $\bar{z}$ (not z^*), and its real and imaginary parts by $\mathscr{Re}(z)$ and $\mathscr{Im}(z)$:

$$\mathscr{Re}(z) = \tfrac{1}{2}(z + \bar{z}), \qquad \mathscr{Im}(z) = \frac{1}{2i}(z - \bar{z}).$$

If X is a finite set, then $|X|$ will denote the number of its elements. If mapping f sends an element x of set X to the element $f(x)$ of set Y, the notation

$$f : x \longmapsto f(x)$$

will be used; the plain arrow $\rightarrow$ will be reserved for denoting limits, as in

$$\lim_{\rho \to \infty} \left(1 + \frac{x}{p}\right)^p = e^x.$$

If X is any set and S is a subset of X, the *indicator function* χ_s of S is the real-valued function on X defined by

$$\begin{aligned} \chi_S(x) &= 1 \quad \text{if } x \in S \\ &= 0 \quad \text{if } x \notin S. \end{aligned}$$

1.3.2.2.1. Metric and topological notions in $\mathbb{R}^n$

The set $\mathbb{R}^n$ can be endowed with the structure of a vector space of dimension n over $\mathbb{R}$, and can be made into a Euclidean space by treating its standard basis as an orthonormal basis and defining the Euclidean norm:

$$\|\mathbf{x}\| = \left(\sum_{i=1}^{n} x_i^2\right)^{1/2}.$$

By misuse of notation, $\mathbf{x}$ will sometimes also designate the column vector of coordinates of $\mathbf{x} \in \mathbb{R}^n$; if these coordinates are referred to an orthonormal basis of $\mathbb{R}^n$, then

$$\|\mathbf{x}\| = (\mathbf{x}^T\mathbf{x})^{1/2},$$

where $\mathbf{x}^T$ denotes the transpose of $\mathbf{x}$.

The distance between two points $\mathbf{x}$ and $\mathbf{y}$ defined by $d(\mathbf{x}, \mathbf{y}) = \|\mathbf{x} - \mathbf{y}\|$ allows the topological structure of $\mathbb{R}$ to be transferred to $\mathbb{R}^n$, making it a *metric space*. The basic notions in a metric space are those of neighbourhoods, of open and closed sets, of limit, of continuity, and of convergence (see Section 1.3.2.2.6.1).

A subset S of $\mathbb{R}^n$ is *bounded* if $\sup \|\mathbf{x} - \mathbf{y}\| < \infty$ as $\mathbf{x}$ and $\mathbf{y}$ run through S; it is *closed* if it contains the limits of all convergent sequences with elements in S. A subset K of $\mathbb{R}^n$ which is both bounded and closed has the property of being *compact*, *i.e.* that whenever K has been covered by a family of open sets, a finite subfamily can be found which suffices to cover K. Compactness is a very useful topological property for the purpose of proof, since it allows one to reduce the task of examining infinitely many local situations to that of examining only finitely many of them.

1.3.2.2.2. Functions over $\mathbb{R}^n$

Let φ be a complex-valued function over $\mathbb{R}^n$. The *support* of φ, denoted Supp φ, is the smallest closed subset of $\mathbb{R}^n$ outside which φ vanishes identically. If Supp φ is compact, φ is said to have compact support.

If $\mathbf{t} \in \mathbb{R}^n$, the *translate* of φ by $\mathbf{t}$, denoted $\tau_{\mathbf{t}}\varphi$, is defined by

$$(\tau_{\mathbf{t}}\varphi)(\mathbf{x}) = \varphi(\mathbf{x} - \mathbf{t}).$$

Its support is the geometric translate of that of φ:

$$\text{Supp } \tau_{\mathbf{t}}\varphi = \{\mathbf{x} + \mathbf{t} | \mathbf{x} \in \text{Supp } \varphi\}.$$

If A is a nonsingular linear transformation in $\mathbb{R}^n$, the *image* of φ by A, denoted $A^{\#}\varphi$, is defined by

$$(A^{\#}\varphi)(\mathbf{x}) = \varphi[A^{-1}(\mathbf{x})].$$

Its support is the geometric image of Supp φ under A:

$$\text{Supp } A^{\#}\varphi = \{A(\mathbf{x}) | \mathbf{x} \in \text{Supp } \varphi\}.$$

If S is a nonsingular affine transformation in $\mathbb{R}^n$ of the form

$$S(\mathbf{x}) = A(\mathbf{x}) + \mathbf{b}$$

with A linear, the image of φ by S is $S^{\#}\varphi = \tau_{\mathbf{b}}(A^{\#}\varphi)$, *i.e.*

$$(S^{\#}\varphi)(\mathbf{x}) = \varphi[A^{-1}(\mathbf{x} - \mathbf{b})].$$

Its support is the geometric image of Supp φ under S:

$$\text{Supp } S^{\#}\varphi = \{S(\mathbf{x}) | \mathbf{x} \in \text{Supp } \varphi\}.$$

It may be helpful to visualize the process of forming the image of a function by a geometric operation as consisting of applying that operation to the *graph* of that function, which is equivalent to applying the *inverse* transformation to the coordinates $\mathbf{x}$. This use of the inverse later affords the 'left-representation property' [see Section 1.3.4.2.2.2(*e*)] when the geometric operations form a group, which is of fundamental importance in the treatment of crystallographic symmetry (Sections 1.3.4.2.2.4, 1.3.4.2.2.5).

1.3.2.2.3. Multi-index notation

When dealing with functions in n variables and their derivatives, considerable abbreviation of notation can be obtained through the use of multi-indices.

A *multi-index* $\mathbf{p} \in \mathbb{N}^n$ is an n-tuple of natural integers: $\mathbf{p} = (p_1, \ldots, p_n)$. The *length* of $\mathbf{p}$ is defined as

$$|\mathbf{p}| = \sum_{i=1}^{n} p_i,$$

and the following abbreviations will be used:

(i) $\mathbf{x}^{\mathbf{p}} = x_1^{p_1} \ldots x_n^{p_n}$

(ii) $D_i f = \dfrac{\partial f}{\partial x_i} = \partial_i f$

(iii) $D^{\mathbf{p}} f = D_1^{p_1} \ldots D_n^{p_n} f = \dfrac{\partial^{|\mathbf{p}|} f}{\partial x_1^{p_1} \ldots \partial x_n^{p_n}}$

(iv) $\mathbf{q} \leq \mathbf{p}$ if and only if $q_i \leq p_i$ for all $i = 1, \ldots, n$

(v) $\mathbf{p} - \mathbf{q} = (p_1 - q_1, \ldots, p_n - q_n)$

(vi) $\mathbf{p}! = p_1! \times \ldots \times p_n!$

(vii) $\dbinom{\mathbf{p}}{\mathbf{q}} = \dbinom{p_1}{q_1} \times \ldots \times \dbinom{p_n}{q_n}$.

Leibniz's formula for the repeated differentiation of products then assumes the concise form

$$D^{\mathbf{p}}(fg) = \sum_{\mathbf{q} \leq \mathbf{p}} \binom{\mathbf{p}}{\mathbf{q}} D^{\mathbf{p}-\mathbf{q}} f D^{\mathbf{q}} g,$$

while the Taylor expansion of f to order m about $\mathbf{x} = \mathbf{a}$ reads

$$f(\mathbf{x}) = \sum_{|\mathbf{p}| \leq m} \frac{1}{\mathbf{p}!} [D^{\mathbf{p}} f(\mathbf{a})](\mathbf{x} - \mathbf{a})^{\mathbf{p}} + o(\|\mathbf{x} - \mathbf{a}\|^m).$$

In certain sections the notation ∇f will be used for the gradient vector of f, and the notation $(\nabla\nabla^T)f$ for the Hessian matrix of its mixed second-order partial derivatives:

$$\nabla = \begin{pmatrix} \dfrac{\partial}{\partial x_1} \\ \vdots \\ \dfrac{\partial}{\partial x_n} \end{pmatrix}, \quad \nabla f = \begin{pmatrix} \dfrac{\partial f}{\partial x_1} \\ \vdots \\ \dfrac{\partial f}{\partial x_n} \end{pmatrix},$$

$$(\nabla\nabla^T)f = \begin{pmatrix} \dfrac{\partial^2 f}{\partial x_1^2} & \cdots & \dfrac{\partial^2 f}{\partial x_1 \partial x_n} \\ \vdots & \ddots & \vdots \\ \dfrac{\partial^2 f}{\partial x_n \partial x_1} & \cdots & \dfrac{\partial^2 f}{\partial x_n^2} \end{pmatrix}.$$

1.3.2.2.4. Integration, L^p spaces

The Riemann integral used in elementary calculus suffers from the drawback that vector spaces of Riemann-integrable functions over $\mathbb{R}^n$ are not *complete* for the topology of convergence in the mean: a Cauchy sequence of integrable functions may converge to a nonintegrable function.

To obtain the property of completeness, which is fundamental in functional analysis, it was necessary to extend the notion of integral. This was accomplished by Lebesgue [see Berberian (1962), Dieudonné (1970), or Chapter 1 of Dym & McKean (1972) and the references therein, or Chapter 9 of Sprecher (1970)], and entailed identifying functions which differed only on a subset of zero measure in $\mathbb{R}^n$ (such functions are said to be equal 'almost everywhere'). The vector spaces $L^p(\mathbb{R}^n)$ consisting of function classes f modulo this identification for which

$$\|\mathbf{f}\|_p = \left(\int_{\mathbb{R}^n} |f(\mathbf{x})|^p \, \mathrm{d}^n\mathbf{x} \right)^{1/p} < \infty$$

are then complete for the topology induced by the norm $\|.\|_p$: the limit of every Cauchy sequence of functions in L^p is itself a function in L^p (Riesz–Fischer theorem).

The space $L^1(\mathbb{R}^n)$ consists of those function classes f such that

$$\|f\|_1 = \int_{\mathbb{R}^n} |f(\mathbf{x})| \, \mathrm{d}^n\mathbf{x} < \infty$$

which are called *summable* or *absolutely integrable*. The convolution product:

$$\begin{aligned}(f * g)(\mathbf{x}) &= \int_{\mathbb{R}^n} f(\mathbf{y}) g(\mathbf{x}-\mathbf{y}) \, \mathrm{d}^n\mathbf{y} \\ &= \int_{\mathbb{R}^n} f(\mathbf{x}-\mathbf{y}) g(\mathbf{y}) \, \mathrm{d}^n\mathbf{y} = (g * f)(\mathbf{x})\end{aligned}$$

is well defined; combined with the vector space structure of L^1, it makes L^1 into a (commutative) *convolution algebra*. However, this algebra has no unit element: there is no $f \in L^1$ such that $f * g = g$ for all $g \in L^1$; it has only approximate units, *i.e.* sequences (f_ν) such that $f_\nu * g$ tends to g in the L^1 topology as $\nu \to \infty$. This is one of the starting points of distribution theory.

The space $L^2(\mathbb{R}^n)$ of *square-integrable* functions can be endowed with a scalar product

$$(f, g) = \int_{\mathbb{R}^n} \overline{f(\mathbf{x})} g(\mathbf{x}) \, \mathrm{d}^n\mathbf{x}$$

which makes it into a *Hilbert space*. The Cauchy–Schwarz inequality

$$|(f, g)| \leq [(f, f)(g, g)]^{1/2}$$

generalizes the fact that the absolute value of the cosine of an angle is less than or equal to 1.

The space $L^\infty(\mathbb{R}^n)$ is defined as the space of functions f such that

$$\|f\|_\infty = \lim_{p\to\infty} \|f\|_p = \lim_{p\to\infty} \left(\int_{\mathbb{R}^n} |f(\mathbf{x})|^p \, \mathrm{d}^n\mathbf{x} \right)^{1/p} < \infty.$$

The quantity $\|f\|_\infty$ is called the 'essential sup norm' of f, as it is the smallest positive number which $|f(\mathbf{x})|$ exceeds only on a subset of zero measure in $\mathbb{R}^n$. A function $f \in L^\infty$ is called *essentially bounded*.

1.3.2.2.5. Tensor products. Fubini's theorem

Let $f \in L^1(\mathbb{R}^m)$, $g \in L^1(\mathbb{R}^n)$. Then the function

$$f \otimes g : (\mathbf{x}, \mathbf{y}) \longmapsto f(\mathbf{x}) g(\mathbf{y})$$

is called the *tensor product* of f and g, and belongs to $L^1(\mathbb{R}^m \times \mathbb{R}^n)$. The finite linear combinations of functions of the form $f \otimes g$ span a subspace of $L^1(\mathbb{R}^m \times \mathbb{R}^n)$ called the tensor product of $L^1(\mathbb{R}^m)$ and $L^1(\mathbb{R}^n)$ and denoted $L^1(\mathbb{R}^m) \otimes L^1(\mathbb{R}^n)$.

The integration of a general function over $\mathbb{R}^m \times \mathbb{R}^n$ may be accomplished in two steps according to *Fubini's theorem*. Given $F \in L^1(\mathbb{R}^m \times \mathbb{R}^n)$, the functions

$$\begin{aligned}F_1 &: \mathbf{x} \longmapsto \int_{\mathbb{R}^n} F(\mathbf{x}, \mathbf{y}) \, \mathrm{d}^n\mathbf{y} \\ F_2 &: \mathbf{y} \longmapsto \int_{\mathbb{R}^m} F(\mathbf{x}, \mathbf{y}) \, \mathrm{d}^m\mathbf{x}\end{aligned}$$

exist for almost all $\mathbf{x} \in \mathbb{R}^m$ and almost all $\mathbf{y} \in \mathbb{R}^n$, respectively, are integrable, and

$$\int_{\mathbb{R}^m\times\mathbb{R}^n} F(\mathbf{x}, \mathbf{y}) \, \mathrm{d}^m\mathbf{x} \, \mathrm{d}^n\mathbf{y} = \int_{\mathbb{R}^m} F_1(\mathbf{x}) \, \mathrm{d}^m\mathbf{x} = \int_{\mathbb{R}^n} F_2(\mathbf{y}) \, \mathrm{d}^n\mathbf{y}.$$

Conversely, if any one of the integrals

(i) $$\int_{\mathbb{R}^m\times\mathbb{R}^n} |F(\mathbf{x}, \mathbf{y})| \, \mathrm{d}^m\mathbf{x} \, \mathrm{d}^n\mathbf{y}$$

(ii) $$\int_{\mathbb{R}^m} \left(\int_{\mathbb{R}^n} |F(\mathbf{x}, \mathbf{y})| \, \mathrm{d}^n\mathbf{y} \right) \mathrm{d}^m\mathbf{x}$$

(iii) $$\int_{\mathbb{R}^n} \left(\int_{\mathbb{R}^m} |F(\mathbf{x}, \mathbf{y})| \, \mathrm{d}^m\mathbf{x} \right) \mathrm{d}^n\mathbf{y}$$

is finite, then so are the other two, and the identity above holds. It is then (and only then) permissible to change the order of integrations.

Fubini's theorem is of fundamental importance in the study of tensor products and convolutions of distributions.

1.3.2.2.6. Topology in function spaces

Geometric intuition, which often makes 'obvious' the topological properties of the real line and of ordinary space, cannot be relied upon in the study of function spaces: the latter are infinite-dimensional, and several inequivalent notions of convergence may exist. A careful analysis of topological concepts and of their interrelationship is thus a necessary prerequisite to the study of these spaces. The reader may consult Dieudonné (1969, 1970), Friedman (1970), Trèves (1967) and Yosida (1965) for detailed expositions.

1.3.2.2.6.1. General topology

Most topological notions are first encountered in the setting of *metric spaces*. A metric space E is a set equipped with a *distance function* d from $E \times E$ to the non-negative reals which satisfies:

(i)	$d(x, y) = d(y, x)$	$\forall x, y \in E$	(symmetry);
(ii)	$d(x, y) = 0$	iff $x = y$	(separation);
(iii)	$d(x, z) \leq d(x, y) + d(y, z)$	$\forall x, y, z \in E$	(triangular inequality).

By means of d, the following notions can be defined: open balls, neighbourhoods; open and closed sets, interior and closure; convergence of sequences, continuity of mappings; Cauchy sequences and completeness; compactness; connectedness. They suffice for the investigation of a great number of questions in analysis and geometry (see *e.g.* Dieudonné, 1969).

Many of these notions turn out to depend only on the properties of the collection $\mathcal{O}(E)$ of open subsets of E: two distance functions leading to the same $\mathcal{O}(E)$ lead to identical topological properties. An axiomatic reformulation of topological notions is thus possible: a *topology* in E is a collection $\mathcal{O}(E)$ of subsets of E which satisfy suitable axioms and are deemed open irrespective

of the way they are obtained. From the practical standpoint, however, a topology which can be obtained from a distance function (called a *metrizable* topology) has the very useful property that *the notions of closure, limit and continuity may be defined by means of sequences*. For nonmetrizable topologies, these notions are much more difficult to handle, requiring the use of 'filters' instead of sequences.

In some spaces E, a topology may be most naturally defined by a family of *pseudo-distances* $(d_\alpha)_{\alpha\in A}$, where each d_α satisfies (i) and (iii) but not (ii). Such spaces are called *uniformizable*. If for every pair $(x, y) \in E \times E$ there exists $\alpha \in A$ such that $d_\alpha(x, y) \neq 0$, then the separation property can be recovered. If furthermore a *countable* subfamily of the d_α suffices to define the topology of E, the latter can be shown to be *metrizable*, so that limiting processes in E may be studied by means of sequences.

1.3.2.2.6.2. Topological vector spaces

The function spaces E of interest in Fourier analysis have an underlying vector space structure over the field $\mathbb{C}$ of complex numbers. A topology on E is said to be *compatible* with a vector space structure on E if vector addition [*i.e.* the map $(\mathbf{x}, \mathbf{y}) \longmapsto \mathbf{x} + \mathbf{y}$] and scalar multiplication [*i.e.* the map $(\lambda, \mathbf{x}) \longmapsto \lambda\mathbf{x}$] are both *continuous*; E is then called a *topological vector space*. Such a topology may be defined by specifying a 'fundamental system S of neighbourhoods of $\mathbf{0}$', which can then be translated by vector addition to construct neighbourhoods of other points $\mathbf{x} \neq \mathbf{0}$.

A *norm* ν on a vector space E is a non-negative real-valued function on $E \times E$ such that

(i′)	$\nu(\lambda\mathbf{x}) = \lvert\lambda\rvert\nu(\mathbf{x})$	for all $\lambda \in \mathbb{C}$ and $\mathbf{x} \in E$;
(ii′)	$\nu(\mathbf{x}) = 0$	if and only if $\mathbf{x} = \mathbf{0}$;
(iii′)	$\nu(\mathbf{x} + \mathbf{y}) \leq \nu(\mathbf{x}) + \nu(\mathbf{y})$	for all $\mathbf{x}, \mathbf{y} \in E$.

Subsets of E defined by conditions of the form $\nu(\mathbf{x}) \leq r$ with $r > 0$ form a fundamental system of neighbourhoods of $\mathbf{0}$. The corresponding topology makes E a *normed space*. This topology is *metrizable*, since it is equivalent to that derived from the translation-invariant distance $d(\mathbf{x}, \mathbf{y}) = \nu(\mathbf{x} - \mathbf{y})$. Normed spaces which are *complete*, *i.e.* in which all Cauchy sequences converge, are called *Banach spaces*; they constitute the natural setting for the study of differential calculus.

A *semi-norm* σ on a vector space E is a positive real-valued function on $E \times E$ which satisfies (i′) and (iii′) but not (ii′). Given a set Σ of semi-norms on E such that any pair $(\mathbf{x}, \mathbf{y})$ in $E \times E$ is separated by at least one $\sigma \in \Sigma$, let B be the set of those subsets $\Gamma_{\sigma,r}$ of E defined by a condition of the form $\sigma(\mathbf{x}) \leq r$ with $\sigma \in \Sigma$ and $r > 0$; and let S be the set of finite intersections of elements of B. Then there exists a unique topology on E for which S is a fundamental system of neighbourhoods of $\mathbf{0}$. This topology is *uniformizable* since it is equivalent to that derived from the family of translation-invariant pseudo-distances $(\mathbf{x}, \mathbf{y}) \longmapsto \sigma(\mathbf{x} - \mathbf{y})$. It is *metrizable* if and only if it can be constructed by the above procedure with Σ a *countable* set of semi-norms. If furthermore E is complete, E is called a *Fréchet space*.

If E is a topological vector space over $\mathbb{C}$, its *dual* E^* is the set of all linear mappings from E to $\mathbb{C}$ (which are also called *linear forms*, or *linear functionals*, over E). The subspace of E^* consisting of all linear forms which are *continuous* for the topology of E is called the *topological dual* of E and is denoted E'. If the topology on E is metrizable, then the continuity of a linear form $T \in E'$ at $f \in E$ can be ascertained by means of sequences, *i.e.* by checking that the sequence $[T(f_j)]$ of complex numbers converges to $T(f)$ in $\mathbb{C}$ whenever the sequence (f_j) converges to f in E.

1.3.2.3. Elements of the theory of distributions

1.3.2.3.1. Origins

At the end of the 19th century, Heaviside proposed under the name of 'operational calculus' a set of rules for solving a class of differential, partial differential and integral equations encountered in electrical engineering (today's 'signal processing'). These rules worked remarkably well but were devoid of mathematical justification (see Whittaker, 1928). In 1926, Dirac introduced his famous δ-function [see Dirac (1958), pp. 58–61], which was found to be related to Heaviside's constructs. Other singular objects, together with procedures to handle them, had already appeared in several branches of analysis [Cauchy's 'principal values'; Hadamard's 'finite parts' (Hadamard, 1932, 1952); Riesz's regularization methods for certain divergent integrals (Riesz, 1938, 1949)] as well as in the theories of Fourier series and integrals (see *e.g.* Bochner, 1932, 1959). Their very definition often verged on violating the rigorous rules governing limiting processes in analysis, so that subsequent recourse to limiting processes could lead to erroneous results; *ad hoc* precautions thus had to be observed to avoid mistakes in handling these objects.

In 1945–1950, Laurent Schwartz proposed his theory of distributions (see Schwartz, 1966), which provided a unified and definitive treatment of all these questions, with a striking combination of rigour and simplicity. Schwartz's treatment of Dirac's δ-function illustrates his approach in a most direct fashion. Dirac's original definition reads:

(i) $\delta(\mathbf{x}) = 0$ for $\mathbf{x} \neq \mathbf{0}$,

(ii) $\int_{\mathbb{R}^n} \delta(\mathbf{x})\, \mathrm{d}^n\mathbf{x} = 1$.

These two conditions are irreconcilable with Lebesgue's theory of integration: by (i), δ vanishes almost everywhere, so that its integral in (ii) must be 0, not 1.

A better definition consists in specifying that

(iii) $\int_{\mathbb{R}^n} \delta(\mathbf{x})\varphi(\mathbf{x})\, \mathrm{d}^n\mathbf{x} = \varphi(\mathbf{0})$

for any function φ sufficiently well behaved near $\mathbf{x} = \mathbf{0}$. This is related to the problem of finding a unit for convolution (Section 1.3.2.2.4). As will now be seen, this definition is still unsatisfactory. Let the sequence (f_ν) in $L^1(\mathbb{R}^n)$ be an approximate convolution unit, *e.g.*

$$f_\nu(\mathbf{x}) = \left(\frac{\nu}{2\pi}\right)^{1/2} \exp(-\tfrac{1}{2}\nu^2\|\mathbf{x}\|^2).$$

Then for any well behaved function φ the integrals

$$\int_{\mathbb{R}^n} f_\nu(\mathbf{x})\varphi(\mathbf{x})\, \mathrm{d}^n\mathbf{x}$$

exist, and the sequence of their numerical values tends to $\varphi(\mathbf{0})$. It is tempting to combine this with (iii) to conclude that δ is the limit of the sequence (f_ν) as $\nu \to \infty$. However,

$$\lim f_\nu(\mathbf{x}) = 0 \quad \text{as } \nu \to \infty$$

almost everywhere in $\mathbb{R}^n$ and the crux of the problem is that

$$\varphi(\mathbf{0}) = \lim_{\nu\to\infty} \int_{\mathbb{R}^n} f_\nu(\mathbf{x})\varphi(\mathbf{x})\,\mathrm{d}^n\mathbf{x}$$
$$\neq \int_{\mathbb{R}^n} \Big[\lim_{\nu\to\infty} f_\nu(\mathbf{x})\Big]\varphi(\mathbf{x})\,\mathrm{d}^n\mathbf{x} = 0$$

because the sequence (f_ν) does not satisfy the hypotheses of Lebesgue's dominated convergence theorem.

Schwartz's solution to this problem is deceptively simple: the regular behaviour one is trying to capture is an attribute not of the sequence of functions (f_ν), but of the sequence of continuous linear functionals

$$T_\nu : \varphi \longmapsto \int_{\mathbb{R}^n} f_\nu(\mathbf{x})\varphi(\mathbf{x})\,\mathrm{d}^n\mathbf{x}$$

which has as a limit the continuous functional

$$T : \varphi \longmapsto \varphi(\mathbf{0}).$$

It is the latter functional which constitutes the proper definition of δ. The previous paradoxes arose because one insisted on writing down the simple linear operation T in terms of an integral.

The essence of Schwartz's theory of distributions is thus that, rather than try to define and handle 'generalized functions' *via* sequences such as (f_ν) [an approach adopted *e.g.* by Lighthill (1958) and Erdélyi (1962)], one should instead look at them as continuous linear functionals over spaces of well behaved functions.

There are many books on distribution theory and its applications. The reader may consult in particular Schwartz (1965, 1966), Gel'fand & Shilov (1964), Bremermann (1965), Trèves (1967), Challifour (1972), Friedlander (1982), and the relevant chapters of Hörmander (1963) and Yosida (1965). Schwartz (1965) is especially recommended as an introduction.

1.3.2.3.2. Rationale

The guiding principle which leads to requiring that the functions φ above (traditionally called 'test functions') should be well behaved is that correspondingly 'wilder' behaviour can then be accommodated in the limiting behaviour of the f_ν while still keeping the integrals $\int_{\mathbb{R}^n} f_\nu\varphi\,\mathrm{d}^n\mathbf{x}$ under control. Thus

(i) to minimize restrictions on the limiting behaviour of the f_ν *at infinity*, the φ's will be chosen to have *compact support*;

(ii) to minimize restrictions on the *local* behaviour of the f_ν, the φ's will be chosen *infinitely differentiable*.

To ensure further the *continuity* of functionals such as T_ν with respect to the test function φ as the f_ν go increasingly wild, very strong control will have to be exercised in the way in which a sequence (φ_j) of test functions will be said to converge towards a limiting φ: conditions will have to be imposed not only on the values of the *functions* φ_j, but also on those of all their *derivatives*. Hence, defining a strong enough topology on the space of test functions φ is an *essential* prerequisite to the development of a satisfactory theory of distributions.

1.3.2.3.3. Test-function spaces

With this rationale in mind, the following function spaces will be defined for any open subset Ω of $\mathbb{R}^n$ (which may be the whole of $\mathbb{R}^n$):

(*a*) $\mathscr{E}(\Omega)$ is the space of complex-valued functions over Ω which are indefinitely differentiable;

(*b*) $\mathscr{D}(\Omega)$ is the subspace of $\mathscr{E}(\Omega)$ consisting of functions with (unspecified) compact support contained in $\mathbb{R}^n$;

(*c*) $\mathscr{D}_K(\Omega)$ is the subspace of $\mathscr{D}(\Omega)$ consisting of functions whose (compact) support is contained within a fixed compact subset K of Ω.

When Ω is unambiguously defined by the context, we will simply write $\mathscr{E}$, $\mathscr{D}$, $\mathscr{D}_K$.

It sometimes suffices to require the existence of continuous derivatives only up to finite order m inclusive. The corresponding spaces are then denoted $\mathscr{E}^{(m)}$, $\mathscr{D}^{(m)}$, $\mathscr{D}_K^{(m)}$ with the convention that if $m = 0$, only continuity is required.

The *topologies* on these spaces constitute the most important ingredients of distribution theory, and will be outlined in some detail.

1.3.2.3.3.1. Topology on $\mathscr{E}(\Omega)$

It is defined by the family of semi-norms

$$\varphi \in \mathscr{E}(\Omega) \longmapsto \sigma_{\mathbf{p},K}(\varphi) = \sup_{\mathbf{x}\in K} |D^{\mathbf{p}}\varphi(\mathbf{x})|,$$

where $\mathbf{p}$ is a multi-index and K a compact subset of Ω. A fundamental system S of neighbourhoods of the origin in $\mathscr{E}(\Omega)$ is given by subsets of $\mathscr{E}(\Omega)$ of the form

$$V(m, \varepsilon, K) = \{\varphi \in \mathscr{E}(\Omega) | |\mathbf{p}| \leq m \Rightarrow \sigma_{\mathbf{p},K}(\varphi) < \varepsilon\}$$

for all natural integers m, positive real ε, and compact subset K of Ω. Since a *countable* family of compact subsets K suffices to cover Ω, and since restricted values of ε of the form $\varepsilon = 1/N$ lead to the same topology, S is equivalent to a *countable* system of neighbourhoods and hence $\mathscr{E}(\Omega)$ *is metrizable*.

Convergence in $\mathscr{E}$ may thus be defined by means of sequences. A sequence (φ_ν) in $\mathscr{E}$ will be said to converge to 0 if for any given $V(m, \varepsilon, K)$ there exists ν_0 such that $\varphi_\nu \in V(m, \varepsilon, K)$ whenever $\nu > \nu_0$; in other words, if the φ_ν and all their derivatives $D^{\mathbf{p}}\varphi_\nu$ converge to 0 uniformly on any given compact K in Ω.

1.3.2.3.3.2. Topology on $\mathscr{D}_k(\Omega)$

It is defined by the family of semi-norms

$$\varphi \in \mathscr{D}_K(\Omega) \longmapsto \sigma_{\mathbf{p}}(\varphi) = \sup_{\mathbf{x}\in K} |D^{\mathbf{p}}\varphi(\mathbf{x})|,$$

where K is now fixed. The fundamental system S of neighbourhoods of the origin in $\mathscr{D}_K$ is given by sets of the form

$$V(m, \varepsilon) = \{\varphi \in \mathscr{D}_K(\Omega) | |\mathbf{p}| \leq m \Rightarrow \sigma_{\mathbf{p}}(\varphi) < \varepsilon\}.$$

It is equivalent to the countable subsystem of the $V(m, 1/N)$, hence $\mathscr{D}_K(\Omega)$ *is metrizable*.

Convergence in $\mathscr{D}_K$ may thus be defined by means of sequences. A sequence (φ_ν) in $\mathscr{D}_K$ will be said to converge to 0 if for any given $V(m, \varepsilon)$ there exists ν_0 such that $\varphi_\nu \in V(m, \varepsilon)$ whenever $\nu > \nu_0$; in other words, if the φ_ν and all their derivatives $D^{\mathbf{p}}\varphi_\nu$ converge to 0 uniformly in K.

1.3.2.3.3.3. Topology on $\mathscr{D}(\Omega)$

It is defined by the fundamental system of neighbourhoods of the origin consisting of sets of the form

$$V((m), (\varepsilon))$$
$$= \left\{\varphi \in \mathscr{D}(\Omega) | |\mathbf{p}| \leq m_\nu \Rightarrow \sup_{\|\mathbf{x}\|\leq\nu} |D^{\mathbf{p}}\varphi(\mathbf{x})| < \varepsilon_\nu \text{ for all } \nu\right\},$$

where (m) is an increasing sequence (m_ν) of integers tending to $+\infty$ and (ε) is a decreasing sequence (ε_ν) of positive reals tending to 0, as $\nu \to \infty$.

This topology is *not metrizable*, because the sets of sequences (m) and (ε) are essentially uncountable. It can, however, be shown to be the *inductive limit* of the topology of the subspaces $\mathscr{D}_K$, in the following sense: V is a neighbourhood of the origin in $\mathscr{D}$ if and only if its intersection with $\mathscr{D}_K$ is a neighbourhood of the origin in $\mathscr{D}_K$ for any given compact K in Ω.

A sequence (φ_ν) in $\mathscr{D}$ will thus be said to converge to 0 in $\mathscr{D}$ if all the φ_ν belong to some $\mathscr{D}_K$ (with K a compact subset of Ω independent of ν) and if (φ_ν) converges to 0 in $\mathscr{D}_K$.

As a result, a complex-valued functional T on $\mathscr{D}$ will be said to be continuous for the topology of $\mathscr{D}$ if and only if, for any given compact K in Ω, its restriction to $\mathscr{D}_K$ is continuous for the topology of $\mathscr{D}_K$, *i.e.* maps convergent sequences in $\mathscr{D}_K$ to convergent sequences in $\mathbb{C}$.

This property of $\mathscr{D}$, *i.e.* having a nonmetrizable topology which is the inductive limit of metrizable topologies in its subspaces $\mathscr{D}_K$, conditions the whole structure of distribution theory and dictates that of many of its proofs.

1.3.2.3.3.4. Topologies on $\mathscr{E}^{(m)}$, $\mathscr{D}_k^{(m)}$, $\mathscr{D}^{(m)}$

These are defined similarly, but only involve conditions on derivatives up to order m.

1.3.2.3.4. Definition of distributions

A *distribution* T on Ω is a *linear form* over $\mathscr{D}(\Omega)$, *i.e.* a map

$$T : \varphi \longmapsto \langle T, \varphi \rangle$$

which associates linearly a complex number $\langle T, \varphi \rangle$ to any $\varphi \in \mathscr{D}(\Omega)$, and which is *continuous* for the topology of that space. In the terminology of Section 1.3.2.2.6.2, T is an element of $\mathscr{D}'(\Omega)$, the *topological dual* of $\mathscr{D}(\Omega)$.

Continuity over $\mathscr{D}$ is equivalent to continuity over $\mathscr{D}_K$ for all compact K contained in Ω, and hence to the condition that for any sequence (φ_ν) in $\mathscr{D}$ such that

(i) Supp φ_ν is contained in some compact K independent of ν,

(ii) the sequences $(|D^{\mathbf{p}}\varphi_\nu|)$ converge uniformly to 0 on K for all multi-indices $\mathbf{p}$;

then the sequence of complex numbers $\langle T, \varphi_\nu \rangle$ converges to 0 in $\mathbb{C}$.

If the continuity of a distribution T requires (ii) for $|\mathbf{p}| \leq m$ only, T may be defined over $\mathscr{D}^{(m)}$ and thus $T \in \mathscr{D}'^{(m)}$; T is said to be a *distribution of finite order m*. In particular, for $m = 0$, $\mathscr{D}^{(0)}$ is the space of continuous functions with compact support, and a distribution $T \in \mathscr{D}'^{(0)}$ is a (Radon) *measure* as used in the theory of integration. Thus measures are particular cases of distributions.

Generally speaking, the *larger* a space of test functions, the *smaller* its topological dual:

$$m < n \Rightarrow \mathscr{D}^{(m)} \supset \mathscr{D}^{(n)} \Rightarrow \mathscr{D}'^{(n)} \supset \mathscr{D}'^{(m)}.$$

This clearly results from the observation that if the φ's are allowed to be less regular, then less wildness can be accommodated in T if the continuity of the map $\varphi \longmapsto \langle T, \varphi \rangle$ with respect to φ is to be preserved.

1.3.2.3.5. First examples of distributions

(i) The linear map $\varphi \longmapsto \langle \delta, \varphi \rangle = \varphi(\mathbf{0})$ is a measure (*i.e.* a zeroth-order distribution) called Dirac's measure or (improperly) Dirac's 'δ-function'.

(ii) The linear map $\varphi \longmapsto \langle \delta_{(\mathbf{a})}, \varphi \rangle = \varphi(\mathbf{a})$ is called Dirac's measure at point $\mathbf{a} \in \mathbb{R}^n$.

(iii) The linear map $\varphi \longmapsto (-1)^{\mathbf{p}} D^{\mathbf{p}}\varphi(\mathbf{a})$ is a distribution of order $m = |\mathbf{p}| > 0$, and hence is not a measure.

(iv) The linear map $\varphi \longmapsto \sum_{\nu>0} \varphi^{(\nu)}(\nu)$ is a distribution of infinite order on $\mathbb{R}$: the order of differentiation is bounded for each φ (because φ has compact support) but is not as φ varies.

(v) If $(\mathbf{p}_\nu)$ is a sequence of multi-indices $\mathbf{p}_\nu = (p_{1\nu}, \ldots, p_{n\nu})$ such that $|\mathbf{p}_\nu| \to \infty$ as $\nu \to \infty$, then the linear map $\varphi \longmapsto \sum_{\nu>0} (D^{\mathbf{p}_\nu}\varphi)(\mathbf{p}_\nu)$ is a distribution of infinite order on $\mathbb{R}^n$.

1.3.2.3.6. Distributions associated to locally integrable functions

Let f be a complex-valued function over Ω such that $\int_K |f(\mathbf{x})|\, \mathrm{d}^n\mathbf{x}$ exists for any given compact K in Ω; f is then called *locally integrable*.

The linear mapping from $\mathscr{D}(\Omega)$ to $\mathbb{C}$ defined by

$$\varphi \longmapsto \int_\Omega f(\mathbf{x})\varphi(\mathbf{x})\, \mathrm{d}^n\mathbf{x}$$

may then be shown to be continuous over $\mathscr{D}(\Omega)$. It thus defines a *distribution* $T_f \in \mathscr{D}'(\Omega)$:

$$\langle T_f, \varphi \rangle = \int_\Omega f(\mathbf{x})\varphi(\mathbf{x})\, \mathrm{d}^n\mathbf{x}.$$

As the continuity of T_f only requires that $\varphi \in \mathscr{D}^{(0)}(\Omega)$, T_f is actually a Radon measure.

It can be shown that two locally integrable functions f and g define the same distribution, *i.e.*

$$\langle T_f, \varphi \rangle = \langle T_K, \varphi \rangle \quad \text{for all } \varphi \in \mathscr{D},$$

if and only if they are equal almost everywhere. The classes of locally integrable functions modulo this equivalence form a vector space denoted $L^1_{\mathrm{loc}}(\Omega)$; each element of $L^1_{\mathrm{loc}}(\Omega)$ may therefore be identified with the distribution T_f defined by any one of its representatives f.

1.3.2.3.7. Support of a distribution

A distribution $T \in \mathscr{D}'(\Omega)$ is said to *vanish* on an open subset ω of Ω if it vanishes on all functions in $\mathscr{D}(\omega)$, *i.e.* if $\langle T, \varphi \rangle = 0$ whenever $\varphi \in \mathscr{D}(\omega)$.

The *support* of a distribution T, denoted Supp T, is then defined as the complement of the set-theoretic union of those open subsets ω on which T vanishes; or equivalently as the smallest closed subset of Ω outside which T vanishes.

When $T = T_f$ for $f \in L^1_{\mathrm{loc}}(\Omega)$, then Supp T = Supp f, so that the two notions coincide. Clearly, if Supp T and Supp φ are disjoint subsets of Ω, then $\langle T, \varphi \rangle = 0$.

It can be shown that any distribution $T \in \mathscr{D}'$ with compact support may be extended from $\mathscr{D}$ to $\mathscr{E}$ while remaining continuous, so that $T \in \mathscr{E}'$; and that conversely, if $S \in \mathscr{E}'$, then its restriction T to $\mathscr{D}$ is a distribution with compact support. Thus, *the topological dual $\mathscr{E}'$ of $\mathscr{E}$ consists of those distributions in $\mathscr{D}'$ which have compact support*. This is intuitively clear since, if the condition of having compact support is fulfilled by T, it needs no longer be required of φ, which may then roam through $\mathscr{E}$ rather than $\mathscr{D}$.

1.3.2.3.8. Convergence of distributions

A *sequence* (T_j) of distributions will be said to converge in $\mathscr{D}'$ to a distribution T as $j \to \infty$ if, for any given $\varphi \in \mathscr{D}$, the sequence of complex numbers $(\langle T_j, \varphi \rangle)$ converges in $\mathbb{C}$ to the complex number $\langle T, \varphi \rangle$.

A *series* $\sum_{j=0}^{\infty} T_j$ of distributions will be said to converge in $\mathscr{D}'$ and to have distribution S as its sum if the sequence of partial sums $S_k = \sum_{j=0}^{k}$ converges to S.

These definitions of convergence in $\mathscr{D}'$ assume that the limits T and S are known in advance, and are distributions. This raises the question of the *completeness* of $\mathscr{D}'$: if a sequence (T_j) in $\mathscr{D}'$ is such that the sequence $(\langle T_j, \varphi\rangle)$ has a limit in $\mathbb{C}$ for all $\varphi \in \mathscr{D}$, does the map

$$\varphi \longmapsto \lim_{j\to\infty} \langle T_j, \varphi\rangle$$

define a distribution $T \in \mathscr{D}'$? In other words, does the limiting process preserve continuity with respect to φ? It is a remarkable theorem that, because of the strong topology on $\mathscr{D}$, this is actually the case. An analogous statement holds for series. This notion of convergence does not coincide with any of the classical notions used for ordinary functions: for example, the sequence (φ_ν) with $\varphi_\nu(x) = \cos \nu x$ converges to 0 in $\mathscr{D}'(\mathbb{R})$, but fails to do so by any of the standard criteria.

An example of convergent sequences of distributions is provided by sequences which converge to δ. If (f_ν) is a sequence of locally summable functions on $\mathbb{R}^n$ such that

(i) $\int_{\|\mathbf{x}\|<b} f_\nu(\mathbf{x})\,\mathrm{d}^n\mathbf{x} \to 1$ as $\nu \to \infty$ for all $b > 0$;

(ii) $\int_{a\le\|\mathbf{x}\|\le 1/a} |f_\nu(\mathbf{x})|\,\mathrm{d}^n\mathbf{x} \to 0$ as $\nu \to \infty$ for all $0 < a < 1$;

(iii) there exists $d > 0$ and $M > 0$ such that $\int_{\|\mathbf{x}\|<d} |f_\nu(\mathbf{x})|\,\mathrm{d}^n\mathbf{x} < M$ for all ν;

then the sequence (T_{f_ν}) of distributions converges to δ in $\mathscr{D}'(\mathbb{R}^n)$.

1.3.2.3.9. Operations on distributions

As a general rule, the definitions are chosen so that the operations coincide with those on functions whenever a distribution is associated to a function.

Most definitions consist in transferring to a distribution T an operation which is well defined on $\varphi \in \mathscr{D}$ by 'transposing' it in the duality product $\langle T, \varphi\rangle$; this procedure will map T to a new distribution provided the original operation maps $\mathscr{D}$ *continuously* into itself.

1.3.2.3.9.1. Differentiation

(*a*) *Definition and elementary properties*

If T is a distribution on $\mathbb{R}^n$, its partial derivative $\partial_i T$ with respect to x_i is defined by

$$\langle \partial_i T, \varphi\rangle = -\langle T, \partial_i \varphi\rangle$$

for all $\varphi \in \mathscr{D}$. This does define a distribution, because the partial differentiations $\varphi \longmapsto \partial_i\varphi$ are continuous for the topology of $\mathscr{D}$.

Suppose that $T = T_f$ with f a locally integrable function such that $\partial_i f$ exists and is almost everywhere continuous. Then integration by parts along the x_i axis gives

$$\begin{aligned}\int_{\mathbb{R}^n} &\partial_i f(x_1, \ldots, x_i, \ldots, x_n)\varphi(x_1, \ldots, x_i, \ldots, x_n)\,\mathrm{d}x_i \\ &= (f\varphi)(x_1, \ldots, +\infty, \ldots, x_n) - (f\varphi)(x_1, \ldots, -\infty, \ldots, x_n) \\ &\quad - \int_{\mathbb{R}^n} f(x_1, \ldots, x_i, \ldots, x_n)\partial_i\varphi(x_1, \ldots, x_i, \ldots, x_n)\,\mathrm{d}x_i;\end{aligned}$$

the integrated term vanishes, since φ has compact support, showing that $\partial_i T_f = T_{\partial_i f}$.

The test functions $\varphi \in \mathscr{D}$ are infinitely differentiable. Therefore, transpositions like that used to define $\partial_i T$ may be repeated, so that *any distribution is infinitely differentiable*. For instance,

$$\begin{aligned}\langle \partial_{ij}^2 T, \varphi\rangle &= -\langle \partial_j T, \partial_i\varphi\rangle = \langle T, \partial_{ij}^2\varphi\rangle, \\ \langle D^{\mathbf{p}} T, \varphi\rangle &= (-1)^{|\mathbf{p}|}\langle T, D^{\mathbf{p}}\varphi\rangle, \\ \langle \Delta T, \varphi\rangle &= \langle T, \Delta\varphi\rangle,\end{aligned}$$

where Δ is the Laplacian operator. The derivatives of Dirac's δ distribution are

$$\langle D^{\mathbf{p}}\delta, \varphi\rangle = (-1)^{|\mathbf{p}|}\langle \delta, D^{\mathbf{p}}\varphi\rangle = (-1)^{|\mathbf{p}|} D^{\mathbf{p}}\varphi(\mathbf{0}).$$

It is remarkable that *differentiation is a continuous operation* for the topology on $\mathscr{D}'$: if a sequence (T_j) of distributions converges to distribution T, then the sequence $(D^{\mathbf{p}} T_j)$ of derivatives converges to $D^{\mathbf{p}} T$ for any multi-index $\mathbf{p}$, since as $j \to \infty$

$$\langle D^{\mathbf{p}} T_j, \varphi\rangle = (-1)^{|\mathbf{p}|}\langle T_j, D^{\mathbf{p}}\varphi\rangle \to (-1)^{|\mathbf{p}|}\langle T, D^{\mathbf{p}}\varphi\rangle = \langle D^{\mathbf{p}} T, \varphi\rangle.$$

An analogous statement holds for series: any convergent series of distributions may be differentiated termwise to all orders. This illustrates how 'robust' the constructs of distribution theory are in comparison with those of ordinary function theory, where similar statements are notoriously untrue.

(*b*) *Differentiation under the duality bracket*

Limiting processes and differentiation may also be carried out under the duality bracket $\langle , \rangle$ as under the integral sign with ordinary functions. Let the function $\varphi = \varphi(\mathbf{x}, \lambda)$ depend on a parameter $\lambda \in \Lambda$ and a vector $\mathbf{x} \in \mathbb{R}^n$ in such a way that all functions

$$\varphi_\lambda : \mathbf{x} \longmapsto \varphi(\mathbf{x}, \lambda)$$

be in $\mathscr{D}(\mathbb{R}^n)$ for all $\lambda \in \Lambda$. Let $T \in \mathscr{D}'(\mathbb{R}^n)$ be a distribution, let

$$I(\lambda) = \langle T, \varphi_\lambda\rangle$$

and let $\lambda_0 \in \Lambda$ be given parameter value. Suppose that, as λ runs through a small enough neighbourhood of λ_0,

(i) all the φ_λ have their supports in a fixed compact subset K of $\mathbb{R}^n$;

(ii) all the derivatives $D^{\mathbf{p}}\varphi_\lambda$ have a partial derivative with respect to λ which is continuous with respect to $\mathbf{x}$ and λ.

Under these hypotheses, $I(\lambda)$ is differentiable (in the usual sense) with respect to λ near λ_0, and its derivative may be obtained by 'differentiation under the $\langle , \rangle$ sign':

$$\frac{\mathrm{d}I}{\mathrm{d}\lambda} = \langle T, \partial_\lambda\varphi_\lambda\rangle.$$

(*c*) *Effect of discontinuities*

When a function f or its derivatives are no longer continuous, the derivatives $D^{\mathbf{p}} T_f$ of the associated distribution T_f may no longer coincide with the distributions associated to the functions $D^{\mathbf{p}} f$.

In dimension 1, the simplest example is Heaviside's unit step function Y [$Y(x) = 0$ for $x < 0$, $Y(x) = 1$ for $x \ge 0$]:

$$\langle (T_Y)', \varphi\rangle = -\langle (T_Y), \varphi'\rangle = -\int_0^{+\infty} \varphi'(x)\,\mathrm{d}x = \varphi(0) = \langle \delta, \varphi\rangle.$$

Hence $(T_Y)' = \delta$, a result long used 'heuristically' by electrical engineers [see also Dirac (1958)].

Let f be infinitely differentiable for $x<0$ and $x>0$ but have discontinuous derivatives $f^{(m)}$ at $x=0$ [$f^{(0)}$ being f itself] with jumps $\sigma_m = f^{(m)}(0+) - f^{(m)}(0-)$. Consider the functions:

$$\begin{aligned} g_0 &= f - \sigma_0 Y \\ g_1 &= g_0' - \sigma_1 Y \\ &\text{- - - - - - - - - -} \\ g_k &= g_{k-1}' - \sigma_k Y. \end{aligned}$$

The g_k are continuous, their derivatives g_k' are continuous almost everywhere [which implies that $(T_{g_k})' = T_{g_k'}$ and $g_k' = f^{(k+1)}$ almost everywhere]. This yields immediately:

$$\begin{aligned} (T_f)' &= T_{f'} + \sigma_0 \delta \\ (T_f)'' &= T_{f''} + \sigma_0 \delta' + \sigma_1 \delta \\ &\text{- - - - - - - - - - - - - - - - - - -} \\ (T_f)^{(m)} &= T_{f^{(m)}} + \sigma_0 \delta^{(m-1)} + \ldots + \sigma_{m-1}\delta. \\ &\text{- - - - - - - - - - - - - - - - - - -} \end{aligned}$$

Thus the 'distributional derivatives' $(T_f)^{(m)}$ differ from the usual functional derivatives $T_{f^{(m)}}$ by singular terms associated with discontinuities.

In dimension n, let f be infinitely differentiable everywhere except on a smooth hypersurface S, across which its partial derivatives show discontinuities. Let σ_0 and σ_ν denote the discontinuities of f and its normal derivative $\partial_\nu \varphi$ across S (both σ_0 and σ_ν are functions of position on S), and let $\delta_{(S)}$ and $\partial_\nu \delta_{(S)}$ be defined by

$$\begin{aligned} \langle \delta_{(S)}, \varphi \rangle &= \int_S \varphi \, \mathrm{d}^{n-1} S \\ \langle \partial_\nu \delta_{(S)}, \varphi \rangle &= -\int_S \partial_\nu \varphi \, \mathrm{d}^{n-1} S. \end{aligned}$$

Integration by parts shows that

$$\partial_i T_f = T_{\partial_i f} + \sigma_0 \cos\theta_i \delta_{(S)},$$

where θ_i is the angle between the x_i axis and the normal to S along which the jump σ_0 occurs, and that the Laplacian of T_f is given by

$$\Delta(T_f) = T_{\Delta f} + \sigma_\nu \delta_{(S)} + \partial_\nu [\sigma_0 \delta_{(S)}].$$

The latter result is a statement of Green's theorem in terms of distributions. It will be used in Section 1.3.4.4.3.5 to calculate the Fourier transform of the indicator function of a molecular envelope.

1.3.2.3.9.2. Integration of distributions in dimension 1

The reverse operation from differentiation, namely calculating the 'indefinite integral' of a distribution S, consists in finding a distribution T such that $T' = S$.

For all $\chi \in \mathscr{D}$ such that $\chi = \psi'$ with $\psi \in \mathscr{D}$, we must have

$$\langle T, \chi \rangle = -\langle S, \psi \rangle.$$

This condition defines T in a 'hyperplane' $\mathscr{H}$ of $\mathscr{D}$, whose equation

$$\langle 1, \chi \rangle \equiv \langle 1, \psi' \rangle = 0$$

reflects the fact that ψ has compact support.

To specify T in the whole of $\mathscr{D}$, it suffices to specify the value of $\langle T, \varphi_0 \rangle$ where $\varphi_0 \in \mathscr{D}$ is such that $\langle 1, \varphi_0 \rangle = 1$: then any $\varphi \in \mathscr{D}$ may be written uniquely as

$$\varphi = \lambda \varphi_0 + \psi'$$

with

$$\lambda = \langle 1, \varphi \rangle, \qquad \chi = \varphi - \lambda \varphi_0, \qquad \psi(x) = \int_0^x \chi(t)\, \mathrm{d}t,$$

and T is defined by

$$\langle T, \varphi \rangle = \lambda \langle T, \varphi_0 \rangle - \langle S, \psi \rangle.$$

The freedom in the choice of φ_0 means that T is defined up to an additive constant.

1.3.2.3.9.3. Multiplication of distributions by functions

The product αT of a distribution T on $\mathbb{R}^n$ by a function α over $\mathbb{R}^n$ will be defined by transposition:

$$\langle \alpha T, \varphi \rangle = \langle T, \alpha \varphi \rangle \quad \text{for all } \varphi \in \mathscr{D}.$$

In order that αT be a distribution, the mapping $\varphi \longmapsto \alpha\varphi$ must send $\mathscr{D}(\mathbb{R}^n)$ continuously into itself; hence *the multipliers α must be infinitely differentiable*. The product of two general distributions cannot be defined. The need for a careful treatment of multipliers of distributions will become clear when it is later shown (Section 1.3.2.5.8) that the Fourier transformation turns convolutions into multiplications and *vice versa*.

If T is a distribution of order m, then α needs only have continuous derivatives up to order m. For instance, δ is a distribution of order zero, and $\alpha\delta = \alpha(\mathbf{0})\delta$ is a distribution provided α is continuous; this relation is of fundamental importance in the theory of sampling and of the properties of the Fourier transformation related to sampling (Sections 1.3.2.6.4, 1.3.2.6.6). More generally, $D^{\mathbf{p}}\delta$ is a distribution of order $|\mathbf{p}|$, and the following formula holds for all $\alpha \in \mathscr{D}^{(m)}$ with $m = |\mathbf{p}|$:

$$\alpha(D^{\mathbf{p}}\delta) = \sum_{\mathbf{q} \le \mathbf{p}} (-1)^{|\mathbf{p}-\mathbf{q}|} \binom{\mathbf{p}}{\mathbf{q}} (D^{\mathbf{p}-\mathbf{q}}\alpha)(\mathbf{0}) D^{\mathbf{q}}\delta.$$

The derivative of a product is easily shown to be

$$\partial_i(\alpha T) = (\partial_i \alpha) T + \alpha(\partial_i T)$$

and generally for any multi-index $\mathbf{p}$

$$D^{\mathbf{p}}(\alpha T) = \sum_{\mathbf{q} \le \mathbf{p}} \binom{\mathbf{p}}{\mathbf{q}} (D^{\mathbf{p}-\mathbf{q}}\alpha)(\mathbf{0}) D^{\mathbf{q}} T.$$

1.3.2.3.9.4. Division of distributions by functions

Given a distribution S on $\mathbb{R}^n$ and an infinitely differentiable multiplier function α, the division problem consists in finding a distribution T such that $\alpha T = S$.

If α never vanishes, $T = S/\alpha$ is the unique answer. If $n = 1$, and if α has only isolated zeros of finite order, it can be reduced to a collection of cases where the multiplier is x^m, for which the general solution can be shown to be of the form

$$T = U + \sum_{i=0}^{m-1} c_i \delta^{(i)},$$

where U is a particular solution of the division problem $x^m U = S$ and the c_i are arbitrary constants.

In dimension $n > 1$, the problem is much more difficult, but is of fundamental importance in the theory of linear partial differential equations, since the Fourier transformation turns the problem of solving these into a division problem for distributions [see Hörmander (1963)].

1.3.2.3.9.5. Transformation of coordinates

Let σ be a smooth nonsingular change of variables in $\mathbb{R}^n$, *i.e.* an infinitely differentiable mapping from an open subset Ω of $\mathbb{R}^n$ to Ω' in $\mathbb{R}^n$, whose Jacobian

$$J(\sigma) = \det\left[\frac{\partial \sigma(\mathbf{x})}{\partial \mathbf{x}}\right]$$

vanishes nowhere in Ω. By the implicit function theorem, the inverse mapping σ^{-1} from Ω' to Ω is well defined.

If f is a locally summable function on Ω, then the function $\sigma^{\#} f$ defined by

$$(\sigma^{\#} f)(\mathbf{x}) = f[\sigma^{-1}(\mathbf{x})]$$

is a locally summable function on Ω', and for any $\varphi \in \mathscr{D}(\Omega')$ we may write:

$$\begin{aligned}\int_{\Omega'} (\sigma^{\#} f)(\mathbf{x})\varphi(\mathbf{x})\,\mathrm{d}^n\mathbf{x} &= \int_{\Omega'} f[\sigma^{-1}(\mathbf{x})]\varphi(\mathbf{x})\,\mathrm{d}^n\mathbf{x} \\ &= \int_{\Omega'} f(\mathbf{y})\varphi[\sigma(\mathbf{y})]|J(\sigma)|\,\mathrm{d}^n\mathbf{y} \quad \text{by } \mathbf{x} = \sigma(\mathbf{y}).\end{aligned}$$

In terms of the associated distributions

$$\langle T_{\sigma^{\#} f}, \varphi\rangle = \langle T_f, |J(\sigma)|(\sigma^{-1})^{\#}\varphi\rangle.$$

This operation can be extended to an arbitrary distribution T by defining its *image* $\sigma^{\#} T$ under coordinate transformation σ through

$$\langle \sigma^{\#} T, \varphi\rangle = \langle T, |J(\sigma)|(\sigma^{-1})^{\#}\varphi\rangle,$$

which is well defined provided that σ is *proper*, *i.e.* that $\sigma^{-1}(K)$ is compact whenever K is compact.

For instance, if $\sigma : \mathbf{x} \longmapsto \mathbf{x} + \mathbf{a}$ is a *translation* by a vector $\mathbf{a}$ in $\mathbb{R}^n$, then $|J(\sigma)| = 1$; $\sigma^{\#}$ is denoted by $\tau_{\mathbf{a}}$, and the translate $\tau_{\mathbf{a}} T$ of a distribution T is defined by

$$\langle \tau_{\mathbf{a}} T, \varphi\rangle = \langle T, \tau_{-\mathbf{a}}\varphi\rangle.$$

Let $A : \mathbf{x} \longmapsto \mathbf{A}\mathbf{x}$ be a linear transformation defined by a nonsingular matrix $\mathbf{A}$. Then $J(A) = \det \mathbf{A}$, and

$$\langle A^{\#} T, \varphi\rangle = |\det \mathbf{A}|\langle T, (A^{-1})^{\#}\varphi\rangle.$$

This formula will be shown later (Sections 1.3.2.6.5, 1.3.4.2.1.1) to be the basis for the definition of the reciprocal lattice.

In particular, if $\mathbf{A} = -\mathbf{I}$, where $\mathbf{I}$ is the identity matrix, A is an inversion through a centre of symmetry at the origin, and denoting $A^{\#}\varphi$ by $\check{\varphi}$ we have:

$$\langle \check{T}, \varphi\rangle = \langle T, \check{\varphi}\rangle.$$

T is called an even distribution if $\check{T} = T$, an odd distribution if $\check{T} = -T$.

If $\mathbf{A} = \lambda\mathbf{I}$ with $\lambda > 0$, A is called a *dilation* and

$$\langle A^{\#} T, \varphi\rangle = \lambda^n \langle T, (A^{-1})^{\#}\varphi\rangle.$$

Writing symbolically δ as $\delta(\mathbf{x})$ and $A^{\#}\delta$ as $\delta(\mathbf{x}/\lambda)$, we have:

$$\delta(\mathbf{x}/\lambda) = \lambda^n \delta(\mathbf{x}).$$

If $n = 1$ and f is a function with isolated simple zeros x_j, then in the same symbolic notation

$$\delta[f(x)] = \sum_j \frac{1}{|f'(x_j)|}\delta(x_j),$$

where each $\lambda_j = 1/|f'(x_j)|$ is analogous to a 'Lorentz factor' at zero x_j.

1.3.2.3.9.6. Tensor product of distributions

The purpose of this construction is to extend Fubini's theorem to distributions. Following Section 1.3.2.2.5, we may define the tensor product $L^1_{\mathrm{loc}}(\mathbb{R}^m) \otimes L^1_{\mathrm{loc}}(\mathbb{R}^n)$ as the vector space of finite linear combinations of functions of the form

$$f \otimes g : (\mathbf{x}, \mathbf{y}) \longmapsto f(\mathbf{x})g(\mathbf{y}),$$

where $\mathbf{x} \in \mathbb{R}^m$, $\mathbf{y} \in \mathbb{R}^n$, $f \in L^1_{\mathrm{loc}}(\mathbb{R}^m)$ and $g \in L^1_{\mathrm{loc}}(\mathbb{R}^n)$.

Let $S_{\mathbf{x}}$ and $T_{\mathbf{y}}$ denote the distributions associated to f and g, respectively, the subscripts $\mathbf{x}$ and $\mathbf{y}$ acting as mnemonics for $\mathbb{R}^m$ and $\mathbb{R}^n$. It follows from Fubini's theorem (Section 1.3.2.2.5) that $f \otimes g \in L^1_{\mathrm{loc}}(\mathbb{R}^m \times \mathbb{R}^n)$, and hence defines a distribution over $\mathbb{R}^m \times \mathbb{R}^n$; the rearrangement of integral signs gives

$$\langle S_{\mathbf{x}} \otimes T_{\mathbf{y}}, \varphi_{\mathbf{x},\mathbf{y}}\rangle = \langle S_{\mathbf{x}}, \langle T_{\mathbf{y}}, \varphi_{\mathbf{x},\mathbf{y}}\rangle\rangle = \langle T_{\mathbf{y}}, \langle S_{\mathbf{x}}, \varphi_{\mathbf{x},\mathbf{y}}\rangle\rangle$$

for all $\varphi_{\mathbf{x},\mathbf{y}} \in \mathscr{D}(\mathbb{R}^m \times \mathbb{R}^n)$. In particular, if $\varphi(\mathbf{x}, \mathbf{y}) = u(\mathbf{x})v(\mathbf{y})$ with $u \in \mathscr{D}(\mathbb{R}^m)$, $v \in \mathscr{D}(\mathbb{R}^n)$, then

$$\langle S \otimes T, u \otimes v\rangle = \langle S, u\rangle\langle T, v\rangle.$$

This construction can be extended to general distributions $S \in \mathscr{D}'(\mathbb{R}^m)$ and $T \in \mathscr{D}'(\mathbb{R}^n)$. Given any test function $\varphi \in \mathscr{D}(\mathbb{R}^m \times \mathbb{R}^n)$, let $\varphi_{\mathbf{x}}$ denote the map $\mathbf{y} \longmapsto \varphi(\mathbf{x}, \mathbf{y})$; let $\varphi_{\mathbf{y}}$ denote the map $\mathbf{x} \longmapsto \varphi(\mathbf{x}, \mathbf{y})$; and define the two functions $\theta(\mathbf{x}) = \langle T, \varphi_{\mathbf{x}}\rangle$ and $\omega(\mathbf{y}) = \langle S, \varphi_{\mathbf{y}}\rangle$. Then, by the lemma on differentiation under the $\langle , \rangle$ sign of Section 1.3.2.3.9.1, $\theta \in \mathscr{D}(\mathbb{R}^m)$, $\omega \in \mathscr{D}(\mathbb{R}^n)$, and there exists a unique distribution $S \otimes T$ such that

$$\langle S \otimes T, \varphi \rangle = \langle S, \theta \rangle = \langle T, \omega \rangle.$$

$S \otimes T$ is called the *tensor product* of S and T.

With the mnemonic introduced above, this definition reads identically to that given above for distributions associated to locally integrable functions:

$$\langle S_{\mathbf{x}} \otimes T_{\mathbf{y}}, \varphi_{\mathbf{x},\mathbf{y}} \rangle = \langle S_{\mathbf{x}}, \langle T_{\mathbf{y}}, \varphi_{\mathbf{x},\mathbf{y}} \rangle \rangle = \langle T_{\mathbf{y}}, \langle S_{\mathbf{x}}, \varphi_{\mathbf{x},\mathbf{y}} \rangle \rangle.$$

The tensor product of distributions is associative:

$$(R \otimes S) \otimes T = R \otimes (S \otimes T).$$

Derivatives may be calculated by

$$D^{\mathbf{p}}_{\mathbf{x}} D^{\mathbf{q}}_{\mathbf{y}} (S_{\mathbf{x}} \otimes T_{\mathbf{y}}) = (D^{\mathbf{p}}_{\mathbf{x}} S_{\mathbf{x}}) \otimes (D^{\mathbf{q}}_{\mathbf{y}} T_{\mathbf{y}}).$$

The support of a tensor product is the Cartesian product of the supports of the two factors.

1.3.2.3.9.7. Convolution of distributions

The convolution $f * g$ of two functions f and g on $\mathbb{R}^n$ is defined by

$$(f * g)(\mathbf{x}) = \int_{\mathbb{R}^n} f(\mathbf{y}) g(\mathbf{x} - \mathbf{y}) \, \mathrm{d}^n\mathbf{y} = \int_{\mathbb{R}^n} f(\mathbf{x} - \mathbf{y}) g(\mathbf{y}) \, \mathrm{d}^n\mathbf{y}$$

whenever the integral exists. This is the case when f and g are both in $L^1(\mathbb{R}^n)$; then $f * g$ is also in $L^1(\mathbb{R}^n)$. Let S, T and W denote the distributions associated to f, g and $f * g$, respectively: a change of variable immediately shows that for any $\varphi \in \mathscr{D}(\mathbb{R}^n)$,

$$\langle W, \varphi \rangle = \int_{\mathbb{R}^n \times \mathbb{R}^n} f(\mathbf{x}) g(\mathbf{y}) \varphi(\mathbf{x} + \mathbf{y}) \, \mathrm{d}^n\mathbf{x} \, \mathrm{d}^n\mathbf{y}.$$

Introducing the map σ from $\mathbb{R}^n \times \mathbb{R}^n$ to $\mathbb{R}^n$ defined by $\sigma(\mathbf{x}, \mathbf{y}) = \mathbf{x} + \mathbf{y}$, the latter expression may be written:

$$\langle S_{\mathbf{x}} \otimes T_{\mathbf{y}}, \varphi \circ \sigma \rangle$$

(where $\circ$ denotes the composition of mappings) or by a slight abuse of notation:

$$\langle W, \varphi \rangle = \langle S_{\mathbf{x}} \otimes T_{\mathbf{y}}, \varphi(\mathbf{x} + \mathbf{y}) \rangle.$$

A difficulty arises in extending this definition to general distributions S and T because the mapping σ is not proper: if K is compact in $\mathbb{R}^n$, then $\sigma^{-1}(K)$ is a cylinder with base K and generator the 'second bisector' $\mathbf{x} + \mathbf{y} = \mathbf{0}$ in $\mathbb{R}^n \times \mathbb{R}^n$. However, $\langle S \otimes T, \varphi \circ \sigma \rangle$ is defined whenever the intersection between Supp $(S \otimes T) =$ (Supp S) $\times$ (Supp T) and σ^{-1}(Supp φ) is compact.

We may therefore define the *convolution* $S * T$ of two distributions S and T on $\mathbb{R}^n$ by

$$\langle S * T, \varphi \rangle = \langle S \otimes T, \varphi \circ \sigma \rangle = \langle S_{\mathbf{x}} \otimes T_{\mathbf{y}}, \varphi(\mathbf{x} + \mathbf{y}) \rangle$$

whenever the following *support condition* is fulfilled:

> 'the set $\{(\mathbf{x}, \mathbf{y}) | \mathbf{x} \in A, \mathbf{y} \in B, \mathbf{x} + \mathbf{y} \in K\}$ is compact in $\mathbb{R}^n \times \mathbb{R}^n$ for all K compact in $\mathbb{R}^n$'.

The latter condition is met, in particular, if S or T has compact support. The support of $S * T$ is easily seen to be contained in the closure of the vector sum

$$A + B = \{\mathbf{x} + \mathbf{y} | \mathbf{x} \in A, \mathbf{y} \in B\}.$$

Convolution by a fixed distribution S is a *continuous* operation for the topology on $\mathscr{D}'$: it maps convergent sequences (T_j) to convergent sequences $(S * T_j)$. Convolution is commutative: $S * T = T * S$.

The convolution of p distributions $T_1, \ldots, T_p$ with supports $A_1, \ldots, A_p$ can be defined by

$$\langle T_1 * \ldots * T_p, \varphi \rangle = \langle (T_1)_{\mathbf{x}_1} \otimes \ldots \otimes (T_p)_{\mathbf{x}_p}, \varphi(\mathbf{x}_1 + \ldots + \mathbf{x}_p) \rangle$$

whenever the following generalized support condition:

> 'the set $\{(\mathbf{x}_1, \ldots, \mathbf{x}_p) | \mathbf{x}_1 \in A_1, \ldots, \mathbf{x}_p \in A_p, \mathbf{x}_1 + \ldots + \mathbf{x}_p \in K\}$ is compact in $(\mathbb{R}^n)^p$ for all K compact in $\mathbb{R}^n$'

is satisfied. It is then associative. Interesting examples of associativity failure, which can be traced back to violations of the support condition, may be found in Bracewell (1986, pp. 436–437).

It follows from previous definitions that, for all distributions $T \in \mathscr{D}'$, the following identities hold:

(i) $\delta * T = T$: δ is the unit convolution;

(ii) $\delta_{(\mathbf{a})} * T = \tau_{\mathbf{a}} T$: translation is a convolution with the corresponding translate of δ;

(iii) $(D^{\mathbf{p}}\delta) * T = D^{\mathbf{p}} T$: differentiation is a convolution with the corresponding derivative of δ;

(iv) translates or derivatives of a convolution may be obtained by translating or differentiating any one of the factors: convolution 'commutes' with translation and differentiation, a property used in Section 1.3.4.4.7.7 to speed up least-squares model refinement for macromolecules.

The latter property is frequently used for the purpose of *regularization*: if T is a distribution, α an infinitely differentiable function, and at least one of the two has compact support, then $T * \alpha$ is an infinitely differentiable ordinary function. Since sequences (α_ν) of such functions α can be constructed which have compact support and converge to δ, it follows that any distribution T can be obtained as the limit of infinitely differentiable functions $T * \alpha_\nu$. In topological jargon: $\mathscr{D}(\mathbb{R}^n)$ is 'everywhere dense' in $\mathscr{D}'(\mathbb{R}^n)$. A standard function in $\mathscr{D}$ which is often used for such proofs is defined as follows: put

$$\theta(x) = \frac{1}{A} \exp\left(-\frac{1}{1 - x^2}\right) \quad \text{for } |x| \leq 1,$$

$$= 0 \qquad\qquad\qquad\qquad \text{for } |x| \geq 1,$$

with

$$A = \int_{-1}^{+1} \exp\left(-\frac{1}{1 - x^2}\right) \mathrm{d}x$$

(so that θ is in $\mathscr{D}$ and is normalized), and put

$$\theta_\varepsilon(x) = \frac{1}{\varepsilon} \theta\left(\frac{x}{\varepsilon}\right) \quad \text{in dimension 1,}$$

$$\theta_\varepsilon(\mathbf{x}) = \prod_{j=1}^{n} \theta_\varepsilon(x_j) \quad \text{in dimension } n.$$

Another related result, also proved by convolution, is the *structure theorem*: the restriction of a distribution $T \in \mathscr{D}'(\mathbb{R}^n)$ to a bounded open set Ω in $\mathbb{R}^n$ is a derivative of finite order of a continuous function.

Properties (i) to (iv) are the basis of the symbolic or operational calculus (see Carslaw & Jaeger, 1948; Van der Pol & Bremmer, 1955; Churchill, 1958; Erdélyi, 1962; Moore, 1971) for solving integro-differential equations with constant coefficients by turning them into convolution equations, then using factorization methods for convolution algebras (Schwartz, 1965).

1.3.2.4. Fourier transforms of functions

1.3.2.4.1. Introduction

Given a complex-valued function f on $\mathbb{R}^n$ subject to suitable regularity conditions, its Fourier transform $\mathscr{F}[f]$ and Fourier cotransform $\bar{\mathscr{F}}[f]$ are defined as follows:

$$\mathscr{F}[f](\xi) = \int_{\mathbb{R}^n} f(\mathbf{x}) \exp(-2\pi i \boldsymbol{\xi}\cdot\mathbf{x})\, \mathrm{d}^n\mathbf{x}$$
$$\bar{\mathscr{F}}[f](\xi) = \int_{\mathbb{R}^n} f(\mathbf{x}) \exp(+2\pi i \boldsymbol{\xi}\cdot\mathbf{x})\, \mathrm{d}^n\mathbf{x},$$

where $\boldsymbol{\xi}\cdot\mathbf{x} = \sum_{i=1}^n \xi_i x_i$ is the ordinary scalar product. The terminology and sign conventions given above are the standard ones in mathematics; those used in crystallography are slightly different (see Section 1.3.4.2.1.1). These transforms enjoy a number of remarkable properties, whose natural settings entail different regularity assumptions on f: for instance, properties relating to convolution are best treated in $L^1(\mathbb{R}^n)$, while Parseval's theorem requires the Hilbert space structure of $L^2(\mathbb{R}^n)$. After a brief review of these classical properties, the Fourier transformation will be examined in a space $\mathscr{S}(\mathbb{R}^n)$ particularly well suited to accommodating the full range of its properties, which will later serve as a space of test functions to extend the Fourier transformation to distributions.

There exists an abundant literature on the 'Fourier integral'. The books by Carslaw (1930), Wiener (1933), Titchmarsh (1948), Katznelson (1968), Sneddon (1951, 1972), and Dym & McKean (1972) are particularly recommended.

1.3.2.4.2. Fourier transforms in L^1

1.3.2.4.2.1. Linearity

Both transformations $\mathscr{F}$ and $\bar{\mathscr{F}}$ are obviously linear maps from L^1 to L^∞ when these spaces are viewed as vector spaces over the field $\mathbb{C}$ of complex numbers.

1.3.2.4.2.2. Effect of affine coordinate transformations

$\mathscr{F}$ and $\bar{\mathscr{F}}$ turn translations into phase shifts:

$$\mathscr{F}[\tau_{\mathbf{a}} f](\xi) = \exp(-2\pi i \boldsymbol{\xi}\cdot\mathbf{a})\mathscr{F}[f](\xi)$$
$$\bar{\mathscr{F}}[\tau_{\mathbf{a}} f](\xi) = \exp(+2\pi i \boldsymbol{\xi}\cdot\mathbf{a})\bar{\mathscr{F}}[f](\xi).$$

Under a general linear change of variable $\mathbf{x} \longmapsto \mathbf{A}\mathbf{x}$ with nonsingular matrix $\mathbf{A}$, the transform of $A^{\#}f$ is

$$\begin{aligned}\mathscr{F}[A^{\#}f](\xi) &= \int_{\mathbb{R}^n} f(\mathbf{A}^{-1}\mathbf{x}) \exp(-2\pi i \boldsymbol{\xi}\cdot\mathbf{x})\, \mathrm{d}^n\mathbf{x} \\ &= \int_{\mathbb{R}^n} f(\mathbf{y}) \exp(-2\pi i (A^T\boldsymbol{\xi})\cdot\mathbf{y}) |\det\mathbf{A}|\, \mathrm{d}^n\mathbf{y} \\ &\qquad\qquad \text{by } \mathbf{x} = \mathbf{A}\mathbf{y} \\ &= |\det\mathbf{A}| \mathscr{F}[f](\mathbf{A}^T\boldsymbol{\xi})\end{aligned}$$

i.e.

$$\mathscr{F}[A^{\#}f] = |\det\mathbf{A}|[(\mathbf{A}^{-1})^T]^{\#}\mathscr{F}[f]$$

and similarly for $\bar{\mathscr{F}}$. The matrix $(\mathbf{A}^{-1})^T$ is called the *contragredient* of matrix $\mathbf{A}$.

Under an affine change of coordinates $\mathbf{x} \longmapsto S(\mathbf{x}) = \mathbf{A}\mathbf{x} + \mathbf{b}$ with nonsingular matrix $\mathbf{A}$, the transform of $S^{\#}f$ is given by

$$\begin{aligned}\mathscr{F}[S^{\#}f](\xi) &= \mathscr{F}[\tau_{\mathbf{b}}(A^{\#}f)](\xi) \\ &= \exp(-2\pi i \boldsymbol{\xi}\cdot\mathbf{b})\mathscr{F}[A^{\#}f](\xi) \\ &= \exp(-2\pi i \boldsymbol{\xi}\cdot\mathbf{b})|\det\mathbf{A}|\mathscr{F}[f](\mathbf{A}^T\boldsymbol{\xi})\end{aligned}$$

with a similar result for $\bar{\mathscr{F}}$, replacing $-i$ by $+i$.

1.3.2.4.2.3. Conjugate symmetry

The kernels of the Fourier transformations $\mathscr{F}$ and $\bar{\mathscr{F}}$ satisfy the following identities:

$$\exp(\pm 2\pi i \boldsymbol{\xi}\cdot\mathbf{x}) = \exp\overline{[\pm 2\pi i \boldsymbol{\xi}\cdot(-\mathbf{x})]} = \exp\overline{[\pm 2\pi i(-\boldsymbol{\xi})\cdot\mathbf{x}]}.$$

As a result the transformations $\mathscr{F}$ and $\bar{\mathscr{F}}$ themselves have the following 'conjugate symmetry' properties [where the notation $\check{f}(\mathbf{x}) = f(-\mathbf{x})$ of Section 1.3.2.2.2 will be used]:

$$\mathscr{F}[f](\xi) = \overline{\mathscr{F}[\bar{f}](-\xi)} = \overline{\mathscr{F}[\check{\bar{f}}](\xi)}$$
$$\mathscr{F}[f](\xi) = \overline{\mathscr{F}[\check{\bar{f}}](\xi)}.$$

Therefore,

(i) f real $\Leftrightarrow f = \bar{f} \Leftrightarrow \mathscr{F}[f] = \overline{\check{\mathscr{F}}[f]} \Leftrightarrow \mathscr{F}[f](\xi) = \overline{\mathscr{F}[f](-\xi)}$: $\mathscr{F}[f]$ is said to possess *Hermitian symmetry*;

(ii) f centrosymmetric $\Leftrightarrow f = \check{f} \Leftrightarrow \mathscr{F}[f] = \overline{\mathscr{F}[\bar{f}]}$;

(iii) f real centrosymmetric $\Leftrightarrow f = \bar{f} = \check{f} \Leftrightarrow \mathscr{F}[f] = \overline{\mathscr{F}[f]} = \overline{\check{\mathscr{F}}[f]} \Leftrightarrow \mathscr{F}[f]$ real centrosymmetric.

Conjugate symmetry is the basis of Friedel's law (Section 1.3.4.2.1.4) in crystallography.

1.3.2.4.2.4. Tensor product property

Another elementary property of $\mathscr{F}$ is its naturality with respect to tensor products. Let $u \in L^1(\mathbb{R}^m)$ and $v \in L^1(\mathbb{R}^n)$, and let $\mathscr{F}_{\mathbf{x}}, \mathscr{F}_{\mathbf{y}}, \mathscr{F}_{\mathbf{x},\mathbf{y}}$ denote the Fourier transformations in $L^1(\mathbb{R}^m)$, $L^1(\mathbb{R}^n)$ and $L^1(\mathbb{R}^m \times \mathbb{R}^n)$, respectively. Then

$$\mathscr{F}_{\mathbf{x},\mathbf{y}}[u \otimes v] = \mathscr{F}_{\mathbf{x}}[u] \otimes \mathscr{F}_{\mathbf{y}}[v].$$

Furthermore, if $f \in L^1(\mathbb{R}^m \times \mathbb{R}^n)$, then $\mathscr{F}_{\mathbf{y}}[f] \in L^1(\mathbb{R}^m)$ as a function of $\mathbf{x}$ and $\mathscr{F}_{\mathbf{x}}[f] \in L^1(\mathbb{R}^n)$ as a function of $\mathbf{y}$, and

$$\mathscr{F}_{\mathbf{x},\mathbf{y}}[f] = \mathscr{F}_{\mathbf{x}}[\mathscr{F}_{\mathbf{y}}[f]] = \mathscr{F}_{\mathbf{y}}[\mathscr{F}_{\mathbf{x}}[f]].$$

This is easily proved by using Fubini's theorem and the fact that $(\boldsymbol{\xi},\boldsymbol{\eta})\cdot(\mathbf{x},\mathbf{y}) = \boldsymbol{\xi}\cdot\mathbf{x} + \boldsymbol{\eta}\cdot\mathbf{y}$, where $\mathbf{x},\boldsymbol{\xi} \in \mathbb{R}^m$, $\mathbf{y},\boldsymbol{\eta} \in \mathbb{R}^n$. This property may be written:

$$\mathscr{F}_{\mathbf{x},\mathbf{y}} = \mathscr{F}_{\mathbf{x}} \otimes \mathscr{F}_{\mathbf{y}}.$$

1.3.2.4.2.5. Convolution property

If f and g are summable, their convolution $f * g$ exists and is summable, and

$$\mathscr{F}[f*g](\boldsymbol{\xi}) = \int_{\mathbb{R}^n}\left[\int_{\mathbb{R}^n} f(\mathbf{y})g(\mathbf{x}-\mathbf{y})\,\mathrm{d}^n\mathbf{y}\right]\exp(-2\pi i\boldsymbol{\xi}\cdot\mathbf{x})\,\mathrm{d}^n\mathbf{x}.$$

With $\mathbf{x} = \mathbf{y} + \mathbf{z}$, so that

$$\exp(-2\pi i\boldsymbol{\xi}\cdot\mathbf{x}) = \exp(-2\pi i\boldsymbol{\xi}\cdot\mathbf{y})\exp(-2\pi i\boldsymbol{\xi}\cdot\mathbf{z}),$$

and with Fubini's theorem, rearrangement of the double integral gives:

$$\mathscr{F}[f*g] = \mathscr{F}[f]\times\mathscr{F}[g]$$

and similarly

$$\bar{\mathscr{F}}[f*g] = \bar{\mathscr{F}}[f]\times\bar{\mathscr{F}}[g].$$

Thus *the Fourier transform and cotransform turn convolution into multiplication*.

1.3.2.4.2.6. Reciprocity property

In general, $\mathscr{F}[f]$ and $\bar{\mathscr{F}}[f]$ are not summable, and hence cannot be further transformed; however, as they are essentially bounded, their products with the Gaussians $G_t(\xi) = \exp(-2\pi^2\|\xi\|^2 t)$ are summable for all $t > 0$, and it can be shown that

$$f = \lim_{t\to 0}\bar{\mathscr{F}}[G_t\mathscr{F}[f]] = \lim_{t\to 0}\mathscr{F}[G_t\bar{\mathscr{F}}[f]],$$

where the limit is taken in the topology of the L^1 norm $\|.\|_1$. Thus $\mathscr{F}$ and $\bar{\mathscr{F}}$ are (in a sense) mutually inverse, which justifies the common practice of calling $\bar{\mathscr{F}}$ the 'inverse Fourier transformation'.

1.3.2.4.2.7. Riemann–Lebesgue lemma

If $f \in L^1(\mathbb{R}^n)$, *i.e.* is summable, then $\mathscr{F}[f]$ and $\bar{\mathscr{F}}[f]$ exist and are continuous and essentially bounded:

$$\|\mathscr{F}[f]\|_\infty = \|\bar{\mathscr{F}}[f]\|_\infty \le \|f\|_1.$$

In fact one has the much stronger property, whose statement constitutes the *Riemann–Lebesgue lemma*, that $\mathscr{F}[f](\boldsymbol{\xi})$ and $\bar{\mathscr{F}}[f](\boldsymbol{\xi})$ both tend to zero as $\|\boldsymbol{\xi}\| \to \infty$.

1.3.2.4.2.8. Differentiation

Let us now suppose that $n = 1$ and that $f \in L^1(\mathbb{R})$ is differentiable with $f' \in L^1(\mathbb{R})$. Integration by parts yields

$$\begin{aligned}\mathscr{F}[f'](\xi) &= \int_{-\infty}^{+\infty} f'(x)\exp(-2\pi i\xi\cdot x)\,\mathrm{d}x\\ &= [f(x)\exp(-2\pi i\xi\cdot x)]_{-\infty}^{+\infty}\\ &\quad + 2\pi i\xi\int_{-\infty}^{+\infty} f(x)\exp(-2\pi i\xi\cdot x)\,\mathrm{d}x.\end{aligned}$$

Since f' is summable, f has a limit when $x \to \pm\infty$, and this limit must be 0 since f is summable. Therefore

$$\mathscr{F}[f'](\xi) = (2\pi i\xi)\mathscr{F}[f](\xi)$$

with the bound

$$\|2\pi\xi\mathscr{F}[f]\|_\infty \le \|f'\|_1$$

so that $|\mathscr{F}[f](\xi)|$ decreases faster than $1/|\xi| \to \infty$.

This result can be easily extended to several dimensions and to any multi-index $\mathbf{m}$: if f is summable and has continuous summable partial derivatives up to order $|\mathbf{m}|$, then

$$\mathscr{F}[D^{\mathbf{m}}f](\boldsymbol{\xi}) = (2\pi i\boldsymbol{\xi})^{\mathbf{m}}\mathscr{F}[f](\boldsymbol{\xi})$$

and

$$\|(2\pi\boldsymbol{\xi})^{\mathbf{m}}\mathscr{F}[f]\|_\infty \le \|D^{\mathbf{m}}f\|_1.$$

Similar results hold for $\bar{\mathscr{F}}$, with $2\pi i\boldsymbol{\xi}$ replaced by $-2\pi i\boldsymbol{\xi}$. Thus, the more differentiable f is, with summable derivatives, the faster $\mathscr{F}[f]$ and $\bar{\mathscr{F}}[f]$ decrease at infinity.

The property of turning differentiation into multiplication by a monomial has many important applications in crystallography, for instance differential syntheses (Sections 1.3.4.2.1.9, 1.3.4.4.7.2, 1.3.4.4.7.5) and moment-generating functions [Section 1.3.4.5.2.1(*c*)].

1.3.2.4.2.9. Decrease at infinity

Conversely, assume that f is summable on $\mathbb{R}^n$ and that f decreases fast enough at infinity for $\mathbf{x}^{\mathbf{m}}f$ also to be summable, for some multi-index $\mathbf{m}$. Then the integral defining $\mathscr{F}[f]$ may be subjected to the differential operator $D^{\mathbf{m}}$, still yielding a convergent integral: therefore $D^{\mathbf{m}}\mathscr{F}[f]$ exists, and

$$D^{\mathbf{m}}(\mathscr{F}[f])(\boldsymbol{\xi}) = \mathscr{F}[(-2\pi i\mathbf{x})^{\mathbf{m}}f](\boldsymbol{\xi})$$

with the bound

$$\|D^{\mathbf{m}}(\mathscr{F}[f])\|_\infty = \|(2\pi\mathbf{x})^{\mathbf{m}}f\|_1.$$

Similar results hold for $\bar{\mathscr{F}}$, with $-2\pi i\mathbf{x}$ replaced by $2\pi i\mathbf{x}$. Thus, the faster f decreases at infinity, the more $\mathscr{F}[f]$ and $\bar{\mathscr{F}}[f]$ are differentiable, with bounded derivatives. This property is the converse of that described in Section 1.3.2.4.2.8, and their combination is fundamental in the definition of the function space $\mathscr{S}$ in Section 1.3.2.4.4.1, of tempered distributions in Section 1.3.2.5, and in the extension of the Fourier transformation to them.

1.3.2.4.2.10. The Paley–Wiener theorem

An extreme case of the last instance occurs when f has *compact support*: then $\mathscr{F}[f]$ and $\bar{\mathscr{F}}[f]$ are so regular that they may be analytically continued from $\mathbb{R}^n$ to $\mathbb{C}^n$ where they are *entire* functions, *i.e.* have no singularities at finite distance (Paley & Wiener, 1934). This is easily seen for $\mathscr{F}[f]$: giving vector $\boldsymbol{\xi} \in \mathbb{R}^n$ a vector $\boldsymbol{\eta} \in \mathbb{R}^n$ of imaginary parts leads to

$$\begin{aligned}\mathscr{F}[f](\boldsymbol{\xi}+i\boldsymbol{\eta}) &= \int_{\mathbb{R}^n} f(\mathbf{x})\exp[-2\pi i(\boldsymbol{\xi}+i\boldsymbol{\eta})\cdot\mathbf{x}]\,\mathrm{d}^n\mathbf{x}\\ &= \mathscr{F}[\exp(2\pi\boldsymbol{\eta}\cdot\mathbf{x})f](\boldsymbol{\xi}),\end{aligned}$$

where the latter transform always exists since $\exp(2\pi\boldsymbol{\eta}\cdot\mathbf{x})f$ is summable with respect to $\mathbf{x}$ for all values of $\boldsymbol{\eta}$. This analytic continuation forms the basis of the saddlepoint method in probability theory [Section 1.3.4.5.2.1(*f*)] and leads to the use of maximum-entropy distributions in the statistical theory of direct phase determination [Section 1.3.4.5.2.2(*e*)].

By Liouville's theorem, an entire function in $\mathbb{C}^n$ cannot vanish identically on the complement of a compact subset of $\mathbb{R}^n$ without vanishing everywhere: therefore $\mathscr{F}[f]$ cannot have compact support if f has, and hence $\mathscr{D}(\mathbb{R}^n)$ *is not stable by Fourier transformation*.

1.3.2.4.3. Fourier transforms in L^2

Let f belong to $L^2(\mathbb{R}^n)$, *i.e.* be such that

$$\|f\|_2 = \left(\int_{\mathbb{R}^n} |f(\mathbf{x})|^2 \,\mathrm{d}^n\mathbf{x}\right)^{1/2} < \infty.$$

1.3.2.4.3.1. Invariance of L^2

$\mathscr{F}[f]$ and $\bar{\mathscr{F}}[f]$ exist and are functions in L^2, *i.e.* $\mathscr{F}L^2 = L^2$, $\bar{\mathscr{F}}L^2 = L^2$.

1.3.2.4.3.2. Reciprocity

$\mathscr{F}[\bar{\mathscr{F}}[f]] = f$ and $\bar{\mathscr{F}}[\mathscr{F}[f]] = f$, equality being taken as 'almost everywhere' equality. This again leads to calling $\bar{\mathscr{F}}$ the 'inverse Fourier transformation' rather than the Fourier cotransformation.

1.3.2.4.3.3. Isometry

$\mathscr{F}$ and $\bar{\mathscr{F}}$ preserve the L^2 norm:

$\|\mathscr{F}[f]\|_2 = \|\bar{\mathscr{F}}[f]\|_2 = \|f\|_2$ (Parseval's/Plancherel's theorem).

This property, which may be written in terms of the inner product $(,)$ in $L^2(\mathbb{R}^n)$ as

$$(\mathscr{F}[f], \mathscr{F}[g]) = (\bar{\mathscr{F}}[f], \bar{\mathscr{F}}[g]) = (f, g),$$

implies that $\mathscr{F}$ and $\bar{\mathscr{F}}$ are *unitary* transformations of $L^2(\mathbb{R}^n)$ into itself, *i.e.* infinite-dimensional 'rotations'.

1.3.2.4.3.4. Eigenspace decomposition of L^2

Some light can be shed on the geometric structure of these rotations by the following simple considerations. Note that

$$\begin{aligned}\mathscr{F}^2[f](\mathbf{x}) &= \int_{\mathbb{R}^n} \mathscr{F}[f](\boldsymbol{\xi}) \exp(-2\pi i \mathbf{x}\cdot\boldsymbol{\xi}) \,\mathrm{d}^n\boldsymbol{\xi} \\ &= \bar{\mathscr{F}}[\mathscr{F}[f]](-\mathbf{x}) = f(-\mathbf{x})\end{aligned}$$

so that $\mathscr{F}^4$ (and similarly $\bar{\mathscr{F}}^4$) is the identity map. Any eigenvalue of $\mathscr{F}$ or $\bar{\mathscr{F}}$ is therefore a fourth root of unity, *i.e.* ± 1 or $\pm i$, and $L^2(\mathbb{R}^n)$ splits into an orthogonal direct sum

$$\mathbf{H}_0 \otimes \mathbf{H}_1 \otimes \mathbf{H}_2 \otimes \mathbf{H}_3,$$

where $\mathscr{F}$ (respectively $\bar{\mathscr{F}}$) acts in each subspace $\mathbf{H}_k$ $(k = 0, 1, 2, 3)$ by multiplication by $(-i)^k$. Orthonormal bases for these subspaces can be constructed from Hermite functions (*cf.* Section 1.3.2.4.4.2) This method was used by Wiener (1933, pp. 51–71).

1.3.2.4.3.5. The convolution theorem and the isometry property

In L^2, the convolution theorem (when applicable) and the Parseval/Plancherel theorem are not independent. Suppose that f, g, $f \times g$ and $f * g$ are all in L^2 (without questioning whether these properties are independent). Then $f * g$ may be written in terms of the inner product in L^2 as follows:

$$(f * g)(\mathbf{x}) = \int_{\mathbb{R}^n} f(\mathbf{x}-\mathbf{y}) g(\mathbf{y}) \,\mathrm{d}^n\mathbf{y} = \int_{\mathbb{R}^n} \overline{\check{\bar{f}}(\mathbf{y}-\mathbf{x})} g(\mathbf{y}) \,\mathrm{d}^n\mathbf{y},$$

i.e.

$$(f * g)(\mathbf{x}) = (\tau_{\mathbf{x}} \check{\bar{f}}, g).$$

Invoking the isometry property, we may rewrite the right-hand side as

$$\begin{aligned}(\mathscr{F}[\tau_{\mathbf{x}} \check{\bar{f}}], \mathscr{F}[g]) &= (\exp(-2\pi i \mathbf{x}\cdot\boldsymbol{\xi}) \overline{\mathscr{F}[f]}_{\xi}, \mathscr{F}[g]_{\xi}) \\ &= \int_{\mathbb{R}^n} (\mathscr{F}[f] \times \mathscr{F}[g])(\mathbf{x}) \\ &\quad \times \exp(+2\pi i \mathbf{x}\cdot\boldsymbol{\xi}) \,\mathrm{d}^n\boldsymbol{\xi} \\ &= \bar{\mathscr{F}}[\mathscr{F}[f] \times \mathscr{F}[g]],\end{aligned}$$

so that the initial identity yields the convolution theorem.

To obtain the converse implication, note that

$$\begin{aligned}(f, g) &= \int_{\mathbb{R}^n} \overline{f(\mathbf{y})} g(\mathbf{y}) \,\mathrm{d}^n\mathbf{y} = (\check{\bar{f}} * g)(\mathbf{0}) \\ &= \bar{\mathscr{F}}[\mathscr{F}[\check{\bar{f}}] \times \mathscr{F}[g]](\mathbf{0}) \\ &= \int_{\mathbb{R}^n} \overline{\mathscr{F}[f](\boldsymbol{\xi})} \mathscr{F}[g](\boldsymbol{\xi}) \,\mathrm{d}^n\boldsymbol{\xi} = (\mathscr{F}[f], \mathscr{F}[g]),\end{aligned}$$

where conjugate symmetry (Section 1.3.2.4.2.2) has been used.

These relations have an important application in the calculation by Fourier transform methods of the derivatives used in the refinement of macromolecular structures (Section 1.3.4.4.7).

1.3.2.4.4. Fourier transforms in $\mathscr{S}$

1.3.2.4.4.1. Definition and properties of $\mathscr{S}$

The duality established in Sections 1.3.2.4.2.8 and 1.3.2.4.2.9 between the local differentiability of a function and the rate of decrease at infinity of its Fourier transform prompts one to consider the space $\mathscr{S}(\mathbb{R}^n)$ of functions f on $\mathbb{R}^n$ which are infinitely differentiable *and* all of whose derivatives are rapidly decreasing, so that for all multi-indices $\mathbf{k}$ and $\mathbf{p}$

$$(\mathbf{x}^{\mathbf{k}} D^{\mathbf{p}} f)(\mathbf{x}) \to 0 \quad \text{as} \quad \|\mathbf{x}\| \to \infty.$$

The product of $f \in \mathscr{S}$ by any polynomial over $\mathbb{R}^n$ is still in $\mathscr{S}$ ($\mathscr{S}$ is an algebra over the ring of polynomials). Furthermore, $\mathscr{S}$ is invariant under translations and differentiation.

If $f \in \mathscr{S}$, then its transforms $\mathscr{F}[f]$ and $\bar{\mathscr{F}}[f]$ are

(i) infinitely differentiable because f is rapidly decreasing;

(ii) rapidly decreasing because f is infinitely differentiable;

hence $\mathscr{F}[f]$ and $\bar{\mathscr{F}}[f]$ are in $\mathscr{S}$: $\mathscr{S}$ *is invariant* under $\mathscr{F}$ and $\bar{\mathscr{F}}$.

Since $L^1 \supset \mathscr{S}$ and $L^2 \supset \mathscr{S}$, all properties of $\mathscr{F}$ and $\bar{\mathscr{F}}$ already encountered above are enjoyed by functions of $\mathscr{S}$, with all restrictions on differentiability and/or integrability lifted. For instance, given two functions f and g in $\mathscr{S}$, then both fg and $f * g$ are in $\mathscr{S}$ (which was not the case with L^1 nor with L^2) so that the reciprocity theorem inherited from L^2

$$\mathscr{F}[\bar{\mathscr{F}}[f]] = f \quad \text{and} \quad \bar{\mathscr{F}}[\mathscr{F}[f]] = f$$

allows one to state the reverse of the convolution theorem first established in L^1:

$$\mathscr{F}[fg] = \mathscr{F}[f] * \mathscr{F}[g]$$
$$\bar{\mathscr{F}}[fg] = \bar{\mathscr{F}}[f] * \bar{\mathscr{F}}[g].$$

1.3.2.4.4.2. Gaussian functions and Hermite functions

Gaussian functions are particularly important elements of $\mathscr{S}$. In dimension 1, a well known contour integration (Schwartz, 1965, p. 184) yields

$$\mathscr{F}[\exp(-\pi x^2)](\xi) = \bar{\mathscr{F}}[\exp(-\pi x^2)](\xi) = \exp(-\pi\xi^2),$$

which shows that the 'standard Gaussian' $\exp(-\pi x^2)$ is invariant under $\mathscr{F}$ and $\bar{\mathscr{F}}$. By a tensor product construction, it follows that the same is true of the standard Gaussian

$$G(\mathbf{x}) = \exp(-\pi\|\mathbf{x}\|^2)$$

in dimension n:

$$\mathscr{F}[G](\boldsymbol{\xi}) = \bar{\mathscr{F}}[G](\boldsymbol{\xi}) = G(\boldsymbol{\xi}).$$

In other words, G is an eigenfunction of $\mathscr{F}$ and $\bar{\mathscr{F}}$ for eigenvalue 1 (Section 1.3.2.4.3.4).

A complete system of eigenfunctions may be constructed as follows. In dimension 1, consider the family of functions

$$H_m = \frac{D^m G^2}{G} \quad (m \geq 0),$$

where D denotes the differentiation operator. The first two members of the family

$$H_0 = G, \qquad H_1 = 2DG,$$

are such that $\mathscr{F}[H_0] = H_0$, as shown above, and

$$DG(x) = -2\pi x G(x) = i(2\pi i x)G(x) = i\mathscr{F}[DG](x),$$

hence

$$\mathscr{F}[H_1] = (-i)H_1.$$

We may thus take as an induction hypothesis that

$$\mathscr{F}[H_m] = (-i)^m H_m.$$

The identity

$$D\left(\frac{D^m G^2}{G}\right) = \frac{D^{m+1}G^2}{G} - \frac{DG}{G}\frac{D^m G^2}{G}$$

may be written

$$H_{m+1}(x) = (DH_m)(x) - 2\pi x H_m(x),$$

and the two differentiation theorems give:

$$\mathscr{F}[DH_m](\xi) = (2\pi i\xi)\mathscr{F}[H_m](\xi)$$
$$\mathscr{F}[-2\pi x H_m](\xi) = -iD(\mathscr{F}[H_m])(\xi).$$

Combination of this with the induction hypothesis yields

$$\mathscr{F}[H_{m+1}](\xi) = (-i)^{m+1}[(DH_m)(\xi) - 2\pi\xi H_m(\xi)]$$
$$= (-i)^{m+1}H_{m+1}(\xi),$$

thus proving that H_m is an eigenfunction of $\mathscr{F}$ for eigenvalue $(-i)^m$ for all $m \geq 0$. The same proof holds for $\bar{\mathscr{F}}$, with eigenvalue i^m. If these eigenfunctions are normalized as

$$\mathscr{H}_m(x) = \frac{(-1)^m 2^{1/4}}{\sqrt{m!}2^m\pi^{m/2}}H_m(x),$$

then it can be shown that the collection of *Hermite functions* $\{\mathscr{H}_m(x)\}_{m\geq 0}$ constitutes an orthonormal basis of $L^2(\mathbb{R})$ such that $\mathscr{H}_m$ is an eigenfunction of $\mathscr{F}$ (respectively $\bar{\mathscr{F}}$) for eigenvalue $(-i)^m$ (respectively i^m).

In dimension n, the same construction can be extended by tensor product to yield the multivariate Hermite functions

$$\mathscr{H}_{\mathbf{m}}(\mathbf{x}) = \mathscr{H}_{m_1}(x_1) \times \mathscr{H}_{m_2}(x_2) \times \ldots \times \mathscr{H}_{m_n}(x_n)$$

(where $\mathbf{m} \geq \mathbf{0}$ is a multi-index). These constitute an orthonormal basis of $L^2(\mathbb{R}^n)$, with $\mathscr{H}_{\mathbf{m}}$ an eigenfunction of $\mathscr{F}$ (respectively $\bar{\mathscr{F}}$) for eigenvalue $(-i)^{|\mathbf{m}|}$ (respectively $i^{|\mathbf{m}|}$). Thus the subspaces $\mathbf{H}_k$ of Section 1.3.2.4.3.4 are spanned by those $\mathscr{H}_{\mathbf{m}}$ with $|\mathbf{m}| \equiv k \bmod 4$ ($k = 0, 1, 2, 3$).

General multivariate Gaussians are usually encountered in the nonstandard form

$$G_{\mathbf{A}}(\mathbf{x}) = \exp(-\tfrac{1}{2}\mathbf{x}^T \cdot \mathbf{A}\mathbf{x}),$$

where $\mathbf{A}$ is a symmetric positive-definite matrix. Diagonalizing $\mathbf{A}$ as $\mathbf{E}\boldsymbol{\Lambda}\mathbf{E}^T$ with $\mathbf{E}\mathbf{E}^T$ the identity matrix, and putting $\mathbf{A}^{1/2} = \mathbf{E}\boldsymbol{\Lambda}^{1/2}\mathbf{E}^T$, we may write

$$G_{\mathbf{A}}(\mathbf{x}) = G\left[\left(\frac{\mathbf{A}}{2\pi}\right)^{1/2}\mathbf{x}\right]$$

i.e.

$$G_{\mathbf{A}} = [(2\pi\mathbf{A}^{-1})^{1/2}]^{\#}G;$$

hence (by Section 1.3.2.4.2.3)

$$\mathscr{F}[G_{\mathbf{A}}] = |\det(2\pi\mathbf{A}^{-1})|^{1/2}\left[\left(\frac{\mathbf{A}}{2\pi}\right)^{1/2}\right]^{\#}G,$$

i.e.

$$\mathscr{F}[G_{\mathbf{A}}](\boldsymbol{\xi}) = |\det(2\pi\mathbf{A}^{-1})|^{1/2}G[(2\pi\mathbf{A}^{-1})^{1/2}\boldsymbol{\xi}],$$

i.e. finally

$$\mathscr{F}[G_{\mathbf{A}}] = |\det(2\pi\mathbf{A}^{-1})|^{1/2} G_{4\pi^2\mathbf{A}^{-1}}.$$

This result is widely used in crystallography, *e.g.* to calculate form factors for anisotropic atoms (Section 1.3.4.2.2.6) and to obtain transforms of derivatives of Gaussian atomic densities (Section 1.3.4.4.7.10).

1.3.2.4.4.3. Heisenberg's inequality, Hardy's theorem

The result just obtained, which also holds for $\bar{\mathscr{F}}$, shows that the 'peakier' $G_{\mathbf{A}}$, the 'broader' $\mathscr{F}[G_{\mathbf{A}}]$. This is a general property of the Fourier transformation, expressed in dimension 1 by the *Heisenberg inequality* (Weyl, 1931):

$$\left(\int x^2 |f(x)|^2 \,\mathrm{d}x\right)\left(\int \xi^2 |\mathscr{F}[f](\xi)|^2 \,\mathrm{d}\xi\right) \geq \frac{1}{16\pi^2}\left(\int |f(x)|^2 \,\mathrm{d}x\right)^2,$$

where, by a beautiful theorem of Hardy (1933), equality can only be attained for f Gaussian. Hardy's theorem is even stronger: if both f and $\mathscr{F}[f]$ behave at infinity as constant multiples of G, then each of them is *everywhere* a constant multiple of G; if both f and $\mathscr{F}[f]$ behave at infinity as constant multiples of $G \times$ monomial, then each of them is a finite linear combination of Hermite functions. Hardy's theorem is invoked in Section 1.3.4.4.5 to derive the optimal procedure for spreading atoms on a sampling grid in order to obtain the most accurate structure factors.

The search for optimal compromises between the confinement of f to a compact domain in x-space and of $\mathscr{F}[f]$ to a compact domain in ξ-space leads to consideration of prolate spheroidal wavefunctions (Pollack & Slepian, 1961; Landau & Pollack, 1961, 1962).

1.3.2.4.4.4. Symmetry property

A final formal property of the Fourier transform, best established in $\mathscr{S}$, is its *symmetry*: if f and g are in $\mathscr{S}$, then by Fubini's theorem

$$\begin{aligned}\langle \mathscr{F}[f], g\rangle &= \int_{\mathbb{R}^n}\left(\int_{\mathbb{R}^n} f(\mathbf{x}) \exp(-2\pi i \boldsymbol{\xi}\cdot\mathbf{x}) \,\mathrm{d}^n\mathbf{x}\right) g(\boldsymbol{\xi}) \,\mathrm{d}^n\boldsymbol{\xi} \\ &= \int_{\mathbb{R}^n} f(\mathbf{x})\left(\int_{\mathbb{R}^n} g(\boldsymbol{\xi}) \exp(-2\pi i \boldsymbol{\xi}\cdot\mathbf{x}) \,\mathrm{d}^n\boldsymbol{\xi}\right) \mathrm{d}^n\mathbf{x} \\ &= \langle f, \mathscr{F}[g]\rangle.\end{aligned}$$

This possibility of 'transposing' $\mathscr{F}$ (and $\bar{\mathscr{F}}$) from the left to the right of the duality bracket will be used in Section 1.3.2.5.4 to extend the Fourier transformation to distributions.

1.3.2.4.5. Various writings of Fourier transforms

Other ways of writing Fourier transforms in $\mathbb{R}^n$ exist besides the one used here. All have the form

$$\mathscr{F}_{h,\omega}[f](\boldsymbol{\xi}) = \frac{1}{h^n}\int_{\mathbb{R}^n} f(\mathbf{x}) \exp(-i\omega\boldsymbol{\xi}\cdot\mathbf{x}) \,\mathrm{d}^n\mathbf{x},$$

where h is real positive and ω real nonzero, with the reciprocity formula written:

$$f(\mathbf{x}) = \frac{1}{k^n}\int_{\mathbb{R}^n} \mathscr{F}_{h,\omega}[f](\boldsymbol{\xi}) \exp(+i\omega\boldsymbol{\xi}\cdot\mathbf{x}) \,\mathrm{d}^n\mathbf{x}$$

with k real positive. The consistency condition between h, k and ω is

$$hk = \frac{2\pi}{|\omega|}.$$

The usual choices are:

(i) $\omega = \pm 2\pi, h = k = 1$ (as here);
(ii) $\omega = \pm 1, h = 1, k = 2\pi$ (in probability theory and in solid-state physics);
(iii) $\omega = \pm 1, h = k = \sqrt{2\pi}$ (in much of classical analysis).

It should be noted that conventions (ii) and (iii) introduce numerical factors of 2π in convolution and Parseval formulae, while (ii) breaks the symmetry between $\mathscr{F}$ and $\bar{\mathscr{F}}$.

1.3.2.4.6. Tables of Fourier transforms

The books by Campbell & Foster (1948), Erdélyi (1954) and Magnus *et al.* (1966) contain extensive tables listing pairs of functions and their Fourier transforms. Bracewell (1986) lists those pairs particularly relevant to electrical engineering applications.

1.3.2.5. Fourier transforms of tempered distributions

1.3.2.5.1. Introduction

It was found in Section 1.3.2.4.2 that the usual space of test functions $\mathscr{D}$ is not invariant under $\mathscr{F}$ and $\bar{\mathscr{F}}$. By contrast, the space $\mathscr{S}$ of infinitely differentiable rapidly decreasing functions *is* invariant under $\mathscr{F}$ and $\bar{\mathscr{F}}$, and furthermore transposition formulae such as

$$\langle \mathscr{F}[f], g\rangle = \langle f, \mathscr{F}[g]\rangle$$

hold for all $f, g \in \mathscr{S}$. It is precisely this type of transposition which was used successfully in Sections 1.3.2.3.9.1 and 1.3.2.3.9.3 to define the derivatives of distributions and their products with smooth functions.

This suggests using $\mathscr{S}$ instead of $\mathscr{D}$ as a space of test functions φ, and defining the Fourier transform $\mathscr{F}[T]$ of a distribution T by

$$\langle \mathscr{F}[T], \varphi\rangle = \langle T, \mathscr{F}[\varphi]\rangle$$

whenever T is capable of being extended from $\mathscr{D}$ to $\mathscr{S}$ while remaining continuous. It is this latter proviso which will be subsumed under the adjective 'tempered'. As was the case with the construction of $\mathscr{D}'$, it is the definition of a sufficiently strong topology (*i.e.* notion of convergence) in $\mathscr{S}$ which will play a key role in transferring to the elements of its topological dual $\mathscr{S}'$ (called tempered distributions) all the properties of the Fourier transformation.

Besides the general references to distribution theory mentioned in Section 1.3.2.3.1 the reader may consult the books by Zemanian (1965, 1968). Lavoine (1963) contains tables of Fourier transforms of distributions.

1.3.2.5.2. $\mathscr{S}$ as a test-function space

A notion of convergence has to be introduced in $\mathscr{S}(\mathbb{R}^n)$ in order to be able to define and test the continuity of linear functionals on it.

A sequence (φ_j) of functions in $\mathscr{S}$ will be said to converge to 0 if, for any given multi-indices $\mathbf{k}$ and $\mathbf{p}$, the sequence $(\mathbf{x}^{\mathbf{k}} D^{\mathbf{p}} \varphi_j)$ tends to 0 uniformly on $\mathbb{R}^n$.

It can be shown that $\mathscr{D}(\mathbb{R}^n)$ is dense in $\mathscr{S}(\mathbb{R}^n)$. Translation is continuous for this topology. For any linear differential operator $P(D) = \sum_{\mathbf{p}} a_{\mathbf{p}} D^{\mathbf{p}}$ and any polynomial $Q(\mathbf{x})$ over $\mathbb{R}^n$, $(\varphi_j) \to 0$ implies $[Q(\mathbf{x}) \times P(D)\varphi_j] \to 0$ in the topology of $\mathscr{S}$. Therefore, differentiation and multiplication by polynomials are continuous for the topology on $\mathscr{S}$.

The Fourier transformations $\mathscr{F}$ and $\bar{\mathscr{F}}$ are also continuous for the topology of $\mathscr{S}$. Indeed, let (φ_j) converge to 0 for the topology on $\mathscr{S}$. Then, by Section 1.3.2.4.2,

$$\|(2\pi\boldsymbol{\xi})^{\mathbf{m}} D^{\mathbf{p}}(\mathscr{F}[\varphi_j])\|_\infty \leq \|D^{\mathbf{m}}[(2\pi\mathbf{x})^{\mathbf{p}} \varphi_j]\|_1.$$

The right-hand side tends to 0 as $j \to \infty$ by definition of convergence in $\mathscr{S}$, hence $\|\boldsymbol{\xi}\|^{\mathbf{m}} D^{\mathbf{p}}(\mathscr{F}[\varphi_j]) \to 0$ uniformly, so that $(\mathscr{F}[\varphi_j]) \to 0$ in $\mathscr{S}$ as $j \to \infty$. The same proof applies to $\bar{\mathscr{F}}$.

1.3.2.5.3. Definition and examples of tempered distributions

A distribution $T \in \mathscr{D}'(\mathbb{R}^n)$ is said to be *tempered* if it can be extended into a continuous linear functional on $\mathscr{S}$.

If $\mathscr{S}'(\mathbb{R}^n)$ is the topological dual of $\mathscr{S}(\mathbb{R}^n)$, and if $S \in \mathscr{S}'(\mathbb{R}^n)$, then its restriction to $\mathscr{D}$ is a tempered distribution; conversely, if $T \in \mathscr{D}'$ is tempered, then its extension to $\mathscr{S}$ is unique (because $\mathscr{D}$ is dense in $\mathscr{S}$), hence it defines an element S of $\mathscr{S}'$. We may therefore identify $\mathscr{S}'$ and the space of tempered distributions.

A distribution with compact support is tempered, *i.e.* $\mathscr{S}' \supset \mathscr{E}'$. By transposition of the corresponding properties of $\mathscr{S}$, it is readily established that the derivative, translate or product by a polynomial of a tempered distribution is still a tempered distribution.

These inclusion relations may be summarized as follows: since $\mathscr{S}$ contains $\mathscr{D}$ but is contained in $\mathscr{E}$, the reverse inclusions hold for the topological duals, and hence $\mathscr{S}'$ contains $\mathscr{E}'$ but is contained in $\mathscr{D}'$.

A locally summable function f on $\mathbb{R}^n$ will be said to be *of polynomial growth* if $|f(\mathbf{x})|$ can be majorized by a polynomial in $\|\mathbf{x}\|$ as $\|\mathbf{x}\| \to \infty$. It is easily shown that such a function f defines a tempered distribution T_f *via*

$$\langle T_f, \varphi \rangle = \int_{\mathbb{R}^n} f(\mathbf{x}) \varphi(\mathbf{x}) \, \mathrm{d}^n \mathbf{x}.$$

In particular, polynomials over $\mathbb{R}^n$ define tempered distributions, and so do functions in $\mathscr{S}$. The latter remark, together with the transposition identity (Section 1.3.2.4.4), invites the extension of $\mathscr{F}$ and $\bar{\mathscr{F}}$ from $\mathscr{S}$ to $\mathscr{S}'$.

1.3.2.5.4. Fourier transforms of tempered distributions

The Fourier transform $\mathscr{F}[T]$ and cotransform $\bar{\mathscr{F}}[T]$ of a tempered distribution T are defined by

$$\langle \mathscr{F}[T], \varphi \rangle = \langle T, \mathscr{F}[\varphi] \rangle$$
$$\langle \bar{\mathscr{F}}[T], \varphi \rangle = \langle T, \bar{\mathscr{F}}[\varphi] \rangle$$

for all test functions $\varphi \in \mathscr{S}$. Both $\mathscr{F}[T]$ and $\bar{\mathscr{F}}[T]$ are themselves tempered distributions, since the maps $\varphi \longmapsto \mathscr{F}[\varphi]$ and $\varphi \longmapsto \bar{\mathscr{F}}[\varphi]$ are both linear and continuous for the topology of $\mathscr{S}$. In the same way that $\mathbf{x}$ and $\boldsymbol{\xi}$ have been used consistently as arguments for φ and $\mathscr{F}[\varphi]$, respectively, the notation $T_{\mathbf{x}}$ and $\mathscr{F}[T]_{\boldsymbol{\xi}}$ will be used to indicate which variables are involved.

When T is a distribution with compact support, its Fourier transform may be written

$$\mathscr{F}[T_{\mathbf{x}}]_{\boldsymbol{\xi}} = \langle T_{\mathbf{x}}, \exp(-2\pi i \boldsymbol{\xi} \cdot \mathbf{x}) \rangle$$

since the function $\mathbf{x} \longmapsto \exp(-2\pi i \boldsymbol{\xi} \cdot \mathbf{x})$ is in $\mathscr{E}$ while $T_{\mathbf{x}} \in \mathscr{E}'$. It can be shown, as in Section 1.3.2.4.2, to be analytically continuable into an entire function over $\mathbb{C}^n$.

1.3.2.5.5. Transposition of basic properties

The duality between differentiation and multiplication by a monomial extends from $\mathscr{S}$ to $\mathscr{S}'$ by transposition:

$$\mathscr{F}[D_{\mathbf{x}}^{\mathbf{p}} T_{\mathbf{x}}]_{\boldsymbol{\xi}} = (2\pi i \boldsymbol{\xi})^{\mathbf{p}} \mathscr{F}[T_{\mathbf{x}}]_{\boldsymbol{\xi}}$$
$$D_{\boldsymbol{\xi}}^{\mathbf{p}}(\mathscr{F}[T_{\mathbf{x}}]_{\boldsymbol{\xi}}) = \mathscr{F}[(-2\pi i \mathbf{x})^{\mathbf{p}} T_{\mathbf{x}}]_{\boldsymbol{\xi}}.$$

Analogous formulae hold for $\bar{\mathscr{F}}$, with i replaced by $-i$.

The formulae expressing the duality between translation and phase shift, *e.g.*

$$\mathscr{F}[\tau_{\mathbf{a}} T_{\mathbf{x}}]_{\boldsymbol{\xi}} = \exp(-2\pi i \mathbf{a} \cdot \boldsymbol{\xi}) \mathscr{F}[T_{\mathbf{x}}]_{\boldsymbol{\xi}}$$
$$\tau_{\boldsymbol{a}}(\mathscr{F}[T_{\mathbf{x}}]_{\boldsymbol{\xi}}) = \mathscr{F}[\exp(2\pi i \boldsymbol{a} \cdot \mathbf{x}) T_{\mathbf{x}}]_{\boldsymbol{\xi}};$$

between a linear change of variable and its contragredient, *e.g.*

$$\mathscr{F}[A^{\#} T] = |\det \mathbf{A}| [(\mathbf{A}^{-1})^T]^{\#} \mathscr{F}[T];$$

are obtained similarly by transposition from the corresponding identities in $\mathscr{S}$. They give a transposition formula for an affine change of variables $\mathbf{x} \longmapsto S(\mathbf{x}) = \mathbf{A}\mathbf{x} + \mathbf{b}$ with nonsingular matrix $\mathbf{A}$:

$$\begin{aligned} \mathscr{F}[S^{\#} T] &= \exp(-2\pi i \boldsymbol{\xi} \cdot \mathbf{b}) \mathscr{F}[A^{\#} T] \\ &= \exp(-2\pi i \boldsymbol{\xi} \cdot \mathbf{b}) |\det \mathbf{A}| [(\mathbf{A}^{-1})^T]^{\#} \mathscr{F}[T], \end{aligned}$$

with a similar result for $\bar{\mathscr{F}}$, replacing $-i$ by $+i$.

Conjugate symmetry is obtained similarly:

$$\mathscr{F}[\bar{T}] = \overline{\check{\mathscr{F}}[T]}, \; \mathscr{F}[\check{\bar{T}}] = \overline{\mathscr{F}[T]},$$

with the same identities for $\bar{\mathscr{F}}$.

The tensor product property also transposes to tempered distributions: if $U \in \mathscr{S}'(\mathbb{R}^m)$, $V \in \mathscr{S}'(\mathbb{R}^n)$,

$$\mathscr{F}[U_{\mathbf{x}} \otimes V_{\mathbf{y}}] = \mathscr{F}[U]_{\boldsymbol{\xi}} \otimes \mathscr{F}[V]_{\boldsymbol{\eta}}$$
$$\bar{\mathscr{F}}[U_{\mathbf{x}} \otimes V_{\mathbf{y}}] = \bar{\mathscr{F}}[U]_{\boldsymbol{\xi}} \otimes \bar{\mathscr{F}}[V]_{\boldsymbol{\eta}}.$$

1.3.2.5.6. Transforms of δ-functions

Since δ has compact support,

$$\mathscr{F}[\delta_{\mathbf{x}}]_{\boldsymbol{\xi}} = \langle \delta_{\mathbf{x}}, \exp(-2\pi i \boldsymbol{\xi} \cdot \mathbf{x}) \rangle = 1_{\boldsymbol{\xi}}, \quad \textit{i.e.} \; \mathscr{F}[\delta] = 1.$$

It is instructive to show that conversely $\mathscr{F}[1] = \delta$ without invoking the reciprocity theorem. Since $\partial_j 1 = 0$ for all $j = 1, \ldots, n$, it follows from Section 1.3.2.3.9.4 that $\mathscr{F}[1] = c\delta$; the

constant c can be determined by using the invariance of the standard Gaussian G established in Section 1.3.2.4.3:

$$\langle \mathscr{F}[1]_{\mathbf{x}}, G_{\mathbf{x}} \rangle = \langle 1_{\xi}, G_{\xi} \rangle = 1;$$

hence $c = 1$. Thus, $\mathscr{F}[1] = \delta$.

The basic properties above then read (using multi-indices to denote differentiation):

$$\mathscr{F}[\delta_{\mathbf{x}}^{(\mathbf{m})}]_{\xi} = (2\pi i \boldsymbol{\xi})^{\mathbf{m}}, \quad \mathscr{F}[\mathbf{x}^{\mathbf{m}}]_{\xi} = (-2\pi i)^{-|\mathbf{m}|} \delta_{\xi}^{(\mathbf{m})};$$
$$\mathscr{F}[\delta_{\mathbf{a}}]_{\xi} = \exp(-2\pi i \mathbf{a} \cdot \boldsymbol{\xi}), \quad \mathscr{F}[\exp(2\pi i \boldsymbol{\alpha} \cdot \mathbf{x})]_{\xi} = \delta_{\boldsymbol{\alpha}},$$

with analogous relations for $\bar{\mathscr{F}}$, i becoming $-i$. Thus derivatives of δ are mapped to monomials (and *vice versa*), while translates of δ are mapped to 'phase factors' (and *vice versa*).

1.3.2.5.7. Reciprocity theorem

The previous results now allow a self-contained and rigorous proof of the reciprocity theorem between $\mathscr{F}$ and $\bar{\mathscr{F}}$ to be given, whereas in traditional settings (*i.e.* in L^1 and L^2) the implicit handling of δ through a limiting process is always the sticking point.

Reciprocity is first established in $\mathscr{S}$ as follows:

$$\begin{aligned}\bar{\mathscr{F}}[\mathscr{F}[\varphi]](\mathbf{x}) &= \int_{\mathbb{R}^n} \mathscr{F}[\varphi](\boldsymbol{\xi}) \exp(2\pi i \boldsymbol{\xi} \cdot \mathbf{x}) \, \mathrm{d}^n \boldsymbol{\xi} \\ &= \int_{\mathbb{R}^n} \mathscr{F}[\tau_{-\mathbf{x}}\varphi](\boldsymbol{\xi}) \, \mathrm{d}^n \boldsymbol{\xi} \\ &= \langle 1, \mathscr{F}[\tau_{-\mathbf{x}}\varphi] \rangle \\ &= \langle \mathscr{F}[1], \tau_{-\mathbf{x}}\varphi \rangle \\ &= \langle \tau_{\mathbf{x}}\delta, \varphi \rangle \\ &= \varphi(\mathbf{x})\end{aligned}$$

and similarly

$$\mathscr{F}[\bar{\mathscr{F}}[\varphi]](\mathbf{x}) = \varphi(\mathbf{x}).$$

The reciprocity theorem is then proved in $\mathscr{S}'$ by transposition:

$$\bar{\mathscr{F}}[\mathscr{F}[T]] = \mathscr{F}[\bar{\mathscr{F}}[T]] = T \quad \text{for all } T \in \mathscr{S}'.$$

Thus the Fourier cotransformation $\bar{\mathscr{F}}$ in $\mathscr{S}'$ may legitimately be called the 'inverse Fourier transformation'.

The method of Section 1.3.2.4.3 may then be used to show that $\mathscr{F}$ and $\bar{\mathscr{F}}$ both have period 4 in $\mathscr{S}'$.

1.3.2.5.8. Multiplication and convolution

Multiplier functions $\alpha(\mathbf{x})$ for tempered distributions must be infinitely differentiable, as for ordinary distributions; furthermore, they must grow sufficiently slowly as $\|x\| \to \infty$ to ensure that $\alpha\varphi \in \mathscr{S}$ for all $\varphi \in \mathscr{S}$ and that the map $\varphi \longmapsto \alpha\varphi$ is continuous for the topology of $\mathscr{S}$. This leads to choosing for multipliers the subspace $\mathscr{O}_M$ consisting of functions $\alpha \in \mathscr{E}$ *of polynomial growth*. It can be shown that if f is in $\mathscr{O}_M$, then the associated distribution T_f is in $\mathscr{S}'$ (*i.e.* is a tempered distribution); and that conversely if T is in $\mathscr{S}'$, $\mu * T$ is in $\mathscr{O}_M$ for all $\mu \in \mathscr{D}$.

Corresponding restrictions must be imposed to define the space $\mathscr{O}'_C$ of those distributions T whose convolution $S * T$ with a tempered distribution S is still a tempered distribution: T must be such that, for all $\varphi \in \mathscr{S}$, $\theta(\mathbf{x}) = \langle T_{\mathbf{y}}, \varphi(\mathbf{x} + \mathbf{y}) \rangle$ is in $\mathscr{S}$; and such that the map $\varphi \longmapsto \theta$ be continuous for the topology of $\mathscr{S}$. This implies that S is 'rapidly decreasing'. It can be shown that if f is in $\mathscr{S}$, then the associated distribution T_f is in $\mathscr{O}'_C$; and that conversely if T is in $\mathscr{O}'_C$, $\mu * T$ is in $\mathscr{S}$ for all $\mu \in \mathscr{D}$.

The two spaces $\mathscr{O}_M$ and $\mathscr{O}'_C$ are mapped into each other by the Fourier transformation

$$\mathscr{F}(\mathscr{O}_M) = \bar{\mathscr{F}}(\mathscr{O}_M) = \mathscr{O}'_C$$
$$\mathscr{F}(\mathscr{O}'_C) = \bar{\mathscr{F}}(\mathscr{O}'_C) = \mathscr{O}_M$$

and the convolution theorem takes the form

$$\mathscr{F}[\alpha S] = \mathscr{F}[\alpha] * \mathscr{F}[S] \quad S \in \mathscr{S}', \alpha \in \mathscr{O}_M, \mathscr{F}[\alpha] \in \mathscr{O}'_C;$$
$$\mathscr{F}[S * T] = \mathscr{F}[S] \times \mathscr{F}[T] \quad S \in \mathscr{S}', T \in \mathscr{O}'_C, \mathscr{F}[T] \in \mathscr{O}_M.$$

The same identities hold for $\bar{\mathscr{F}}$. Taken together with the reciprocity theorem, these show that $\mathscr{F}$ and $\bar{\mathscr{F}}$ establish mutually inverse isomorphisms between $\mathscr{O}_M$ and $\mathscr{O}'_C$, and exchange multiplication for convolution in $\mathscr{S}'$.

It may be noticed that most of the basic properties of $\mathscr{F}$ and $\bar{\mathscr{F}}$ may be deduced from this theorem and from the properties of δ. Differentiation operators $D^{\mathbf{m}}$ and translation operators $\tau_{\mathbf{a}}$ are convolutions with $D^{\mathbf{m}}\delta$ and $\tau_{\mathbf{a}}\delta$; they are turned, respectively, into multiplication by monomials $(\pm 2\pi i \boldsymbol{\xi})^{\mathbf{m}}$ (the transforms of $D^{\mathbf{m}}\delta$) or by phase factors $\exp(\pm 2\pi i \boldsymbol{\xi} \cdot \boldsymbol{\alpha})$ (the transforms of $\tau_{\mathbf{a}}\delta$).

Another consequence of the convolution theorem is the duality established by the Fourier transformation between sections and projections of a function and its transform. For instance, in $\mathbb{R}^3$, the *projection* of $f(x, y, z)$ on the x, y plane along the z axis may be written

$$(\delta_x \otimes \delta_y \otimes 1_z) * f;$$

its Fourier transform is then

$$(1_{\xi} \otimes 1_{\eta} \otimes \delta_{\zeta}) \times \mathscr{F}[f],$$

which is the *section* of $\mathscr{F}[f]$ by the plane $\zeta = 0$, orthogonal to the z axis used for projection. There are numerous applications of this property in crystallography (Section 1.3.4.2.1.8) and in fibre diffraction (Section 1.3.4.5.1.3).

1.3.2.5.9. L^2 aspects, Sobolev spaces

The special properties of $\mathscr{F}$ in the space of square-integrable functions $L^2(\mathbb{R}^n)$, such as Parseval's identity, can be accommodated within distribution theory: if $u \in L^2(\mathbb{R}^n)$, then T_u is a tempered distribution in $\mathscr{S}'$ (the map $u \longmapsto T_u$ being continuous) and it can be shown that $S = \mathscr{F}[T_u]$ is of the form S_v, where $u = \mathscr{F}[u]$ is the Fourier transform of u in $L^2(\mathbb{R}^n)$. By Plancherel's theorem, $\|u\|_2 = \|v\|_2$.

This embedding of L^2 into $\mathscr{S}'$ can be used to derive the convolution theorem for L^2. If u and v are in $L^2(\mathbb{R}^n)$, then $u * v$ can be shown to be a bounded continuous function; thus $u * v$ is not in L^2, but it is in $\mathscr{S}'$, so that its Fourier transform is a distribution, and

$$\mathscr{F}[u * v] = \mathscr{F}[u] \times \mathscr{F}[v].$$

Spaces of tempered distributions related to $L^2(\mathbb{R}^n)$ can be defined as follows. For any real s, define the Sobolev space $H_s(\mathbb{R}^n)$ to consist of all tempered distributions $S \in \mathscr{S}'(\mathbb{R}^n)$ such that

$$(1 + |\boldsymbol{\xi}|^2)^{s/2} \mathscr{F}[S]_{\xi} \in L^2(\mathbb{R}^n).$$

These spaces play a fundamental role in the theory of partial differential equations, and in the mathematical theory of tomographic reconstruction – a subject not unrelated to the crystallographic phase problem (Natterer, 1986).

1.3.2.6. Periodic distributions and Fourier series

1.3.2.6.1. Terminology

Let $\mathbb{Z}^n$ be the subset of $\mathbb{R}^n$ consisting of those points with (signed) integer coordinates; it is an n-dimensional *lattice*, *i.e.* a free Abelian group on n generators. A particularly simple set of n generators is given by the standard basis of $\mathbb{R}^n$, and hence $\mathbb{Z}^n$ will be called the *standard lattice in* $\mathbb{R}^n$. Any other 'nonstandard' n-dimensional lattice Λ in $\mathbb{R}^n$ is the image of this standard lattice by a general linear transformation.

If we identify any two points in $\mathbb{R}^n$ whose coordinates are congruent modulo $\mathbb{Z}^n$, *i.e.* differ by a vector in $\mathbb{Z}^n$, we obtain the *standard n-torus* $\mathbb{R}^n/\mathbb{Z}^n$. The latter may be viewed as $(\mathbb{R}/\mathbb{Z})^n$, *i.e.* as the Cartesian product of n circles. The same identification may be carried out modulo a nonstandard lattice Λ, yielding a *nonstandard n-torus* $\mathbb{R}^n/\Lambda$. The correspondence to crystallographic terminology is that 'standard' coordinates over the standard 3-torus $\mathbb{R}^3/\mathbb{Z}^3$ are called 'fractional' coordinates over the unit cell; while Cartesian coordinates, *e.g.* in ångströms, constitute a set of nonstandard coordinates.

Finally, we will denote by I the unit cube $[0, 1]^n$ and by C_ε the subset

$$C_\varepsilon = \{\mathbf{x} \in \mathbb{R}^n \| x_j| < \varepsilon \text{ for all } j = 1, \ldots, n\}.$$

1.3.2.6.2. $\mathbb{Z}^n$-periodic distributions in $\mathbb{R}^n$

A distribution $T \in \mathscr{D}'(\mathbb{R}^n)$ is called *periodic with period lattice* $\mathbb{Z}^n$ (or $\mathbb{Z}^n$-periodic) if $\tau_{\mathbf{m}} T = T$ for all $\mathbf{m} \in \mathbb{Z}^n$ (in crystallography the period lattice is the *direct* lattice).

Given a distribution with compact support $T^0 \in \mathscr{E}'(\mathbb{R}^n)$, then $T = \sum_{\mathbf{m}\in\mathbb{Z}^n} \tau_{\mathbf{m}} T^0$ is a $\mathbb{Z}^n$-periodic distribution. Note that we may write $T = r * T^0$, where $r = \sum_{\mathbf{m}\in\mathbb{Z}^n} \delta_{(\mathbf{m})}$ consists of Dirac δ's at all nodes of the period lattice $\mathbb{Z}^n$.

Conversely, any $\mathbb{Z}^n$-periodic distribution T may be written as $r * T^0$ for some $T^0 \in \mathscr{E}'$. To retrieve such a 'motif' T^0 from T, a function ψ will be constructed in such a way that $\psi \in \mathscr{D}$ (hence has compact support) and $r * \psi = 1$; then $T^0 = \psi T$. Indicator functions (Section 1.3.2.2) such as χ_1 or $\chi_{C_{1/2}}$ cannot be used directly, since they are discontinuous; but regularized versions of them may be constructed by convolution (see Section 1.3.2.3.9.7) as $\psi_0 = \chi_{C_\varepsilon} * \theta_\eta$, with ε and η such that $\psi_0(\mathbf{x}) = 1$ on $C_{1/2}$ and $\psi_0(\mathbf{x}) = 0$ outside $C_{3/4}$. Then the function

$$\psi = \frac{\psi_0}{\sum_{\mathbf{m}\in\mathbb{Z}^n} \tau_{\mathbf{m}} \psi_0}$$

has the desired property. The sum in the denominator contains at most 2^n nonzero terms at any given point $\mathbf{x}$ and acts as a smoothly varying 'multiplicity correction'.

1.3.2.6.3. Identification with distributions over $\mathbb{R}^n/\mathbb{Z}^n$

Throughout this section, 'periodic' will mean '$\mathbb{Z}^n$-periodic'.

Let $s \in \mathbb{R}$, and let $[s]$ denote the largest integer $\leq s$. For $x = (x_1, \ldots, x_n) \in \mathbb{R}^n$, let $\tilde{\mathbf{x}}$ be the unique vector $(\tilde{x}_1, \ldots, \tilde{x}_n)$ with $\tilde{x}_j = x_j - [x_j]$. If $\mathbf{x}, \mathbf{y} \in \mathbb{R}^n$, then $\tilde{\mathbf{x}} = \tilde{\mathbf{y}}$ if and only if $\mathbf{x} - \mathbf{y} \in \mathbb{Z}^n$. The image of the map $\mathbf{x} \longmapsto \tilde{\mathbf{x}}$ is thus $\mathbb{R}^n$ modulo $\mathbb{Z}^n$, or $\mathbb{R}^n/\mathbb{Z}^n$.

If f is a periodic function over $\mathbb{R}^n$, then $\tilde{\mathbf{x}} = \tilde{\mathbf{y}}$ implies $f(\mathbf{x}) = f(\mathbf{y})$; we may thus define a function $\tilde{f}$ over $\mathbb{R}^n/\mathbb{Z}^n$ by putting $\tilde{f}(\tilde{\mathbf{x}}) = f(\mathbf{x})$ for any $\mathbf{x} \in \mathbb{R}^n$ such that $\mathbf{x} - \tilde{\mathbf{x}} \in \mathbb{Z}^n$. Conversely, if $\tilde{f}$ is a function over $\mathbb{R}^n/\mathbb{Z}^n$, then we may define a function f over $\mathbb{R}^n$ by putting $f(\mathbf{x}) = \tilde{f}(\tilde{\mathbf{x}})$, and f will be periodic. Periodic functions over $\mathbb{R}^n$ may thus be identified with functions over $\mathbb{R}^n/\mathbb{Z}^n$, and this identification preserves the notions of convergence, local summability and differentiability.

Given $\varphi^0 \in \mathscr{D}(\mathbb{R}^n)$, we may define

$$\varphi(\mathbf{x}) = \sum_{\mathbf{m}\in\mathbb{Z}^n} (\tau_{\mathbf{m}} \varphi^0)(\mathbf{x})$$

since the sum only contains finitely many nonzero terms; φ is periodic, and $\tilde{\varphi} \in \mathscr{D}(\mathbb{R}^n/\mathbb{Z}^n)$. Conversely, if $\tilde{\varphi} \in \mathscr{D}(\mathbb{R}^n/\mathbb{Z}^n)$ we may define $\varphi \in \mathscr{E}(\mathbb{R}^n)$ periodic by $\varphi(\mathbf{x}) = \tilde{\varphi}(\tilde{\mathbf{x}})$, and $\varphi^0 \in \mathscr{D}(\mathbb{R}^n)$ by putting $\varphi^0 = \psi\varphi$ with ψ constructed as above.

By transposition, a distribution $\tilde{T} \in \mathscr{D}'(\mathbb{R}^n/\mathbb{Z}^n)$ defines a unique periodic distribution $T \in \mathscr{D}'(\mathbb{R}^n)$ by $\langle T, \varphi^0\rangle = \langle \tilde{T}, \tilde{\varphi}\rangle$; conversely, $T \in \mathscr{D}'(\mathbb{R}^n)$ periodic defines uniquely $\tilde{T} \in \mathscr{D}'(\mathbb{R}^n/\mathbb{Z}^n)$ by $\langle \tilde{T}, \tilde{\varphi}\rangle = \langle T, \varphi^0\rangle$.

We may therefore identify $\mathbb{Z}^n$-periodic distributions over $\mathbb{R}^n$ with distributions over $\mathbb{R}^n/\mathbb{Z}^n$. We will, however, use mostly the former presentation, as it is more closely related to the crystallographer's perception of periodicity (see Section 1.3.4.1).

1.3.2.6.4. Fourier transforms of periodic distributions

The content of this section is perhaps the central result in the relation between Fourier theory and crystallography (Section 1.3.4.2.1.1).

Let $T = r * T^0$ with r defined as in Section 1.3.2.6.2. Then $r \in \mathscr{S}'$, $T^0 \in \mathscr{E}'$ hence $T^0 \in \mathscr{O}'_C$, so that $T \in \mathscr{S}'$: $\mathbb{Z}^n$-periodic distributions are tempered, hence have a Fourier transform. The convolution theorem (Section 1.3.2.5.8) is applicable, giving:

$$\mathscr{F}[T] = \mathscr{F}[r] \times \mathscr{F}[T^0]$$

and similarly for $\bar{\mathscr{F}}$.

Since $\mathscr{F}[\delta_{(\mathbf{m})}](\xi) = \exp(-2\pi i \boldsymbol{\xi} \cdot \mathbf{m})$, formally

$$\mathscr{F}[r]_\xi = \sum_{\mathbf{m}\in\mathbb{Z}^n} \exp(-2\pi i \boldsymbol{\xi} \cdot \mathbf{m}) = Q,$$

say.

It is readily shown that Q is tempered and periodic, so that $Q = \sum_{\boldsymbol{\mu}\in\mathbb{Z}^n} \tau_{\boldsymbol{\mu}}(\psi Q)$, while the periodicity of r implies that

$$[\exp(-2\pi i \xi_j) - 1]\psi Q = 0, \quad j = 1, \ldots, n.$$

Since the first factors have single isolated zeros at $\xi_j = 0$ in $C_{3/4}$, $\psi Q = c\delta$ (see Section 1.3.2.3.9.4) and hence by periodicity $Q = cr$; convoluting with χ_{C_1} shows that $c = 1$. Thus we have the fundamental result:

$$\boxed{\mathscr{F}[r] = r}$$

so that

$$\mathscr{F}[T] = r \times \mathscr{F}[T^0];$$

i.e., according to Section 1.3.2.3.9.3,

$$\mathscr{F}[T]_\xi = \sum_{\boldsymbol{\mu}\in\mathbb{Z}^n} \mathscr{F}[T^0](\boldsymbol{\mu}) \times \delta_{(\boldsymbol{\mu})}.$$

The right-hand side is a *weighted* lattice distribution, whose nodes $\boldsymbol{\mu} \in \mathbb{Z}^n$ are weighted by the *sample values* $\mathscr{F}[T^0](\boldsymbol{\mu})$ of the transform of the motif T^0 at those nodes. Since $T^0 \in \mathscr{E}'$, the latter values may be written

$$\mathscr{F}[T^0](\boldsymbol{\mu}) = \langle T^0_{\mathbf{x}}, \exp(-2\pi i \boldsymbol{\mu}\cdot\mathbf{x})\rangle.$$

By the structure theorem for distributions with compact support (Section 1.3.2.3.9.7), T^0 is a derivative of finite order of a continuous function; therefore, from Section 1.3.2.4.2.8 and Section 1.3.2.5.8, $\mathscr{F}[T^0](\boldsymbol{\mu})$ grows at most polynomially as $\|\boldsymbol{\mu}\| \to \infty$ (see also Section 1.3.2.6.10.3 about this property). Conversely, let $W = \sum_{\boldsymbol{\mu}\in\mathbb{Z}^n} w_{\boldsymbol{\mu}}\delta_{(\boldsymbol{\mu})}$ be a weighted lattice distribution such that the weights $w_{\boldsymbol{\mu}}$ grow at most polynomially as $\|\boldsymbol{\mu}\| \to \infty$. Then W is a tempered distribution, whose Fourier cotransform $T_{\mathbf{x}} = \sum_{\boldsymbol{\mu}\in\mathbb{Z}^n} w_{\boldsymbol{\mu}} \exp(+2\pi i\boldsymbol{\mu}\cdot\mathbf{x})$ is periodic. If T is now written as $r * T^0$ for some $T^0 \in \mathscr{E}'$, then by the reciprocity theorem

$$w_{\boldsymbol{\mu}} = \mathscr{F}[T^0](\boldsymbol{\mu}) = \langle T^0_{\mathbf{x}}, \exp(-2\pi i\boldsymbol{\mu}\cdot\mathbf{x})\rangle.$$

Although the choice of T^0 is not unique, and need not yield back the same motif as may have been used to build T initially, different choices of T^0 will lead to the same coefficients $w_{\boldsymbol{\mu}}$ because of the periodicity of $\exp(-2\pi i\boldsymbol{\mu}\cdot\mathbf{x})$.

The Fourier transformation thus establishes a duality between periodic distributions and weighted lattice distributions. The pair of relations

(i) $$w_{\boldsymbol{\mu}} = \langle T^0_{\mathbf{x}}, \exp(-2\pi i\boldsymbol{\mu}\cdot\mathbf{x})\rangle$$

(ii) $$T_{\mathbf{x}} = \sum_{\boldsymbol{\mu}\in\mathbb{Z}^n} w_{\boldsymbol{\mu}} \exp(+2\pi i\boldsymbol{\mu}\cdot\mathbf{x})$$

are referred to as the *Fourier analysis* and the *Fourier synthesis* of T, respectively (there is a discrepancy between this terminology and the crystallographic one, see Section 1.3.4.2.1.1). In other words, any periodic distribution $T \in \mathscr{S}'$ may be represented by a Fourier series (ii), whose coefficients are calculated by (i). The convergence of (ii) towards T in $\mathscr{S}'$ will be investigated later (Section 1.3.2.6.10).

1.3.2.6.5. The case of nonstandard period lattices

Let Λ denote the nonstandard lattice consisting of all vectors of the form $\sum_{j=1} m_j\mathbf{a}_j$, where the m_j are rational integers and $\mathbf{a}_1, \ldots, \mathbf{a}_n$ are n linearly independent vectors in $\mathbb{R}^n$. Let R be the corresponding lattice distribution: $R = \sum_{x\in\Lambda}\delta_{(\mathbf{x})}$.

Let $\mathbf{A}$ be the nonsingular $n \times n$ matrix whose successive columns are the coordinates of vectors $\mathbf{a}_1, \ldots, \mathbf{a}_n$ in the standard basis of $\mathbb{R}^n$; $\mathbf{A}$ will be called the *period matrix* of Λ, and the mapping $\mathbf{x} \longmapsto \mathbf{Ax}$ will be denoted by A. According to Section 1.3.2.3.9.5 we have

$$\langle R, \varphi\rangle = \sum_{\mathbf{m}\in\mathbb{Z}^n} \varphi(\mathbf{Am}) = \langle r, (A^{-1})^{\#}\varphi\rangle = |\det\mathbf{A}|^{-1}\langle A^{\#}r, \varphi\rangle$$

for any $\varphi \in \mathscr{S}$, and hence $R = |\det\mathbf{A}|^{-1}A^{\#}r$. By Fourier transformation, according to Section 1.3.2.5.5,

$$\mathscr{F}[R] = |\det\mathbf{A}|^{-1}\mathscr{F}[A^{\#}r] = [(\mathbf{A}^{-1})^T]^{\#}\mathscr{F}[r] = [(\mathbf{A}^{-1})^T]^{\#}r,$$

which we write:

$$\mathscr{F}[R] = |\det\mathbf{A}|^{-1}R^*$$

with

$$R^* = |\det\mathbf{A}|[(\mathbf{A}^{-1})^T]^{\#}r.$$

R^* is a lattice distribution:

$$R^* = \sum_{\boldsymbol{\mu}\in\mathbb{Z}^n}\delta_{[(\mathbf{A}^{-1})^T\boldsymbol{\mu}]} = \sum_{\boldsymbol{\xi}\in\Lambda^*}\delta_{(\boldsymbol{\xi})}$$

associated with the *reciprocal lattice* Λ^* whose basis vectors $\mathbf{a}_1^*, \ldots, \mathbf{a}_n^*$ are the columns of $(\mathbf{A}^{-1})^T$. Since the latter matrix is equal to the adjoint matrix (*i.e.* the matrix of co-factors) of $\mathbf{A}$ divided by $\det\mathbf{A}$, the components of the reciprocal basis vectors can be written down explicitly (see Section 1.3.4.2.1.1 for the crystallographic case $n = 3$).

A distribution T will be called Λ-*periodic* if $\tau_{\boldsymbol{\xi}}T = T$ for all $\boldsymbol{\xi} \in \Lambda$; as previously, T may be written $R * T^0$ for some motif distribution T^0 with compact support. By Fourier transformation,

$$\begin{aligned}\mathscr{F}[T] &= |\det\mathbf{A}|^{-1}R^*\cdot\mathscr{F}[T^0]\\ &= |\det\mathbf{A}|^{-1}\sum_{\boldsymbol{\xi}\in\Lambda^*}\mathscr{F}[T^0](\boldsymbol{\xi})\delta_{(\boldsymbol{\xi})}\\ &= |\det\mathbf{A}|^{-1}\sum_{\boldsymbol{\mu}\in\mathbb{Z}^n}\mathscr{F}[T^0][(\mathbf{A}^{-1})^T\boldsymbol{\mu}]\delta_{[(\mathbf{A}^{-1})^T\boldsymbol{\mu}]}\end{aligned}$$

so that $\mathscr{F}[T]$ is a weighted reciprocal-lattice distribution, the weight attached to node $\boldsymbol{\xi} \in \Lambda^*$ being $|\det\mathbf{A}|^{-1}$ times the value $\mathscr{F}[T^0](\boldsymbol{\xi})$ of the Fourier transform of the motif T^0.

This result may be further simplified if T and its motif T^0 are referred to the standard period lattice $\mathbb{Z}^n$ by defining t and t^0 so that $T = A^{\#}t$, $T^0 = A^{\#}t^0$, $t = r * t^0$. Then

$$\mathscr{F}[T^0](\boldsymbol{\xi}) = |\det\mathbf{A}|\mathscr{F}[t^0](\mathbf{A}^T\boldsymbol{\xi}),$$

hence

$$\mathscr{F}[T^0][(\mathbf{A}^{-1})^T\boldsymbol{\mu}] = |\det\mathbf{A}|\mathscr{F}[t^0](\boldsymbol{\mu}),$$

so that

$$\mathscr{F}[T] = \sum_{\boldsymbol{\mu}\in\mathbb{Z}^n}\mathscr{F}[t^0](\boldsymbol{\mu})\delta_{[(\mathbf{A}^{-1})^T\boldsymbol{\mu}]}$$

in nonstandard coordinates, while

$$\mathscr{F}[t] = \sum_{\boldsymbol{\mu}\in\mathbb{Z}^n}\mathscr{F}[t^0](\boldsymbol{\mu})\delta_{(\boldsymbol{\mu})}$$

in standard coordinates.

The reciprocity theorem may then be written:

(iii) $$W_{\boldsymbol{\xi}} = |\det\mathbf{A}|^{-1}\langle T^0_{\mathbf{x}}, \exp(-2\pi i\boldsymbol{\xi}\cdot\mathbf{x})\rangle, \quad \boldsymbol{\xi} \in \boldsymbol{\Lambda}^*$$

(iv) $$T_{\mathbf{x}} = \sum_{\boldsymbol{\xi}\in\Lambda^*} W_{\boldsymbol{\xi}} \exp(+2\pi i\boldsymbol{\xi}\cdot\mathbf{x})$$

in nonstandard coordinates, or equivalently:

(v) $$w_{\boldsymbol{\mu}} = \langle t^0_{\mathbf{x}}, \exp(-2\pi i\boldsymbol{\mu}\cdot\mathbf{x})\rangle, \quad \boldsymbol{\mu} \in \mathbb{Z}^n$$

(vi) $$t_{\mathbf{x}} = \sum_{\boldsymbol{\mu}\in\mathbb{Z}^n} w_{\boldsymbol{\mu}} \exp(+2\pi i\boldsymbol{\mu}\cdot\mathbf{x})$$

in standard coordinates. It gives an n-dimensional Fourier series representation for any periodic distribution over $\mathbb{R}^n$. The convergence of such series in $\mathscr{S}'(\mathbb{R}^n)$ will be examined in Section 1.3.2.6.10.

1.3.2.6.6. Duality between periodization and sampling

Let T^0 be a distribution with compact support (the 'motif'). Its Fourier transform $\bar{\mathscr{F}}[T^0]$ is analytic (Section 1.3.2.5.4) and may thus be used as a multiplier.

We may rephrase the preceding results as follows:

(i) if T^0 is 'periodized by R' to give $R * T^0$, then $\bar{\mathscr{F}}[T^0]$ is 'sampled by R^*' to give $|\det \mathbf{A}|^{-1} R^* \cdot \bar{\mathscr{F}}[T^0]$;

(ii) if $\bar{\mathscr{F}}[T^0]$ is 'sampled by R^*' to give $R^* \cdot \bar{\mathscr{F}}[T^0]$, then T^0 is 'periodized by R' to give $|\det \mathbf{A}| R * T^0$.

Thus the Fourier transformation establishes a duality between the periodization of a distribution by a period lattice Λ and the sampling of its transform at the nodes of lattice Λ^* reciprocal to Λ. This is a particular instance of the convolution theorem of Section 1.3.2.5.8.

At this point it is traditional to break the symmetry between $\mathscr{F}$ and $\bar{\mathscr{F}}$ which distribution theory has enabled us to preserve even in the presence of periodicity, and to perform two distinct identifications:

(i) a Λ-periodic distribution T will be handled as a distribution $\tilde{T}$ on $\mathbb{R}^n/\Lambda$, was done in Section 1.3.2.6.3;

(ii) a weighted lattice distribution $W = \sum_{\boldsymbol{\mu} \in \mathbb{Z}^n} W_{\boldsymbol{\mu}} \delta_{[(\mathbf{A}^{-1})^T \boldsymbol{\mu}]}$ will be identified with the collection $\{W_{\boldsymbol{\mu}} | \boldsymbol{\mu} \in \mathbb{Z}^n\}$ of its n-tuply indexed coefficients.

1.3.2.6.7. The Poisson summation formula

Let $\varphi \in \mathscr{S}$, so that $\mathscr{F}[\varphi] \in \mathscr{S}$. Let R be the lattice distribution associated to lattice Λ, with period matrix $\mathbf{A}$, and let R^* be associated to the reciprocal lattice Λ^*. Then we may write:

$$\begin{aligned} \langle R, \varphi \rangle &= \langle R, \bar{\mathscr{F}}[\mathscr{F}[\varphi]] \rangle \\ &= \langle \bar{\mathscr{F}}[R], \mathscr{F}[\varphi] \rangle \\ &= |\det \mathbf{A}|^{-1} \langle R^*, \mathscr{F}[\varphi] \rangle \end{aligned}$$

i.e.

$$\sum_{\mathbf{x} \in \Lambda} \varphi(\mathbf{x}) = |\det \mathbf{A}|^{-1} \sum_{\boldsymbol{\xi} \in \Lambda^*} \mathscr{F}[\varphi](\boldsymbol{\xi}).$$

This identity, which also holds for $\bar{\mathscr{F}}$, is called the *Poisson summation formula*. Its usefulness follows from the fact that the speed of decrease at infinity of φ and $\mathscr{F}[\varphi]$ are inversely related (Section 1.3.2.4.4.3), so that if one of the series (say, the left-hand side) is slowly convergent, the other (say, the right-hand side) will be rapidly convergent. This procedure has been used by Ewald (1921) [see also Bertaut (1952), Born & Huang (1954)] to evaluate lattice sums (Madelung constants) involved in the calculation of the internal electrostatic energy of crystals (see Chapter 3.4 in this volume on convergence acceleration techniques for crystallographic lattice sums and Chapter 3.5 on modern extensions of the Ewald summation method).

When φ is a multivariate Gaussian

$$\varphi(\mathbf{x}) = G_{\mathbf{B}}(\mathbf{x}) = \exp(-\tfrac{1}{2} \mathbf{x}^T \mathbf{B} \mathbf{x}),$$

then

$$\mathscr{F}[\varphi](\boldsymbol{\xi}) = |\det(2\pi \mathbf{B}^{-1})|^{1/2} G_{\mathbf{B}^{-1}}(\boldsymbol{\xi}),$$

and Poisson's summation formula for a lattice with period matrix $\mathbf{A}$ reads:

$$\begin{aligned} \sum_{\mathbf{m} \in \mathbb{Z}^n} G_{\mathbf{B}}(\mathbf{A}\mathbf{m}) = |\det \mathbf{A}|^{-1} |\det(2\pi \mathbf{B}^{-1})|^{1/2} \\ \times \sum_{\boldsymbol{\mu} \in \mathbb{Z}^n} G_{4\pi^2 \mathbf{B}^{-1}}[(\mathbf{A}^{-1})^T \boldsymbol{\mu}] \end{aligned}$$

or equivalently

$$\sum_{\mathbf{m} \in \mathbb{Z}^n} G_{\mathbf{C}}(\mathbf{m}) = |\det(2\pi \mathbf{C}^{-1})|^{1/2} \sum_{\boldsymbol{\mu} \in \mathbb{Z}^n} G_{4\pi^2 \mathbf{C}^{-1}}(\boldsymbol{\mu})$$

with $\mathbf{C} = \mathbf{A}^T \mathbf{B} \mathbf{A}$.

1.3.2.6.8. Convolution of Fourier series

Let $S = R * S^0$ and $T = R * T^0$ be two Λ-periodic distributions, the motifs S^0 and T^0 having compact support. The convolution $S * T$ does not exist, because S and T do not satisfy the support condition (Section 1.3.2.3.9.7). However, the three distributions R, S^0 and T^0 do satisfy the generalized support condition, so that their convolution is defined; then, by associativity and commutativity:

$$R * S^0 * T^0 = S * T^0 = S^0 * T.$$

By Fourier transformation and by the convolution theorem:

$$\begin{aligned} R^* \times \mathscr{F}[S^0 * T^0] &= (R^* \times \mathscr{F}[S^0]) \times \mathscr{F}[T^0] \\ &= \mathscr{F}[T^0] \times (R^* \times \mathscr{F}[S^0]). \end{aligned}$$

Let $\{U_\xi\}_{\xi \in \Lambda^*}$, $\{V_\xi\}_{\xi \in \Lambda^*}$ and $\{W_\xi\}_{\xi \in \Lambda^*}$ be the sets of Fourier coefficients associated to S, T and $S * T^0 (= S^0 * T)$, respectively. Identifying the coefficients of δ_ξ for $\boldsymbol{\xi} \in \Lambda^*$ yields the forward version of the convolution theorem for Fourier series:

$$W_\xi = |\det \mathbf{A}| U_\xi V_\xi.$$

The backward version of the theorem requires that T be infinitely differentiable. The distribution $S \times T$ is then well defined and its Fourier coefficients $\{Q_\xi\}_{\xi \in \Lambda^*}$ are given by

$$Q_\xi = \sum_{\boldsymbol{\eta} \in \Lambda^*} U_{\boldsymbol{\eta}} V_{\xi - \boldsymbol{\eta}}.$$

1.3.2.6.9. Toeplitz forms, Szegö's theorem

Toeplitz forms were first investigated by Toeplitz (1907, 1910, 1911*a*). They occur in connection with the 'trigonometric moment problem' (Shohat & Tamarkin, 1943; Akhiezer, 1965) and probability theory (Grenander, 1952) and play an important role in several direct approaches to the crystallographic phase problem [see Sections 1.3.4.2.1.10, 1.3.4.5.2.2(*e*)]. Many aspects of their theory and applications are presented in the book by Grenander & Szegö (1958).

1.3.2.6.9.1. Toeplitz forms

Let $f \in L^1(\mathbb{R}/\mathbb{Z})$ be real-valued, so that its Fourier coefficients satisfy the relations $c_{-m}(f) = \overline{c_m(f)}$. The Hermitian form in $n+1$ complex variables

$$T_n[f](\mathbf{u}) = \sum_{\mu=0}^{n}\sum_{\nu=0}^{n} \overline{u_\mu} c_{\mu-\nu} u_\nu$$

is called the nth *Toeplitz form* associated to f. It is a straightforward consequence of the convolution theorem and of Parseval's identity that $T_n[f]$ may be written:

$$T_n[f](\mathbf{u}) = \int_0^1 \left| \sum_{\nu=0}^{n} u_\nu \exp(2\pi i \nu x) \right|^2 f(x)\,\mathrm{d}x.$$

1.3.2.6.9.2. The Toeplitz–Carathéodory–Herglotz theorem

It was shown independently by Toeplitz (1911*b*), Carathéodory (1911) and Herglotz (1911) that a function $f \in L^1$ is almost everywhere non-negative *if and only if* the Toeplitz forms $T_n[f]$ associated to f are positive semidefinite for all values of n.

This is equivalent to the infinite system of determinantal inequalities

$$D_n = \det \begin{pmatrix} c_0 & c_{-1} & \cdot & \cdot & c_{-n} \\ c_1 & c_0 & c_{-1} & \cdot & \cdot \\ \cdot & c_1 & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & c_{-1} \\ c_n & \cdot & \cdot & c_1 & c_0 \end{pmatrix} \geq 0 \quad \text{for all } n.$$

The D_n are called *Toeplitz determinants*. Their application to the crystallographic phase problem is described in Section 1.3.4.2.1.10.

1.3.2.6.9.3. Asymptotic distribution of eigenvalues of Toeplitz forms

The eigenvalues of the Hermitian form $T_n[f]$ are defined as the $n+1$ real roots of the characteristic equation $\det\{T_n[f-\lambda]\} = 0$. They will be denoted by

$$\lambda_1^{(n)}, \lambda_2^{(n)}, \ldots, \lambda_{n+1}^{(n)}.$$

It is easily shown that if $m \leq f(x) \leq M$ for all x, then $m \leq \lambda_\nu^{(n)} \leq M$ for all n and all $\nu = 1, \ldots, n+1$. As $n \to \infty$ these bounds, and the distribution of the $\lambda^{(n)}$ within these bounds, can be made more precise by introducing two new notions.

(i) *Essential bounds*: define ess inf f as the largest m such that $f(x) \geq m$ except for values of x forming a set of measure 0; and define ess sup f similarly.

(ii) *Equal distribution*. For each n, consider two sets of $n+1$ real numbers:

$$a_1^{(n)}, a_2^{(n)}, \ldots, a_{n+1}^{(n)}, \quad \text{and} \quad b_1^{(n)}, b_2^{(n)}, \ldots, b_{n+1}^{(n)}.$$

Assume that for each ν and each n, $|a_\nu^{(n)}| < K$ and $|b_\nu^{(n)}| < K$ with K independent of ν and n. The sets $\{a_\nu^{(n)}\}$ and $\{b_\nu^{(n)}\}$ are said to be equally distributed in $[-K, +K]$ if, for any function F over $[-K, +K]$,

$$\lim_{n\to\infty} \frac{1}{n+1} \sum_{\nu=1}^{n+1} [F(a_\nu^{(n)}) - F(b_\nu^{(n)})] = 0.$$

We may now state an important theorem of Szegö (1915, 1920). Let $f \in L^1$, and put $m = \text{ess inf}\, f$, $M = \text{ess sup}\, f$. If m and M are finite, then for any continuous function $F(\lambda)$ defined in the interval $[m, M]$ we have

$$\lim_{n\to\infty} \frac{1}{n+1} \sum_{\nu=1}^{n+1} F(\lambda_\nu^{(n)}) = \int_0^1 F[f(x)]\,\mathrm{d}x.$$

In other words, the eigenvalues $\lambda_\nu^{(n)}$ of the T_n and the values $f[\nu/(n+2)]$ of f on a regular subdivision of]0, 1[are equally distributed.

Further investigations into the spectra of Toeplitz matrices may be found in papers by Hartman & Wintner (1950, 1954), Kac *et al.* (1953), Widom (1965), and in the notes by Hirschman & Hughes (1977).

1.3.2.6.9.4. Consequences of Szegö's theorem

(i) If the λ's are ordered in ascending order, then

$$\lim_{n\to\infty} \lambda_1^{(n)} = m = \text{ess inf}\, f, \quad \lim_{n\to\infty} \lambda_{n+1}^{(n)} = M = \text{ess sup}\, f.$$

Thus, when $f \geq 0$, the condition number $\lambda_{n+1}^{(n)}/\lambda_1^{(n)}$ of $T_n[f]$ tends towards the 'essential dynamic range' M/m of f.

(ii) Let $F(\lambda) = \lambda^s$ where s is a positive integer. Then

$$\lim_{n\to\infty} \frac{1}{n+1} \sum_{\nu=1}^{n+1} [\lambda_\nu^{(n)}]^s = \int_0^1 [f(x)]^s\,\mathrm{d}x.$$

(iii) Let $m > 0$, so that $\lambda_\nu^{(n)} > 0$, and let $D_n(f) = \det T_n(f)$. Then

$$D_n(f) = \prod_{\nu=1}^{n+1} \lambda_\nu^{(n)},$$

hence

$$\log D_n(f) = \sum_{\nu=1}^{n+1} \log \lambda_\nu^{(n)}.$$

Putting $F(\lambda) = \log \lambda$, it follows that

$$\lim_{n\to\infty} [D_n(f)]^{1/(n+1)} = \exp\left\{ \int_0^1 \log f(x)\,\mathrm{d}x \right\}.$$

Further terms in this limit were obtained by Szegö (1952) and interpreted in probabilistic terms by Kac (1954).

1.3.2.6.10. Convergence of Fourier series

The investigation of the convergence of Fourier series and of more general trigonometric series has been the subject of intense study for over 150 years [see *e.g.* Zygmund (1976)]. It has been a constant source of new mathematical ideas and theories, being directly responsible for the birth of such fields as set theory, topology and functional analysis.

This section will briefly survey those aspects of the classical results in dimension 1 which are relevant to the practical use of Fourier series in crystallography. The books by Zygmund (1959), Tolstov (1962) and Katznelson (1968) are standard references in the field, and Dym & McKean (1972) is recommended as a stimulant.

1.3.2.6.10.1. Classical L^1 theory

The space $L^1(\mathbb{R}/\mathbb{Z})$ consists of (equivalence classes of) complex-valued functions f on the circle which are summable, *i.e.* for which

$$\|f\|_1 \equiv \int_0^1 |f(x)|\,\mathrm{d}x < +\infty.$$

It is a convolution algebra: If f and g are in L^1, then $f * g$ is in L^1.

The mth Fourier coefficient $c_m(f)$ of f,

$$c_m(f) = \int_0^1 f(x)\exp(-2\pi imx)\,\mathrm{d}x$$

is bounded: $|c_m(f)| \le \|f\|_1$, and by the Riemann–Lebesgue lemma $c_m(f) \to 0$ as $m \to \infty$. By the convolution theorem, $c_m(f * g) = c_m(f)c_m(g)$.

The pth *partial sum* $S_p(f)$ of the Fourier series of f,

$$S_p(f)(x) = \sum_{|m|\le p} c_m(f)\exp(2\pi imx),$$

may be written, by virtue of the convolution theorem, as $S_p(f) = D_p * f$, where

$$D_p(x) = \sum_{|m|\le p}\exp(2\pi imx) = \frac{\sin[(2p+1)\pi x]}{\sin \pi x}$$

is the *Dirichlet kernel*. Because D_p comprises numerous slowly decaying oscillations, both positive and negative, $S_p(f)$ may not converge towards f in a strong sense as $p \to \infty$. Indeed, spectacular pathologies are known to exist where the partial sums, examined pointwise, diverge everywhere (Zygmund, 1959, Chapter VIII). When f is piecewise continuous, but presents isolated jumps, convergence near these jumps is marred by the *Gibbs phenomenon*: $S_p(f)$ always 'overshoots the mark' by about 9%, the area under the spurious peak tending to 0 as $p \to \infty$ but not its height [see Larmor (1934) for the history of this phenomenon].

By contrast, the *arithmetic mean* of the partial sums, also called the pth Cesàro sum,

$$C_p(f) = \frac{1}{p+1}[S_0(f) + \ldots + S_p(f)],$$

converges to f in the sense of the L^1 norm: $\|C_p(f) - f\|_1 \to 0$ as $p \to \infty$. If furthermore f is *continuous*, then the convergence is *uniform*, *i.e.* the error is bounded everywhere by a quantity which goes to 0 as $p \to \infty$. It may be shown that

$$C_p(f) = F_p * f,$$

where

$$F_p(x) = \sum_{|m|\le p}\left(1 - \frac{|m|}{p+1}\right)\exp(2\pi imx) = \frac{1}{p+1}\left[\frac{\sin(p+1)\pi x}{\sin \pi x}\right]^2$$

is the *Fejér kernel*. F_p has over D_p the advantage of being everywhere positive, so that the Cesàro sums $C_p(f)$ of a positive function f are always positive.

The de la Vallée Poussin kernel

$$V_p(x) = 2F_{2p+1}(x) - F_p(x)$$

has a trapezoidal distribution of coefficients and is such that $c_m(V_p) = 1$ if $|m| \le p+1$; therefore $V_p * f$ is a trigonometric polynomial with the same Fourier coefficients as f over that range of values of m.

The Poisson kernel

$$P_r(x) = 1 + 2\sum_{m=1}^{\infty} r^m \cos 2\pi mx = \frac{1 - r^2}{1 - 2r\cos 2\pi mx + r^2}$$

with $0 \le r < 1$ gives rise to an Abel summation procedure [Tolstov (1962, p. 162); Whittaker & Watson (1927, p. 57)] since

$$(P_r * f)(x) = \sum_{m\in\mathbb{Z}} c_m(f) r^{|m|}\exp(2\pi imx).$$

Compared with the other kernels, P_r has the disadvantage of not being a trigonometric polynomial; however, P_r is the real part of the Cauchy kernel (Cartan, 1961; Ahlfors, 1966):

$$P_r(x) = \mathscr{R}e\left[\frac{1 + r\exp(2\pi ix)}{1 - r\exp(2\pi ix)}\right]$$

and hence provides a link between trigonometric series and analytic functions of a complex variable.

Other methods of summation involve forming a moving average of f by convolution with other sequences of functions $\alpha_p(\mathbf{x})$ besides D_p of F_p which 'tend towards δ' as $p \to \infty$. The convolution is performed by multiplying the Fourier coefficients of f by those of α_p, so that one forms the quantities

$$S'_p(f)(x) = \sum_{|m|\le p} c_m(\alpha_p)c_m(f)\exp(2\pi imx).$$

For instance the 'sigma factors' of Lanczos (Lanczos, 1966, p. 65), defined by

$$\sigma_m = \frac{\sin[m\pi/p]}{m\pi/p},$$

lead to a summation procedure whose behaviour is intermediate between those using the Dirichlet and the Fejér kernels; it corresponds to forming a moving average of f by convolution with

$$\alpha_p = p\,\chi_{[-1/(2p),\,1/(2p)]} * D_p,$$

which is itself the convolution of a 'rectangular pulse' of width $1/p$ and of the Dirichlet kernel of order p.

A review of the summation problem in crystallography is given in Section 1.3.4.2.1.3.

1.3.2.6.10.2. Classical L^2 theory

The space $L^2(\mathbb{R}/\mathbb{Z})$ of (equivalence classes of) square-integrable complex-valued functions f on the circle is contained in $L^1(\mathbb{R}/\mathbb{Z})$, since by the Cauchy–Schwarz inequality

$$\|f\|_1^2 = \left(\int_0^1 |f(x)| \times 1 \, \mathrm{d}x\right)^2 \leq \left(\int_0^1 |f(x)|^2 \, \mathrm{d}x\right)\left(\int_0^1 1^2 \, \mathrm{d}x\right) = \|f\|_2^2 \leq \infty.$$

Thus all the results derived for L^1 hold for L^2, a great simplification over the situation in $\mathbb{R}$ or $\mathbb{R}^n$ where neither L^1 nor L^2 was contained in the other.

However, more can be proved in L^2, because L^2 is a Hilbert space (Section 1.3.2.2.4) for the inner product

$$(f, g) = \int_0^1 \overline{f(x)} g(x) \, \mathrm{d}x,$$

and because the family of functions $\{\exp(2\pi imx)\}_{m\in\mathbb{Z}}$ constitutes an orthonormal Hilbert basis for L^2.

The sequence of Fourier coefficients $c_m(f)$ of $f \in L^2$ belongs to the space $\ell^2(\mathbb{Z})$ of square-summable sequences:

$$\sum_{m\in\mathbb{Z}} |c_m(f)|^2 < \infty.$$

Conversely, every element $c = (c_m)$ of ℓ^2 is the sequence of Fourier coefficients of a unique function in L^2. The inner product

$$(c, d) = \sum_{m\in\mathbb{Z}} \overline{c_m} d_m$$

makes ℓ^2 into a Hilbert space, and the map from L^2 to ℓ^2 established by the Fourier transformation is an isometry (Parseval/Plancherel):

$$\|f\|_{L^2} = \|c(f)\|_{\ell^2}$$

or equivalently:

$$(f, g) = (c(f), c(g)).$$

This is a useful property in applications, since (f, g) may be calculated either from f and g themselves, or from their Fourier coefficients $c(f)$ and $c(g)$ (see Section 1.3.4.4.6) for crystallographic applications).

By virtue of the orthogonality of the basis $\{\exp(2\pi imx)\}_{m\in\mathbb{Z}}$, the partial sum $S_p(f)$ is the best mean-square fit to f in the linear subspace of L^2 spanned by $\{\exp(2\pi imx)\}_{|m|\leq p}$, and hence (Bessel's inequality)

$$\sum_{|m|\leq p} |c_m(f)|^2 = \|f\|_2^2 - \sum_{|M|\geq p} |c_M(f)|^2 \leq \|f\|_2^2.$$

1.3.2.6.10.3. The viewpoint of distribution theory

The use of distributions enlarges considerably the range of behaviour which can be accommodated in a Fourier series, even in the case of general dimension n where classical theories meet with even more difficulties than in dimension 1.

Let $\{w_m\}_{m\in\mathbb{Z}}$ be a sequence of complex numbers with $|w_m|$ growing at most polynomially as $|m| \to \infty$, say $|w_m| \leq C|m|^K$. Then the sequence $\{w_m/(2\pi im)^{K+2}\}_{m\in\mathbb{Z}}$ is in ℓ^2 and even defines a *continuous* function $f \in L^2(\mathbb{R}/\mathbb{Z})$ and an associated tempered distribution $T_f \in \mathscr{D}'(\mathbb{R}/\mathbb{Z})$. Differentiation of T_f $(K + 2)$ times then yields a tempered distribution whose Fourier transform leads to the original sequence of coefficients. Conversely, by the structure theorem for distributions with compact support (Section 1.3.2.3.9.7), the motif T^0 of a $\mathbb{Z}$-periodic distribution is a derivative of finite order of a continuous function; hence its Fourier coefficients will grow at most polynomially with $|m|$ as $|m| \to \infty$.

Thus distribution theory allows the manipulation of Fourier series whose coefficients exhibit polynomial growth as their order goes to infinity, while those derived from functions had to tend to 0 by virtue of the Riemann–Lebesgue lemma. The distribution-theoretic approach to Fourier series holds even in the case of general dimension n, where classical theories meet with even more difficulties (see Ash, 1976) than in dimension 1.

1.3.2.7. The discrete Fourier transformation

1.3.2.7.1. Shannon's sampling theorem and interpolation formula

Let $\varphi \in \mathscr{E}(\mathbb{R}^n)$ be such that $\Phi = \mathscr{F}[\varphi]$ has compact support K. Let φ be sampled at the nodes of a lattice Λ^*, yielding the lattice distribution $R^* \times \varphi$. The Fourier transform of this sampled version of φ is

$$\mathscr{F}[R^* \times \varphi] = |\det \mathbf{A}|(R * \Phi),$$

which is essentially Φ periodized by period lattice $\Lambda = (\Lambda^*)^*$, with period matrix $\mathbf{A}$.

Let us assume that Λ is such that the translates of K by different period vectors of Λ are disjoint. Then we may recover Φ from $R * \Phi$ by masking the contents of a 'unit cell' $\mathscr{V}$ of Λ (*i.e.* a fundamental domain for the action of Λ in $\mathbb{R}^n$) whose boundary does not meet K. If $\chi_{\mathscr{V}}$ is the indicator function of $\mathscr{V}$, then

$$\Phi = \chi_{\mathscr{V}} \times (R * \Phi).$$

Transforming both sides by $\bar{\mathscr{F}}$ yields

$$\varphi = \bar{\mathscr{F}}\left[\chi_{\mathscr{V}} \times \frac{1}{|\det \mathbf{A}|} \mathscr{F}[R^* \times \varphi]\right],$$

i.e.

$$\varphi = \left(\frac{1}{V} \bar{\mathscr{F}}[\chi_{\mathscr{V}}]\right) * (R^* \times \varphi)$$

since $|\det \mathbf{A}|$ is the volume V of $\mathscr{V}$.

This interpolation formula is traditionally credited to Shannon (1949), although it was discovered much earlier by Whittaker (1915). It shows that φ may be recovered from its sample values on Λ^* (*i.e.* from $R^* \times \varphi$) provided Λ^* is sufficiently fine that no overlap (or 'aliasing') occurs in the periodization of Φ by the dual lattice Λ. The interpolation kernel is the transform of the normalized indicator function of a unit cell of Λ containing the support K of Φ.

If K is contained in a sphere of radius $1/\Delta$ and if Λ and Λ^* are rectangular, the length of each basis vector of Λ must be greater than $2/\Delta$, and thus the sampling interval must be smaller than $\Delta/2$. This requirement constitutes the Shannon sampling criterion.

1.3.2.7.2. Duality between subdivision and decimation of period lattices

1.3.2.7.2.1. Geometric description of sublattices

Let $\Lambda_{\mathbf{A}}$ be a period lattice in $\mathbb{R}^n$ with matrix $\mathbf{A}$, and let $\Lambda^*_{\mathbf{A}}$ be the lattice reciprocal to $\Lambda_{\mathbf{A}}$, with period matrix $(A^{-1})^T$. Let $\Lambda_{\mathbf{B}}$, $\mathbf{B}$, $\Lambda^*_{\mathbf{B}}$ be defined similarly, and let us suppose that $\Lambda_{\mathbf{A}}$ *is a sublattice of* $\Lambda_{\mathbf{B}}$, *i.e.* that $\Lambda_{\mathbf{B}} \supset \Lambda_{\mathbf{A}}$ as a set.

The relation between $\Lambda_{\mathbf{A}}$ and $\Lambda_{\mathbf{B}}$ may be described in two different fashions: (i) multiplicatively, and (ii) additively.

(i) We may write $\mathbf{A} = \mathbf{BN}$ for some nonsingular matrix $\mathbf{N}$ with integer entries. $\mathbf{N}$ may be viewed as the period matrix of the coarser lattice $\Lambda_{\mathbf{A}}$ with respect to the period basis of the finer lattice $\Lambda_{\mathbf{B}}$. It will be more convenient to write $\mathbf{A} = \mathbf{DB}$, where $\mathbf{D} = \mathbf{BNB}^{-1}$ is a rational matrix (with integer determinant since $\det \mathbf{D} = \det \mathbf{N}$) in terms of which the two lattices are related by

$$\Lambda_{\mathbf{A}} = \mathbf{D}\Lambda_{\mathbf{B}}.$$

(ii) Call two vectors in $\Lambda_{\mathbf{B}}$ *congruent modulo* $\Lambda_{\mathbf{A}}$ if their difference lies in $\Lambda_{\mathbf{A}}$. Denote the set of congruence classes (or 'cosets') by $\Lambda_{\mathbf{B}}/\Lambda_{\mathbf{A}}$, and the number of these classes by $[\Lambda_{\mathbf{B}} : \Lambda_{\mathbf{A}}]$. The 'coset decomposition'

$$\Lambda_{\mathbf{B}} = \bigcup_{\ell \in \Lambda_{\mathbf{B}}/\Lambda_{\mathbf{A}}} (\ell + \Lambda_{\mathbf{A}})$$

represents $\Lambda_{\mathbf{B}}$ as the disjoint union of $[\Lambda_{\mathbf{B}} : \Lambda_{\mathbf{A}}]$ translates of $\Lambda_{\mathbf{A}}$. $\Lambda_{\mathbf{B}}/\Lambda_{\mathbf{A}}$ is a finite lattice with $[\Lambda_{\mathbf{B}} : \Lambda_{\mathbf{A}}]$ elements, called the *residual lattice* of $\Lambda_{\mathbf{B}}$ modulo $\Lambda_{\mathbf{A}}$.

The two descriptions are connected by the relation $[\Lambda_{\mathbf{B}} : \Lambda_{\mathbf{A}}] = \det \mathbf{D} = \det \mathbf{N}$, which follows from a volume calculation. We may also combine (i) and (ii) into

$$\text{(iii)} \qquad \Lambda_{\mathbf{B}} = \bigcup_{\ell \in \Lambda_{\mathbf{B}}/\Lambda_{\mathbf{A}}} (\ell + \mathbf{D}\Lambda_{\mathbf{B}})$$

which may be viewed as the n-dimensional equivalent of the Euclidean algorithm for integer division: ℓ is the 'remainder' of the division by $\Lambda_{\mathbf{A}}$ of a vector in $\Lambda_{\mathbf{B}}$, the quotient being the matrix $\mathbf{D}$.

1.3.2.7.2.2. Sublattice relations for reciprocal lattices

Let us now consider the two *reciprocal lattices* $\Lambda^*_{\mathbf{A}}$ and $\Lambda^*_{\mathbf{B}}$. Their period matrices $(\mathbf{A}^{-1})^T$ and $(\mathbf{B}^{-1})^T$ are related by: $(\mathbf{B}^{-1})^T = (\mathbf{A}^{-1})^T \mathbf{N}^T$, where $\mathbf{N}^T$ is an integer matrix; or equivalently by $(\mathbf{B}^{-1})^T = \mathbf{D}^T (\mathbf{A}^{-1})^T$. This shows that the roles are reversed in that $\Lambda^*_{\mathbf{B}}$ *is a sublattice of* $\Lambda^*_{\mathbf{A}}$, which we may write:

$$\text{(i)}^* \qquad \Lambda^*_{\mathbf{B}} = \mathbf{D}^T \Lambda^*_{\mathbf{A}}$$

$$\text{(ii)}^* \qquad \Lambda^*_{\mathbf{A}} = \bigcup_{\ell^* \in \Lambda^*_{\mathbf{A}}/\Lambda^*_{\mathbf{B}}} (\ell^* + \Lambda^*_{\mathbf{B}}).$$

The residual lattice $\Lambda^*_{\mathbf{A}}/\Lambda^*_{\mathbf{B}}$ is finite, with $[\Lambda^*_{\mathbf{A}} : \Lambda^*_{\mathbf{B}}] = \det \mathbf{D} = \det \mathbf{N} = [\Lambda_{\mathbf{B}} : \Lambda_{\mathbf{A}}]$, and we may again combine (i)* and (ii)* into

$$\text{(iii)}^* \qquad \Lambda^*_{\mathbf{A}} = \bigcup_{\ell^* \in \Lambda^*_{\mathbf{A}}/\Lambda^*_{\mathbf{B}}} (\ell^* + \mathbf{D}^T \Lambda^*_{\mathbf{A}}).$$

1.3.2.7.2.3. Relation between lattice distributions

The above relations between lattices may be rewritten in terms of the corresponding *lattice distributions* as follows:

$$\text{(i)} \qquad R_{\mathbf{A}} = \frac{1}{|\det \mathbf{D}|} \mathbf{D}^{\#} R^*_{\mathbf{B}}$$

$$\text{(ii)} \qquad R_{\mathbf{B}} = T_{\mathbf{B/A}} * R_{\mathbf{A}}$$

$$\text{(i)}^* \qquad R^*_{\mathbf{B}} = \frac{1}{|\det \mathbf{D}|} (\mathbf{D}^T)^{\#} R^*_{\mathbf{A}}$$

$$\text{(ii)}^* \qquad R^*_{\mathbf{A}} = T^*_{\mathbf{A/B}} * R^*_{\mathbf{B}}$$

where

$$T_{\mathbf{B/A}} = \sum_{\ell \in \Lambda_{\mathbf{B}}/\Lambda_{\mathbf{A}}} \delta_{(\ell)}$$

and

$$T^*_{\mathbf{A/B}} = \sum_{\ell^* \in \Lambda^*_{\mathbf{A}}/\Lambda^*_{\mathbf{B}}} \delta_{(\ell^*)}$$

are (finite) residual-lattice distributions. We may incorporate the factor $1/|\det \mathbf{D}|$ in (i) and (i)* into these distributions and define

$$S_{\mathbf{B/A}} = \frac{1}{|\det \mathbf{D}|} T_{\mathbf{B/A}}, \quad S^*_{\mathbf{A/B}} = \frac{1}{|\det \mathbf{D}|} T^*_{\mathbf{A/B}}.$$

Since $|\det \mathbf{D}| = [\Lambda_{\mathbf{B}} : \Lambda_{\mathbf{A}}] = [\Lambda^*_{\mathbf{A}} : \Lambda^*_{\mathbf{B}}]$, convolution with $S_{\mathbf{B/A}}$ and $S^*_{\mathbf{A/B}}$ has the effect of *averaging* the translates of a distribution under the elements (or 'cosets') of the residual lattices $\Lambda_{\mathbf{B}}/\Lambda_{\mathbf{A}}$ and $\Lambda^*_{\mathbf{A}}/\Lambda^*_{\mathbf{B}}$, respectively. This process will be called 'coset averaging'. Eliminating $R_{\mathbf{A}}$ and $R_{\mathbf{B}}$ between (i) and (ii), and $R^*_{\mathbf{A}}$ and $R^*_{\mathbf{B}}$ between (i)* and (ii)*, we may write:

$$\text{(i}') \qquad R_{\mathbf{A}} = \mathbf{D}^{\#}(S_{\mathbf{B/A}} * R_{\mathbf{A}})$$

$$\text{(ii}') \qquad R_{\mathbf{B}} = S_{\mathbf{B/A}} * (\mathbf{D}^{\#} R_{\mathbf{B}})$$

$$\text{(i}')^* \qquad R^*_{\mathbf{B}} = (\mathbf{D}^T)^{\#}(S^*_{\mathbf{A/B}} * R^*_{\mathbf{B}})$$

$$\text{(ii}')^* \qquad R^*_{\mathbf{A}} = S^*_{\mathbf{A/B}} * [(\mathbf{D}^T)^{\#} R^*_{\mathbf{A}}].$$

These identities show that *period subdivision* by convolution with $S_{\mathbf{B/A}}$ (respectively $S^*_{\mathbf{A/B}}$) on the one hand, and *period decimation* by 'dilation' by $\mathbf{D}^{\#}$ on the other hand, are mutually inverse operations on $R_{\mathbf{A}}$ and $R_{\mathbf{B}}$ (respectively $R^*_{\mathbf{A}}$ and $R^*_{\mathbf{B}}$).

1.3.2.7.2.4. Relation between Fourier transforms

Finally, let us consider the relations between the *Fourier transforms* of these lattice distributions. Recalling the basic relation of Section 1.3.2.6.5,

$$\begin{aligned} \mathscr{F}[R_{\mathbf{A}}] &= \frac{1}{|\det \mathbf{A}|} R^*_{\mathbf{A}} \\ &= \frac{1}{|\det \mathbf{DB}|} T^*_{\mathbf{A/B}} * R^*_{\mathbf{B}} \qquad \text{by (ii)}^* \\ &= \left(\frac{1}{|\det \mathbf{D}|} T^*_{\mathbf{A/B}} \right) * \left(\frac{1}{|\det \mathbf{B}|} R^*_{\mathbf{B}} \right) \end{aligned}$$

i.e.

$$\text{(iv)} \qquad \mathscr{F}[R_{\mathbf{A}}] = S^*_{\mathbf{A/B}} * \mathscr{F}[R_{\mathbf{B}}]$$

and similarly:

$$\text{(v)} \qquad \mathscr{F}[R^*_{\mathbf{B}}] = S_{\mathbf{B/A}} * \mathscr{F}[R^*_{\mathbf{A}}].$$

Thus $R_{\mathbf{A}}$ (respectively $R^*_{\mathbf{B}}$), a *decimated* version of $R_{\mathbf{B}}$ (respectively $R^*_{\mathbf{A}}$), is transformed by $\mathscr{F}$ into a *subdivided* version of $\mathscr{F}[R_{\mathbf{B}}]$ (respectively $\mathscr{F}[R^*_{\mathbf{A}}]$).

The converse is also true:

$$\begin{aligned}\mathscr{F}[R_{\mathbf{B}}] &= \frac{1}{|\det \mathbf{B}|} R^*_{\mathbf{B}} \\ &= \frac{1}{|\det \mathbf{B}|}\frac{1}{|\det \mathbf{D}|}(\mathbf{D}^T)^{\#} R^*_{\mathbf{A}} \qquad \text{by (i)}^* \\ &= (\mathbf{D}^T)^{\#}\left(\frac{1}{|\det \mathbf{A}|} R^*_{\mathbf{A}}\right)\end{aligned}$$

i.e.

$$\text{(iv}') \qquad \mathscr{F}[R_{\mathbf{B}}] = (\mathbf{D}^T)^{\#}\mathscr{F}[R_{\mathbf{A}}]$$

and similarly

$$\text{(v}') \qquad \mathscr{F}[R^*_{\mathbf{A}}] = \mathbf{D}^{\#}\mathscr{F}[R^*_{\mathbf{B}}].$$

Thus $R_{\mathbf{B}}$ (respectively $R^*_{\mathbf{A}}$), a *subdivided* version of $R_{\mathbf{A}}$ (respectively $R^*_{\mathbf{B}}$) is transformed by $\mathscr{F}$ into a *decimated* version of $\mathscr{F}[R_{\mathbf{A}}]$ (respectively $\mathscr{F}[R^*_{\mathbf{B}}]$). Therefore, *the Fourier transform exchanges subdivision and decimation of period lattices for lattice distributions*.

Further insight into this phenomenon is provided by applying $\bar{\mathscr{F}}$ to both sides of (iv) and (v) and invoking the convolution theorem:

$$\text{(iv}'') \qquad R_{\mathbf{A}} = \bar{\mathscr{F}}[S^*_{\mathbf{A/B}}] \times R_{\mathbf{B}}$$

$$\text{(v}'') \qquad R^*_{\mathbf{B}} = \bar{\mathscr{F}}[S_{\mathbf{B/A}}] \times R^*_{\mathbf{A}}.$$

These identities show that multiplication by the transform of the period-subdividing distribution $S^*_{\mathbf{A/B}}$ (respectively $S_{\mathbf{B/A}}$) has the effect of decimating $R_{\mathbf{B}}$ to $R_{\mathbf{A}}$ (respectively $R^*_{\mathbf{A}}$ to $R^*_{\mathbf{B}}$). They clearly imply that, if $\ell \in \Lambda_{\mathbf{B}}/\Lambda_{\mathbf{A}}$ and $\ell^* \in \Lambda^*_{\mathbf{A}}/\Lambda^*_{\mathbf{B}}$, then

$$\begin{aligned}\bar{\mathscr{F}}[S^*_{\mathbf{A/B}}](\ell) &= 1 \text{ if } \ell = \mathbf{0} \quad (\textit{i.e.} \text{ if } \ell \text{ belongs} \\ &\qquad\qquad \text{to the class of } \Lambda_{\mathbf{A}}), \\ &= 0 \text{ if } \ell \neq \mathbf{0}; \\ \bar{\mathscr{F}}[S_{\mathbf{B/A}}](\ell^*) &= 1 \text{ if } \ell^* = \mathbf{0} \quad (\textit{i.e.} \text{ if } \ell^* \text{ belongs} \\ &\qquad\qquad \text{to the class of } \Lambda^*_{\mathbf{B}}), \\ &= 0 \text{ if } \ell^* \neq \mathbf{0}.\end{aligned}$$

Therefore, the duality between subdivision and decimation may be viewed as another aspect of that between convolution and multiplication.

There is clearly a strong analogy between the sampling/periodization duality of Section 1.3.2.6.6 and the decimation/subdivision duality, which is viewed most naturally in terms of subgroup relationships: both sampling and decimation involve restricting a function to a *discrete additive subgroup* of the domain over which it is initially given.

1.3.2.7.2.5. Sublattice relations in terms of periodic distributions

The usual presentation of this duality is not in terms of lattice distributions, but of periodic distributions obtained by convolving them with a motif.

Given $T^0 \in \mathscr{E}'(\mathbb{R}^n)$, let us form $R_{\mathbf{A}} * T^0$, then *decimate* its transform $(1/|\det \mathbf{A}|)R^*_{\mathbf{A}} \times \bar{\mathscr{F}}[T^0]$ by keeping only its values at the points of the coarser lattice $\Lambda^*_{\mathbf{B}} = \mathbf{D}^T\Lambda^*_{\mathbf{A}}$; as a result, $R^*_{\mathbf{A}}$ is replaced by $(1/|\det \mathbf{D}|)R^*_{\mathbf{B}}$, and the reverse transform then yields

$$\frac{1}{|\det \mathbf{D}|} R_{\mathbf{B}} * T^0 = S_{\mathbf{B/A}} * (R_{\mathbf{A}} * T^0) \qquad \text{by (ii)},$$

which is the *coset-averaged* version of the original $R_{\mathbf{A}} * T^0$. The converse situation is analogous to that of Shannon's sampling theorem. Let a function $\varphi \in \mathscr{E}(\mathbb{R}^n)$ whose transform $\Phi = \mathscr{F}[\varphi]$ has compact support be sampled as $R_{\mathbf{B}} \times \varphi$ at the nodes of $\Lambda_{\mathbf{B}}$. Then

$$\mathscr{F}[R_{\mathbf{B}} \times \varphi] = \frac{1}{|\det \mathbf{B}|}(R^*_{\mathbf{B}} * \Phi)$$

is periodic with period lattice $\Lambda^*_{\mathbf{B}}$. If the sampling lattice $\Lambda_{\mathbf{B}}$ is decimated to $\Lambda_{\mathbf{A}} = \mathbf{D}\Lambda_{\mathbf{B}}$, the inverse transform becomes

$$\begin{aligned}\mathscr{F}[R_{\mathbf{A}} \times \varphi] &= \frac{1}{|\det \mathbf{D}|}(R^*_{\mathbf{A}} * \Phi) \\ &= S^*_{\mathbf{A/B}} * (R^*_{\mathbf{B}} * \Phi) \qquad \text{by (ii)}^*,\end{aligned}$$

hence becomes periodized more finely by averaging over the cosets of $\Lambda^*_{\mathbf{A}}/\Lambda^*_{\mathbf{B}}$. With this finer periodization, the various copies of Supp Φ may start to overlap (a phenomenon called 'aliasing'), indicating that decimation has produced too coarse a sampling of φ.

1.3.2.7.3. Discretization of the Fourier transformation

Let $\varphi^0 \in \mathscr{E}(\mathbb{R}^n)$ be such that $\Phi^0 = \mathscr{F}[\varphi^0]$ has compact support (φ^0 is said to be *band-limited*). Then $\varphi = R_{\mathbf{A}} * \varphi^0$ is $\Lambda_{\mathbf{A}}$-periodic, and $\Phi = \mathscr{F}[\varphi] = (1/|\det \mathbf{A}|)R^*_{\mathbf{A}} \times \Phi^0$ is such that only a finite number of points $\lambda^*_{\mathbf{A}}$ of $\Lambda^*_{\mathbf{A}}$ have a nonzero Fourier coefficient $\Phi^0(\lambda^*_{\mathbf{A}})$ attached to them. We may therefore find a *decimation* $\Lambda^*_{\mathbf{B}} = \mathbf{D}^T\Lambda^*_{\mathbf{A}}$ of $\Lambda^*_{\mathbf{A}}$ such that the distinct translates of Supp Φ^0 by vectors of $\Lambda^*_{\mathbf{B}}$ do not intersect.

The distribution Φ can be uniquely recovered from $R^*_{\mathbf{B}} * \Phi$ by the procedure of Section 1.3.2.7.1, and we may write:

$$\begin{aligned}R^*_{\mathbf{B}} * \Phi &= \frac{1}{|\det \mathbf{A}|} R^*_{\mathbf{B}} * (R^*_{\mathbf{A}} \times \Phi^0) \\ &= \frac{1}{|\det \mathbf{A}|} R^*_{\mathbf{A}} \times (R^*_{\mathbf{B}} * \Phi^0) \\ &= \frac{1}{|\det \mathbf{A}|} R^*_{\mathbf{B}} * [T^*_{\mathbf{A/B}} \times (R^*_{\mathbf{B}} * \Phi^0)];\end{aligned}$$

these rearrangements being legitimate because Φ^0 and $T^*_{\mathbf{A/B}}$ have compact supports which are intersection-free under the action of $\Lambda^*_{\mathbf{B}}$. By virtue of its $\Lambda^*_{\mathbf{B}}$-periodicity, this distribution is entirely characterized by its 'motif' $\tilde{\Phi}$ with respect to $\Lambda^*_{\mathbf{B}}$:

$$\tilde{\Phi} = \frac{1}{|\det \mathbf{A}|} T^*_{\mathbf{A/B}} \times (R^*_{\mathbf{B}} * \Phi^0).$$

Similarly, φ may be uniquely recovered by Shannon interpolation from the distribution sampling its values at the nodes of $\Lambda_{\mathbf{B}} = \mathbf{D}^{-1}\Lambda_{\mathbf{A}}$($\Lambda_{\mathbf{B}}$ is a *subdivision* of $\Lambda_{\mathbf{B}}$). By virtue of its $\Lambda_{\mathbf{A}}$-periodicity, this distribution is completely characterized by its motif:

$$\tilde{\varphi} = T_{\mathbf{B/A}} \times \varphi = T_{\mathbf{B/A}} \times (R^*_{\mathbf{A}} * \varphi^0).$$

Let $\ell \in \Lambda_{\mathbf{B}}/\Lambda_{\mathbf{A}}$ and $\ell^* \in \Lambda^*_{\mathbf{A}}/\Lambda^*_{\mathbf{B}}$, and define the two sets of coefficients

(1) $\tilde{\varphi}(\ell) = \varphi(\ell + \boldsymbol{\lambda}_{\mathbf{A}})$ for any $\boldsymbol{\lambda}_{\mathbf{A}} \in \Lambda_{\mathbf{A}}$ (all choices of $\boldsymbol{\lambda}_{\mathbf{A}}$ give the same $\tilde{\varphi}$),

(2) $\tilde{\Phi}(\ell^*) = \Phi^0(\ell^* + \boldsymbol{\lambda}^*_{\mathbf{B}})$ for the unique $\boldsymbol{\lambda}^*_{\mathbf{B}}$ (if it exists) such that $\ell^* + \boldsymbol{\lambda}^*_{\mathbf{B}} \in \text{Supp } \Phi^0$,
$= 0$ if no such $\boldsymbol{\lambda}^*_{\mathbf{B}}$ exists.

Define the two distributions

$$\omega = \sum_{\ell \in \Lambda_{\mathbf{B}}/\Lambda_{\mathbf{A}}} \tilde{\varphi}(\ell)\delta_{(\ell)}$$

and

$$\Omega = \sum_{\ell^* \in \Lambda^*_{\mathbf{A}}/\Lambda^*_{\mathbf{B}}} \tilde{\Phi}(\ell^*)\delta_{(\ell^*)}.$$

The relation between ω and Ω has two equivalent forms:

(i) $R_{\mathbf{A}} * \omega = \mathscr{F}[R^*_{\mathbf{B}} * \Omega]$

(ii) $\bar{\mathscr{F}}[R_{\mathbf{A}} * \omega] = R^*_{\mathbf{B}} * \Omega.$

By (i), $R_{\mathbf{A}} * \omega = |\det \mathbf{B}| R_{\mathbf{B}} \times \mathscr{F}[\Omega]$. Both sides are weighted lattice distributions concentrated at the nodes of $\Lambda_{\mathbf{B}}$, and equating the weights at $\boldsymbol{\lambda}_{\mathbf{B}} = \ell + \boldsymbol{\lambda}_{\mathbf{A}}$ gives

$$\tilde{\varphi}(\ell) = \frac{1}{|\det \mathbf{D}|} \sum_{\ell^* \in \Lambda^*_{\mathbf{A}}/\Lambda^*_{\mathbf{B}}} \tilde{\Phi}(\ell^*) \exp[-2\pi i \ell^* \cdot (\ell + \boldsymbol{\lambda}_{\mathbf{A}})].$$

Since $\ell^* \in \Lambda^*_{\mathbf{A}}$, $\ell^* \cdot \boldsymbol{\lambda}_{\mathbf{A}}$ is an integer, hence

$$\tilde{\varphi}(\ell) = \frac{1}{|\det \mathbf{D}|} \sum_{\ell^* \in \Lambda^*_{\mathbf{A}}/\Lambda^*_{\mathbf{B}}} \tilde{\Phi}(\ell^*) \exp(-2\pi i \ell^* \cdot \ell).$$

By (ii), we have

$$\frac{1}{|\det \mathbf{A}|} R^*_{\mathbf{B}} * [T^*_{\mathbf{A/B}} \times (R^*_{\mathbf{B}} * \Phi^0)] = \frac{1}{|\det \mathbf{A}|} \bar{\mathscr{F}}[R_{\mathbf{A}} * \omega].$$

Both sides are weighted lattice distributions concentrated at the nodes of $\Lambda^*_{\mathbf{B}}$, and equating the weights at $\boldsymbol{\lambda}^*_{\mathbf{A}} = \ell^* + \boldsymbol{\lambda}^*_{\mathbf{B}}$ gives

$$\tilde{\Phi}(\ell^*) = \sum_{\ell \in \Lambda_{\mathbf{B}}/\Lambda_{\mathbf{A}}} \tilde{\varphi}(\ell) \exp[+2\pi i \ell \cdot (\ell^* + \boldsymbol{\lambda}^*_{\mathbf{B}})].$$

Since $\ell \in \Lambda_{\mathbf{B}}$, $\ell \cdot \boldsymbol{\lambda}^*_{\mathbf{B}}$ is an integer, hence

$$\tilde{\Phi}(\ell^*) = \sum_{\ell \in \Lambda_{\mathbf{B}}/\Lambda_{\mathbf{A}}} \tilde{\varphi}(\ell) \exp(+2\pi i \ell \cdot \ell^*).$$

Now the decimation/subdivision relations between $\Lambda_{\mathbf{A}}$ and $\Lambda_{\mathbf{B}}$ may be written:

$$\mathbf{A} = \mathbf{DB} = \mathbf{BN},$$

so that

$$\ell = \mathbf{B}\mathscr{k} \quad \text{for } \mathscr{k} \in \mathbb{Z}^n$$
$$\ell^* = (\mathbf{A}^{-1})^T \mathscr{k}^* \quad \text{for } \mathscr{k}^* \in \mathbb{Z}^n$$

with $(\mathbf{A}^{-1})^T = (\mathbf{B}^{-1})^T(\mathbf{N}^{-1})^T$, hence finally

$$\ell^* \cdot \ell = \ell \cdot \ell^* = \mathscr{k}^* \cdot (\mathbf{N}^{-1}\mathscr{k}).$$

Denoting $\tilde{\varphi}(\mathbf{B}\mathscr{k})$ by $\psi(\mathscr{k})$ and $\tilde{\Phi}[(\mathbf{A}^{-1})^T\mathscr{k}^*]$ by $\Psi(\mathscr{k}^*)$, the relation between ω and Ω may be written in the equivalent form

(i) $$\psi(\mathscr{k}) = \frac{1}{|\det \mathbf{N}|} \sum_{\mathscr{k}^* \in \mathbb{Z}^n/\mathbf{N}^T\mathbb{Z}^n} \Psi(\mathscr{k}^*) \exp[-2\pi i \mathscr{k}^* \cdot (\mathbf{N}^{-1}\mathscr{k})]$$

(ii) $$\Psi(\mathscr{k}^*) = \sum_{\mathscr{k} \in \mathbb{Z}^n/\mathbf{N}\mathbb{Z}^n} \psi(\mathscr{k}) \exp[+2\pi i \mathscr{k}^* \cdot (\mathbf{N}^{-1}\mathscr{k})],$$

where the summations are now over *finite* residual lattices in standard form.

Equations (i) and (ii) describe two mutually inverse linear transformations $\mathscr{F}(\mathbf{N})$ and $\bar{\mathscr{F}}(\mathbf{N})$ between two vector spaces $W_{\mathbf{N}}$ and $W^*_{\mathbf{N}}$ of dimension $|\det \mathbf{N}|$. $\mathscr{F}(\mathbf{N})$ [respectively $\bar{\mathscr{F}}(\mathbf{N})$] is the *discrete* Fourier (respectively inverse Fourier) transform associated to matrix $\mathbf{N}$.

The vector spaces $W_{\mathbf{N}}$ and $W^*_{\mathbf{N}}$ may be viewed from two different standpoints:

(1) as vector spaces of *weighted residual-lattice distributions*, of the form $\alpha(\mathbf{x})T_{\mathbf{B/A}}$ and $\beta(\mathbf{x})T^*_{\mathbf{A/B}}$; the canonical basis of $W_{\mathbf{N}}$ (respectively $W^*_{\mathbf{N}}$) then consists of the $\delta_{(\mathscr{k})}$ for $\mathscr{k} \in \mathbb{Z}^n/\mathbf{N}\mathbb{Z}^n$ [respectively $\delta_{(\mathscr{k}^*)}$ for $\mathscr{k}^* \in \mathbb{Z}^n/\mathbf{N}^T\mathbb{Z}^n$];

(2) as vector spaces of *weight vectors* for the $|\det \mathbf{N}|$ δ-functions involved in the expression for $T_{\mathbf{B/A}}$ (respectively $T^*_{\mathbf{A/B}}$); the canonical basis of $W_{\mathbf{N}}$ (respectively $W^*_{\mathbf{N}}$) consists of weight vectors $\mathbf{u}_{\mathscr{k}}$ (respectively $\mathbf{v}_{\mathscr{k}^*}$) giving weight 1 to element $\mathscr{k}$ (respectively $\mathscr{k}^*$) and 0 to the others.

These two spaces are said to be 'isomorphic' (a relation denoted $\cong$), the isomorphism being given by the one-to-one correspondence:

$$\omega = \sum_{\mathscr{k}} \psi(\mathscr{k})\delta_{(\mathscr{k})} \quad \leftrightarrow \quad \psi = \sum_{\mathscr{k}} \psi(\mathscr{k})\mathbf{u}_{\mathscr{k}}$$
$$\Omega = \sum_{\mathscr{k}^*} \Psi(\mathscr{k}^*)\delta_{(\mathscr{k}^*)} \quad \leftrightarrow \quad \Psi = \sum_{\mathscr{k}^*} \Psi(\mathscr{k}^*)\mathbf{v}_{\mathscr{k}^*}.$$

The second viewpoint will be adopted, as it involves only linear algebra. However, it is most helpful to keep the first one in mind and to think of the data or results of a discrete Fourier transform as representing (through their sets of unique weights) two periodic lattice distributions related by the full, distribution-theoretic Fourier transform.

We therefore view $W_{\mathbf{N}}$ (respectively $W^*_{\mathbf{N}}$) as the vector space of complex-valued functions over the finite residual lattice $\Lambda_{\mathbf{B}}/\Lambda_{\mathbf{A}}$ (respectively $\Lambda^*_{\mathbf{A}}/\Lambda^*_{\mathbf{B}}$) and write:

$$W_{\mathbf{N}} \cong L(\Lambda_{\mathbf{B}}/\Lambda_{\mathbf{A}}) \cong L(\mathbb{Z}^n/\mathbf{N}\mathbb{Z}^n)$$
$$W_{\mathbf{N}}^* \cong L(\Lambda_{\mathbf{A}}^*/\Lambda_{\mathbf{B}}^*) \cong L(\mathbb{Z}^n/\mathbf{N}^T\mathbb{Z}^n)$$

since a vector such as ψ is in fact the function $\mathbf{k} \longmapsto \psi(\mathbf{k})$.

The two spaces $W_{\mathbf{N}}$ and $W_{\mathbf{N}}^*$ may be equipped with the following Hermitian inner products:

$$(\varphi, \psi)_W = \sum_{\mathbf{k}} \overline{\varphi(\mathbf{k})}\psi(\mathbf{k})$$
$$(\Phi, \Psi)_{W^*} = \sum_{\mathbf{k}} \overline{\Phi(\mathbf{k}^*)}\Psi(\mathbf{k}^*),$$

which makes each of them into a *Hilbert space*. The canonical bases $\{\mathbf{u}_{\mathbf{k}} | \mathbf{k} \in \mathbb{Z}^n/\mathbf{N}\mathbb{Z}^n\}$ and $\{\mathbf{v}_{\mathbf{k}^*} | \mathbf{k}^* \in \mathbb{Z}^n/\mathbf{N}^T\mathbb{Z}^n\}$ and $W_{\mathbf{N}}$ and $W_{\mathbf{N}}^*$ are *orthonormal* for their respective product.

1.3.2.7.4. Matrix representation of the discrete Fourier transform (DFT)

By virtue of definitions (i) and (ii),

$$\mathscr{F}(\mathbf{N})\mathbf{v}_{\mathbf{k}^*} = \frac{1}{|\det \mathbf{N}|} \sum_{\mathbf{k}} \exp[-2\pi i \mathbf{k}^* \cdot (\mathbf{N}^{-1}\mathbf{k})]\mathbf{u}_{\mathbf{k}}$$
$$\bar{\mathscr{F}}(\mathbf{N})\mathbf{u}_{\mathbf{k}} = \sum_{\mathbf{k}^*} \exp[+2\pi i \mathbf{k}^* \cdot (\mathbf{N}^{-1}\mathbf{k})]\mathbf{v}_{\mathbf{k}^*}$$

so that $\mathscr{F}(\mathbf{N})$ and $\bar{\mathscr{F}}(\mathbf{N})$ may be represented, in the canonical bases of $W_{\mathbf{N}}$ and $W_{\mathbf{N}}^*$, by the following matrices:

$$[\mathscr{F}(\mathbf{N})]_{\mathbf{k}\mathbf{k}^*} = \frac{1}{|\det \mathbf{N}|} \exp[-2\pi i \mathbf{k}^* \cdot (\mathbf{N}^{-1}\mathbf{k})]$$
$$[\bar{\mathscr{F}}(\mathbf{N})]_{\mathbf{k}^*\mathbf{k}} = \exp[+2\pi i \mathbf{k}^* \cdot (\mathbf{N}^{-1}\mathbf{k})].$$

When $\mathbf{N}$ is symmetric, $\mathbb{Z}^n/\mathbf{N}\mathbb{Z}^n$ and $\mathbb{Z}^n/\mathbf{N}^T\mathbb{Z}^n$ may be identified in a natural manner, and the above matrices are symmetric.

When $\mathbf{N}$ is diagonal, say $\mathbf{N} = \mathrm{diag}(\nu_1, \nu_2, \ldots, \nu_n)$, then the tensor product structure of the full multidimensional Fourier transform (Section 1.3.2.4.2.4)

$$\mathscr{F}_{\mathbf{x}} = \mathscr{F}_{x_1} \otimes \mathscr{F}_{x_2} \otimes \ldots \otimes \mathscr{F}_{x_n}$$

gives rise to a tensor product structure for the DFT matrices. The tensor product of matrices is defined as follows:

$$\mathbf{A} \otimes \mathbf{B} = \begin{pmatrix} a_{11}\mathbf{B} & \ldots & a_{1n}\mathbf{B} \\ \vdots & & \vdots \\ a_{n1}\mathbf{B} & \ldots & a_{nn}\mathbf{B} \end{pmatrix}.$$

Let the index vectors $\mathbf{k}$ and $\mathbf{k}^*$ be ordered in the same way as the elements in a Fortran array, *e.g.* for $\mathbf{k}$ with k_1 increasing fastest, k_2 next fastest, ..., k_n slowest; then

$$\mathscr{F}(\mathbf{N}) = \mathscr{F}(\nu_1) \otimes \mathscr{F}(\nu_2) \otimes \ldots \otimes \mathscr{F}(\nu_n),$$

where

$$[\mathscr{F}(\nu_j)]_{k_j, k_j^*} = \frac{1}{\nu_j} \exp\left(-2\pi i \frac{k_j^* k_j}{\nu_j}\right),$$

and

$$\bar{\mathscr{F}}(\mathbf{N}) = \bar{\mathscr{F}}(\nu_1) \otimes \bar{\mathscr{F}}(\nu_2) \otimes \ldots \otimes \bar{\mathscr{F}}(\nu_n),$$

where

$$[\bar{\mathscr{F}}_{\nu_j}]_{k_j^*, k_j} = \exp\left(+2\pi i \frac{k_j^* k_j}{\nu_j}\right).$$

1.3.2.7.5. Properties of the discrete Fourier transform

The DFT inherits most of the properties of the Fourier transforms, but with certain numerical factors ('Jacobians') due to the transition from continuous to discrete measure.

(1) *Linearity* is obvious.

(2) *Shift property*. If $(\tau_a \psi)(\mathbf{k}) = \psi(\mathbf{k} - \mathbf{a})$ and $(\tau_{a^*}\Psi)(\mathbf{k}^*) = \Psi(\mathbf{k}^* - \mathbf{a}^*)$, where subtraction takes place by modular vector arithmetic in $\mathbb{Z}^n/\mathbf{N}\mathbb{Z}^n$ and $\mathbb{Z}^n/\mathbf{N}^T\mathbb{Z}^n$, respectively, then the following identities hold:

$$\bar{\mathscr{F}}(\mathbf{N})[\tau_{\mathbf{k}}\psi](\mathbf{k}^*) = \exp[+2\pi i \mathbf{k}^* \cdot (\mathbf{N}^{-1}\mathbf{k})]\bar{\mathscr{F}}(\mathbf{N})[\psi](\mathbf{k}^*)$$
$$\mathscr{F}(\mathbf{N})[\tau_{\mathbf{k}^*}\Psi](\mathbf{k}) = \exp[-2\pi i \mathbf{k}^* \cdot (\mathbf{N}^{-1}\mathbf{k})]\mathscr{F}(\mathbf{N})[\Psi](\mathbf{k}).$$

(3) *Differentiation identities*. Let vectors $\boldsymbol{\psi}$ and $\boldsymbol{\Psi}$ be constructed from $\varphi^0 \in \mathscr{E}(\mathbb{R}^n)$ as in Section 1.3.2.7.3, hence be related by the DFT. If $D^{\mathbf{p}}\boldsymbol{\psi}$ designates the vector of sample values of $D_{\mathbf{x}}^{\mathbf{p}}\varphi^0$ at the points of $\Lambda_{\mathbf{B}}/\Lambda_{\mathbf{A}}$, and $D^{\mathbf{p}}\boldsymbol{\Psi}$ the vector of values of $D_{\boldsymbol{\xi}}^{\mathbf{p}}\Phi^0$ at points of $\Lambda_{\mathbf{A}}^*/\Lambda_{\mathbf{B}}^*$, then for all multi-indices $\mathbf{p} = (p_1, p_2, \ldots, p_n)$

$$(D^{\mathbf{p}}\boldsymbol{\psi})(\mathbf{k}) = \bar{\mathscr{F}}(\mathbf{N})[(+2\pi i \mathbf{k}^*)^{\mathbf{p}}\boldsymbol{\Psi}](\mathbf{k})$$
$$(D^{\mathbf{p}}\boldsymbol{\Psi})(\mathbf{k}^*) = \mathscr{F}(\mathbf{N})[(-2\pi i \mathbf{k})^{\mathbf{p}}\boldsymbol{\psi}](\mathbf{k}^*)$$

or equivalently

$$\mathscr{F}(\mathbf{N})[D^{\mathbf{p}}\boldsymbol{\psi}](\mathbf{k}^*) = (+2\pi i \mathbf{k}^*)^{\mathbf{p}}\boldsymbol{\Psi}(\mathbf{k}^*)$$
$$\bar{\mathscr{F}}(\mathbf{N})[D^{\mathbf{p}}\boldsymbol{\Psi}](\mathbf{k}) = (-2\pi i \mathbf{k})^{\mathbf{p}}\boldsymbol{\psi}(\mathbf{k}).$$

(4) *Convolution property*. Let $\boldsymbol{\varphi} \in W_{\mathbf{N}}$ and $\boldsymbol{\Phi} \in W_{\mathbf{N}}^*$ (respectively $\boldsymbol{\psi}$ and $\boldsymbol{\Psi}$) be related by the DFT, and define

$$(\boldsymbol{\varphi} * \boldsymbol{\psi})(\mathbf{k}) = \sum_{\mathbf{k}' \in \mathbb{Z}^n/\mathbf{N}\mathbb{Z}^n} \boldsymbol{\varphi}(\mathbf{k}')\boldsymbol{\psi}(\mathbf{k} - \mathbf{k}')$$
$$(\boldsymbol{\Phi} * \boldsymbol{\Psi})(\mathbf{k}^*) = \sum_{\mathbf{k}^{*'} \in \mathbb{Z}^n/\mathbf{N}^T\mathbb{Z}^n} \boldsymbol{\Phi}(\mathbf{k}^{*'})\boldsymbol{\Psi}(\mathbf{k}^* - \mathbf{k}^{*'}).$$

Then

$$\bar{\mathscr{F}}(\mathbf{N})[\boldsymbol{\Phi} * \boldsymbol{\Psi}](\mathbf{k}) = |\det \mathbf{N}|\boldsymbol{\varphi}(\mathbf{k})\boldsymbol{\psi}(\mathbf{k})$$
$$\mathscr{F}(\mathbf{N})[\boldsymbol{\varphi} * \boldsymbol{\psi}](\mathbf{k}^*) = \boldsymbol{\Phi}(\mathbf{k}^*)\boldsymbol{\Psi}(\mathbf{k}^*)$$

and

$$\bar{\mathscr{F}}(\mathbf{N})[\boldsymbol{\varphi} \times \boldsymbol{\psi}](\mathbf{k}^*) = \frac{1}{|\det \mathbf{N}|}(\boldsymbol{\Phi} * \boldsymbol{\Psi})(\mathbf{k}^*)$$
$$\mathscr{F}(\mathbf{N})[\boldsymbol{\Phi} \times \boldsymbol{\Psi}](\mathbf{k}) = (\boldsymbol{\varphi} * \boldsymbol{\psi})(\mathbf{k}).$$

Since addition on $\mathbb{Z}^n/\mathbf{N}\mathbb{Z}^n$ and $\mathbb{Z}^n/\mathbf{N}^T\mathbb{Z}^n$ is modular, this type of convolution is called *cyclic* convolution.

(5) *Parseval/Plancherel property*. If $\boldsymbol{\varphi}$, $\boldsymbol{\psi}$, $\boldsymbol{\Phi}$, $\boldsymbol{\Psi}$ are as above, then

$$(\mathscr{F}(\mathbf{N})[\boldsymbol{\Phi}], \mathscr{F}(\mathbf{N})[\boldsymbol{\Psi}])_W = \frac{1}{|\det \mathbf{N}|}(\boldsymbol{\Phi}, \boldsymbol{\Psi})_{W^*}$$
$$(\bar{\mathscr{F}}(\mathbf{N})[\boldsymbol{\varphi}], \bar{\mathscr{F}}(\mathbf{N})[\boldsymbol{\psi}])_W = \frac{1}{|\det \mathbf{N}|}(\boldsymbol{\varphi}, \boldsymbol{\psi})_W.$$

(6) *Period* 4. When $\mathbf{N}$ is symmetric, so that the ranges of indices $\mathscr{k}$ and $\mathscr{k}^*$ can be identified, it makes sense to speak of powers of $\mathscr{F}(\mathbf{N})$ and $\bar{\mathscr{F}}(\mathbf{N})$. Then the 'standardized' matrices $(1/|\det \mathbf{N}|^{1/2})\mathscr{F}(\mathbf{N})$ and $(1/|\det \mathbf{N}|^{1/2})\bar{\mathscr{F}}(\mathbf{N})$ are *unitary* matrices whose fourth power is the identity matrix (Section 1.3.2.4.3.4); their eigenvalues are therefore ± 1 and $\pm i$.

1.3.3. Numerical computation of the discrete Fourier transform

1.3.3.1. Introduction

The Fourier transformation's most remarkable property is undoubtedly that of turning convolution into multiplication. As distribution theory has shown, other valuable properties – such as the shift property, the conversion of differentiation into multiplication by monomials, and the duality between periodicity and sampling – are special instances of the convolution theorem.

This property is exploited in many areas of applied mathematics and engineering (Campbell & Foster, 1948; Sneddon, 1951; Champeney, 1973; Bracewell, 1986). For example, the passing of a signal through a linear filter, which results in its being convolved with the response of the filter to a δ-function 'impulse', may be modelled as a multiplication of the signal's transform by the transform of the impulse response (also called transfer function). Similarly, the solution of systems of partial differential equations may be turned by Fourier transformation into a division problem for distributions. In both cases, the formulations obtained after Fourier transformation are considerably simpler than the initial ones, and lend themselves to constructive solution techniques.

Whenever the functions to which the Fourier transform is applied are band-limited, or can be well approximated by band-limited functions, the discrete Fourier transform (DFT) provides a means of constructing explicit numerical solutions to the problems at hand. A great variety of investigations in physics, engineering and applied mathematics thus lead to DFT calculations, to such a degree that, at the time of writing, about 50% of all supercomputer CPU time is alleged to be spent calculating DFTs.

The straightforward use of the defining formulae for the DFT leads to calculations of size N^2 for N sample points, which become unfeasible for any but the smallest problems. Much ingenuity has therefore been exerted on the design and implementation of faster algorithms for calculating the DFT (McClellan & Rader, 1979; Nussbaumer, 1981; Blahut, 1985; Brigham, 1988). The most famous is that of Cooley & Tukey (1965) which heralded the age of digital signal processing. However, it had been preceded by the prime factor algorithm of Good (1958, 1960), which has lately been the basis of many new developments. Recent historical research (Goldstine, 1977, pp. 249–253; Heideman *et al.*, 1984) has shown that Gauss essentially knew the Cooley–Tukey algorithm as early as 1805 (before Fourier's 1807 work on harmonic analysis!); while it has long been clear that Dirichlet knew of the basis of the prime factor algorithm and used it extensively in his theory of multiplicative characters [see *e.g.* Chapter I of Ayoub (1963), and Chapters 6 and 8 of Apostol (1976)]. Thus the computation of the DFT, far from being a purely technical and rather narrow piece of specialized numerical analysis, turns out to have very rich connections with such central areas of pure mathematics as number theory (algebraic and analytic), the representation theory of certain Lie groups and coding theory – to list only a few. The interested reader may consult Auslander & Tolimieri (1979); Auslander, Feig & Winograd (1982, 1984); Auslander & Tolimieri (1985); Tolimieri (1985).

One-dimensional algorithms are examined first. The Sande mixed-radix version of the Cooley–Tukey algorithm only calls upon the additive structure of congruence classes of integers. The prime factor algorithm of Good begins to exploit some of their multiplicative structure, and the use of relatively prime factors leads to a stronger factorization than that of Sande. Fuller use of the multiplicative structure, *via* the group of units, leads to the Rader algorithm; and the factorization of short convolutions then yields the Winograd algorithms.

Multidimensional algorithms are at first built as tensor products of one-dimensional elements. The problem of factoring the DFT in several dimensions simultaneously is then examined. The section ends with a survey of attempts at formalizing the interplay between algorithm structure and computer architecture for the purpose of automating the design of optimal DFT code.

It was originally intended to incorporate into this section a survey of all the basic notions and results of abstract algebra which are called upon in the course of these developments, but time limitations have made this impossible. This material, however, is adequately covered by the first chapter of Tolimieri *et al.* (1989) in a form tailored for the same purposes. Similarly, the inclusion of numerous detailed examples of the algorithms described here has had to be postponed to a later edition, but an abundant supply of such examples may be found in the signal processing literature, for instance in the books by McClellan & Rader (1979), Blahut (1985), and Tolimieri *et al.* (1989).

1.3.3.2. One-dimensional algorithms

Throughout this section we will denote by $e(t)$ the expression $\exp(2\pi i t)$, $t \in \mathbb{R}$. The mapping $t \longmapsto e(t)$ has the following properties:

$$e(t_1 + t_2) = e(t_1)e(t_2)$$
$$e(-t) = \overline{e(t)} = [e(t)]^{-1}$$
$$e(t) = 1 \Leftrightarrow t \in \mathbb{Z}.$$

Thus e defines an isomorphism between the additive group $\mathbb{R}/\mathbb{Z}$ (the reals modulo the integers) and the multiplicative group of complex numbers of modulus 1. It follows that the mapping $\ell \longmapsto e(\ell/N)$, where $\ell \in \mathbb{Z}$ and N is a positive integer, defines an isomorphism between the one-dimensional residual lattice $\mathbb{Z}/N\mathbb{Z}$ and the multiplicative group of Nth roots of unity.

The DFT on N points then relates vectors $\mathbf{X}$ and $\mathbf{X}^*$ in W and W^* through the linear transformations:

$$F(N): \quad X(k) = \frac{1}{N}\sum_{k^* \in \mathbb{Z}/N\mathbb{Z}} X^*(k^*)e(-k^*k/N)$$
$$\bar{F}(N): \quad X^*(k^*) = \sum_{k \in \mathbb{Z}/N\mathbb{Z}} X(k)e(k^*k/N).$$

1.3.3.2.1. The Cooley–Tukey algorithm

The presentation of Gentleman & Sande (1966) will be followed first [see also Cochran *et al.* (1967)]. It will then be reinterpreted in geometric terms which will prepare the way for the treatment of multidimensional transforms in Section 1.3.3.3.

Suppose that the number of sample points N is composite, say $N = N_1N_2$. We may write k to the base N_1 and k^* to the base N_2 as follows:

$$k = k_1 + N_1 k_2 \quad k_1 \in \mathbb{Z}/N_1\mathbb{Z}, \quad k_2 \in \mathbb{Z}/N_2\mathbb{Z}$$
$$k^* = k_2^* + k_1^* N_2 \quad k_1^* \in \mathbb{Z}/N_1\mathbb{Z}, \quad k_2^* \in \mathbb{Z}/N_2\mathbb{Z}.$$

The defining relation for $\bar{F}(N)$ may then be written:

$$X^*(k_2^* + k_1^* N_2) = \sum_{k_1 \in \mathbb{Z}/N_1\mathbb{Z}} \sum_{k_2 \in \mathbb{Z}/N_2\mathbb{Z}} X(k_1 + N_1 k_2) \times e\left[\frac{(k_2^* + k_1^* N_2)(k_1 + N_1 k_2)}{N_1 N_2}\right].$$

The argument of $e[.]$ may be expanded as

$$\frac{k_2^* k_1}{N} + \frac{k_1^* k_1}{N_1} + \frac{k_2^* k_2}{N_2} + k_1^* k_2,$$

and the last summand, being an integer, may be dropped:

$$X^*(k_2^* + k_1^* N_2) = \sum_{k_1} \left\{ e\left(\frac{k_2^* k_1}{N}\right) \left[\sum_{k_2} X(k_1 + N_1 k_2) e\left(\frac{k_2^* k_2}{N_2}\right) \right] \right\} \times e\left(\frac{k_1^* k_1}{N_1}\right).$$

This computation may be decomposed into five stages, as follows:

(i) form the N_1 vectors $\mathbf{Y}_{k_1}$ of length N_2 by the prescription

$$Y_{k_1}(k_2) = X(k_1 + N_1 k_2), \quad k_1 \in \mathbb{Z}/N_1\mathbb{Z}, \quad k_2 \in \mathbb{Z}/N_2\mathbb{Z};$$

(ii) calculate the N_1 transforms $\mathbf{Y}_{k_1}^*$ on N_2 points:

$$\mathbf{Y}_{k_1}^* = \bar{F}(N_2)[\mathbf{Y}_{k_1}], \quad k_1 \in \mathbb{Z}/N_1\mathbb{Z};$$

(iii) form the N_2 vectors $\mathbf{Z}_{k_2^*}$ of length N_1 by the prescription

$$\mathbf{Z}_{k_2^*}(k_1) = e\left(\frac{k_2^* k_1}{N}\right) Y_{k_1}^*(k_2^*), \quad k_1 \in \mathbb{Z}/N_1\mathbb{Z}, \quad k_2^* \in \mathbb{Z}/N_2\mathbb{Z};$$

(iv) calculate the N_2 transforms $\mathbf{Z}_{k_2^*}^*$ on N_1 points:

$$\mathbf{Z}_{k_2^*}^* = \bar{F}(N_1)[\mathbf{Z}_{k_2^*}], \quad k_2^* \in \mathbb{Z}/N_2\mathbb{Z};$$

(v) collect $X^*(k_2^* + k_1^* N_2)$ as $Z_{k_2^*}^*(k_1^*)$.

If the intermediate transforms in stages (ii) and (iv) are performed *in place*, *i.e.* with the results overwriting the data, then at stage (v) the result $X^*(k_2^* + k_1^* N_2)$ will be found at address $k_1^* + N_1 k_2^*$. This phenomenon is called *scrambling* by 'digit reversal', and stage (v) is accordingly known as *unscrambling*.

The initial *N-point* transform $\bar{F}(N)$ has thus been performed as N_1 transforms $\bar{F}(N_2)$ on N_2 points, followed by N_2 transforms $\bar{F}(N_1)$ on N_1 points, thereby reducing the arithmetic cost from $(N_1 N_2)^2$ to $N_1 N_2 (N_1 + N_2)$. The phase shifts applied at stage (iii) are traditionally called 'twiddle factors', and the transposition between k_1 and k_2^* can be performed by the fast recursive technique of Eklundh (1972). Clearly, this procedure can be applied recursively if N_1 and N_2 are themselves composite, leading to an overall arithmetic cost of order $N \log N$ if N has no large prime factors.

The Cooley–Tukey factorization may also be derived from a geometric rather than arithmetic argument. The decomposition $k = k_1 + N_1 k_2$ is associated to a geometric partition of the residual lattice $\mathbb{Z}/N\mathbb{Z}$ into N_1 copies of $\mathbb{Z}/N_2\mathbb{Z}$, each translated by $k_1 \in \mathbb{Z}/N_1\mathbb{Z}$ and 'blown up' by a factor N_1. This partition in turn induces a (direct sum) decomposition of $\mathbf{X}$ as

$$\mathbf{X} = \sum_{k_1} \mathbf{X}_{k_1},$$

where

$$X_{k_1}(k) = X(k) \quad \text{if } k \equiv k_1 \bmod N_1,$$
$$= 0 \qquad \text{otherwise.}$$

According to (i), $\mathbf{X}_{k_1}$ is related to $\mathbf{Y}_{k_1}$ by *decimation by* N_1 and *offset by* k_1. By Section 1.3.2.7.2, $\bar{F}(N)[\mathbf{X}_{k_1}]$ is related to $\bar{F}(N_2)[\mathbf{Y}_{k_1}]$ by *periodization by* N_2 and *phase shift by* $e(k^* k_1/N)$, so that

$$X^*(k^*) = \sum_{k_1} e\left(\frac{k^* k_1}{N}\right) Y_{k_1}^*(k_2^*),$$

the periodization by N_2 being reflected by the fact that $Y_{k_1}^*$ does not depend on k_1^*. Writing $k^* = k_2^* + k_1^* N_2$ and expanding $k^* k_1$ shows that the phase shift contains both the twiddle factor $e(k_2^* k_1/N)$ and the kernel $e(k_1^* k_1/N_1)$ of $\bar{F}(N_1)$. The Cooley–Tukey algorithm is thus naturally associated to the coset decomposition of a lattice modulo a sublattice (Section 1.3.2.7.2).

It is readily seen that essentially the same factorization can be obtained for $F(N)$, up to the complex conjugation of the twiddle factors. The normalizing constant $1/N$ arises from the normalizing constants $1/N_1$ and $1/N_2$ in $F(N_1)$ and $F(N_2)$, respectively.

Factors of 2 are particularly simple to deal with and give rise to a characteristic computational structure called a 'butterfly loop'. If $N = 2M$, then two options exist:

(*a*) using $N_1 = 2$ and $N_2 = M$ leads to collecting the even-numbered coordinates of $\mathbf{X}$ into $\mathbf{Y}_0$ and the odd-numbered coordinates into $\mathbf{Y}_1$

$$Y_0(k_2) = X(2k_2), \qquad k_2 = 0, \ldots, M-1,$$
$$Y_1(k_2) = X(2k_2 + 1), \quad k_2 = 0, \ldots, M-1,$$

and writing:

$$X^*(k_2^*) = Y_0^*(k_2^*) + e(k_2^*/N) Y_1^*(k_2^*), \quad k_2^* = 0, \ldots, M-1;$$
$$X^*(k_2^* + M) = Y_0^*(k_2^*) - e(k_2^*/N) Y_1^*(k_2^*), \quad k_2^* = 0, \ldots, M-1.$$

This is the original version of Cooley & Tukey, and the process of formation of $\mathbf{Y}_0$ and $\mathbf{Y}_1$ is referred to as 'decimation in time' (*i.e.* decimation along the *data* index $\mathbf{k}$).

(*b*) using $N_1 = M$ and $N_2 = 2$ leads to forming

$$Z_0(k_1) = X(k_1) + X(k_1 + M), \qquad k_1 = 0, \ldots, M-1,$$
$$Z_1(k_1) = [X(k_1) - X(k_1 + M)] e\left(\frac{k_1}{N}\right), \qquad k_1 = 0, \ldots, M-1,$$

then obtaining separately the even-numbered and odd-numbered components of $\mathbf{X}^*$ by transforming $\mathbf{Z}_0$ and $\mathbf{Z}_1$:

$$X^*(2k_1^*) = Z_0^*(k_1^*), \quad k_1^* = 0, \ldots, M-1;$$
$$X^*(2k_1^*+1) = Z_1^*(k_1^*), \quad k_1^* = 0, \ldots, M-1.$$

This version is due to Sande (Gentleman & Sande, 1966), and the process of separately obtaining even-numbered and odd-numbered results has led to its being referred to as 'decimation in frequency' (*i.e.* decimation along the *result* index k^*).

By repeated factoring of the number N of sample points, the calculation of $F(N)$ and $\bar{F}(N)$ can be reduced to a succession of stages, the smallest of which operate on single prime factors of N. The reader is referred to Gentleman & Sande (1966) for a particularly lucid analysis of the programming considerations which help implement this factorization efficiently; see also Singleton (1969). Powers of two are often grouped together into factors of 4 or 8, which are advantageous in that they require fewer complex multiplications than the repeated use of factors of 2. In this approach, large prime factors P are detrimental, since they require a full P^2-size computation according to the defining formula.

1.3.3.2.2. The Good (or prime factor) algorithm

1.3.3.2.2.1. Ring structure on $\mathbb{Z}/N\mathbb{Z}$

The set $\mathbb{Z}/N\mathbb{Z}$ of congruence classes of integers modulo an integer N [see *e.g.* Apostol (1976), Chapter 5] inherits from $\mathbb{Z}$ not only the additive structure used in deriving the Cooley–Tukey factorization, but also a *multiplicative* structure in which the product of two congruence classes mod N is uniquely defined as the class of the ordinary product (in $\mathbb{Z}$) of representatives of each class. The multiplication can be distributed over addition in the usual way, endowing $\mathbb{Z}/N\mathbb{Z}$ with the structure of a *commutative ring*.

If N is composite, the ring $\mathbb{Z}/N\mathbb{Z}$ has *zero divisors*. For example, let $N = N_1N_2$, let $n_1 \equiv N_1 \bmod N$, and let $n_2 \equiv N_2 \bmod N$: then $n_1n_2 \equiv 0 \bmod N$. In the general case, a product of nonzero elements will be zero whenever these elements collect together all the factors of N. These circumstances give rise to a fundamental theorem in the theory of commutative rings, the *Chinese Remainder Theorem* (CRT), which will now be stated and proved [see Apostol (1976), Chapter 5; Schroeder (1986), Chapter 16].

1.3.3.2.2.2. The Chinese remainder theorem

Let $N = N_1N_2 \ldots N_d$ be factored into a product of pairwise coprime integers, so that g.c.d. $(N_i, N_j) = 1$ for $i \neq j$. Then the system of congruence equations

$$\ell \equiv \ell_j \bmod N_j, \qquad j = 1, \ldots, d,$$

has a unique solution $\ell \bmod N$. In other words, each $\ell \in \mathbb{Z}/N\mathbb{Z}$ is associated in a one-to-one fashion to the d-tuple $(\ell_1, \ell_2, \ldots, \ell_d)$ of its residue classes in $\mathbb{Z}/N_1\mathbb{Z}, \mathbb{Z}/N_2\mathbb{Z}, \ldots, \mathbb{Z}/N_d\mathbb{Z}$.

The proof of the CRT goes as follows. Let

$$Q_j = \frac{N}{N_j} = \prod_{i \neq j} N_i.$$

Since g.c.d. $(N_j, Q_j) = 1$ there exist integers n_j and q_j such that

$$n_jN_j + q_jQ_j = 1, \qquad j = 1, \ldots, d,$$

then the integer

$$\ell = \sum_{i=1}^{d} \ell_i q_i Q_i \bmod N$$

is the solution. Indeed,

$$\ell \equiv \ell_j q_j Q_j \bmod N_j$$

because all terms with $i \neq j$ contain N_j as a factor; and

$$q_jQ_j \equiv 1 \bmod N_j$$

by the defining relation for q_j.

It may be noted that

$$(q_iQ_i)(q_jQ_j) \equiv 0 \qquad \bmod N \text{ for } i \neq j,$$
$$(q_jQ_j)^2 \equiv q_jQ_j \qquad \bmod N, \ j = 1, \ldots, d,$$

so that the q_jQ_j are mutually orthogonal *idempotents* in the ring $\mathbb{Z}/N\mathbb{Z}$, with properties formally similar to those of mutually orthogonal *projectors onto subspaces* in linear algebra. The analogy is exact, since by virtue of the CRT the ring $\mathbb{Z}/N\mathbb{Z}$ may be considered as the direct product

$$\mathbb{Z}/N_1\mathbb{Z} \times \mathbb{Z}/N_2\mathbb{Z} \times \ldots \times \mathbb{Z}/N_d\mathbb{Z}$$

via the two mutually inverse mappings:

(i) $\ell \longmapsto (\ell_1, \ell_2, \ldots, \ell_d)$ by $\ell \equiv \ell_j \bmod N_j$ for each j;

(ii) $(\ell_1, \ell_2, \ldots, \ell_d) \longmapsto \ell$ by $\ell = \sum_{i=1}^{d} \ell_i q_i Q_i \bmod N$.

The mapping defined by (ii) is sometimes called the 'CRT reconstruction' of ℓ from the ℓ_j.

These two mappings have the property of sending sums to sums and products to products, *i.e*:

(i) $\ell + \ell' \longmapsto (\ell_1 + \ell_1', \ell_2 + \ell_2', \ldots, \ell_d + \ell_d')$
$\ell\ell' \longmapsto (\ell_1\ell_1', \ell_2\ell_2', \ldots, \ell_d\ell_d')$

(ii) $(\ell_1 + \ell_1', \ell_2 + \ell_2', \ldots, \ell_d + \ell_d') \longmapsto \ell + \ell'$
$(\ell_1\ell_1', \ell_2\ell_2', \ldots, \ell_d\ell_d') \longmapsto \ell\ell'$

(the last proof requires using the properties of the idempotents q_jQ_j). This may be described formally by stating that the CRT establishes a *ring isomorphism*:

$$\mathbb{Z}/N\mathbb{Z} \cong (\mathbb{Z}/N_1\mathbb{Z}) \times \ldots \times (\mathbb{Z}/N_d\mathbb{Z}).$$

1.3.3.2.2.3. The prime factor algorithm

The CRT will now be used to factor the N-point DFT into a tensor product of d transforms, the jth of length N_j.

Let the indices k and k^* be subjected to the following mappings:

(i) $k \longmapsto (k_1, k_2, \ldots, k_d)$, $k_j \in \mathbb{Z}/N_j\mathbb{Z}$, by $k_j \equiv k \bmod N_j$ for each j, with reconstruction formula

$$k = \sum_{i=1}^{d} k_i q_i Q_i \bmod N;$$

(ii) $k^* \longmapsto (k_1^*, k_2^*, \ldots, k_d^*)$, $k_j^* \in \mathbb{Z}/N_j\mathbb{Z}$, by $k_j^* \equiv q_jk^* \bmod N_j$ for each j, with reconstruction formula

$$k^* = \sum_{i=1}^{d} k_i^* Q_i \bmod N.$$

Then

$$k^*k = \left(\sum_{i=1}^{d} k_i^* Q_i\right)\left(\sum_{j=1}^{d} k_j q_j Q_j\right) \bmod N$$
$$= \sum_{i,j=1}^{d} k_i^* k_j Q_i q_j Q_j \bmod N.$$

Cross terms with $i \neq j$ vanish since they contain all the factors of N, hence

$$k^*k = \sum_{j=1}^{d} q_j Q_j^2 k_j^* k_j \bmod N$$
$$= \sum_{j=1}^{d} (1 - n_j N_j) Q_j k_j^* k_j \bmod N.$$

Dividing by N, which may be written as $N_j Q_j$ for each j, yields

$$\frac{k^*k}{N} = \sum_{j=1}^{d} (1 - n_j N_j) \frac{Q_j}{N_j Q_j} k_j^* k_j \bmod 1$$
$$= \sum_{j=1}^{d} \left(\frac{1}{N_j} - n_j\right) k_j^* k_j \bmod 1,$$

and hence

$$\frac{k^*k}{N} \equiv \sum_{j=1}^{d} \frac{k_j^* k_j}{N_j} \bmod 1.$$

Therefore, by the multiplicative property of $e(.)$,

$$e\left(\frac{k^*k}{N}\right) \equiv \bigotimes_{j=1}^{d} e\left(\frac{k_j^* k_j}{N_j}\right).$$

Let $\mathbf{X} \in L(\mathbb{Z}/N\mathbb{Z})$ be described by a one-dimensional array $X(k)$ indexed by k. The index mapping (i) turns $\mathbf{X}$ into an element of $L(\mathbb{Z}/N_1\mathbb{Z} \times \ldots \times \mathbb{Z}/N_d\mathbb{Z})$ described by a d-dimensional array $X(k_1, \ldots, k_d)$; the latter may be transformed by $\bar{F}(N_1) \bigotimes \ldots \bigotimes \bar{F}(N_d)$ into a new array $X^*(k_1^*, k_2^*, \ldots, k_d^*)$. Finally, the one-dimensional array of results $X^*(k^*)$ will be obtained by reconstructing k^* according to (ii).

The prime factor algorithm, like the Cooley–Tukey algorithm, reindexes a 1D transform to turn it into d separate transforms, but the use of coprime factors and CRT index mapping leads to the further gain that *no twiddle factors* need to be applied between the successive transforms (see Good, 1971). This makes up for the cost of the added complexity of the CRT index mapping.

The natural factorization of N for the prime factor algorithm is thus its factorization into prime powers: $\bar{F}(N)$ is then the tensor product of separate transforms (one for each prime power factor $N_j = p_j^{v_j}$) whose results can be reassembled without twiddle factors. The separate factors p_j within each N_j must then be dealt with by another algorithm (*e.g.* Cooley–Tukey, which does require twiddle factors). Thus, the DFT on a prime number of points remains undecomposable.

1.3.3.2.3. The Rader algorithm

The previous two algorithms essentially reduce the calculation of the DFT on N points for N composite to the calculation of smaller DFTs on prime numbers of points, the latter remaining irreducible. However, Rader (1968) showed that the p-point DFT for p an odd prime can itself be factored by invoking some extra arithmetic structure present in $\mathbb{Z}/p\mathbb{Z}$.

1.3.3.2.3.1. N an odd prime

The ring $\mathbb{Z}/p\mathbb{Z} = \{0, 1, 2, \ldots, p-1\}$ has the property that its $p-1$ nonzero elements, called *units*, form a *multiplicative group* $U(p)$. In particular, all units $r \in U(p)$ have a unique multiplicative inverse in $\mathbb{Z}/p\mathbb{Z}$, *i.e.* a unit $s \in U(p)$ such that $rs \equiv 1 \bmod p$. This endows $\mathbb{Z}/p\mathbb{Z}$ with the structure of a *finite field*.

Furthermore, $U(p)$ is a *cyclic* group, *i.e.* consists of the successive powers $g^m \bmod p$ of a generator g called a *primitive root mod p* (such a g may not be unique, but it always exists). For instance, for $p = 7$, $U(7) = \{1, 2, 3, 4, 5, 6\}$ is generated by $g = 3$, whose successive powers mod 7 are:

$$g^0 = 1, \quad g^1 = 3, \quad g^2 = 2, \quad g^3 = 6, \quad g^4 = 4, \quad g^5 = 5$$

[see Apostol (1976), Chapter 10].

The basis of Rader's algorithm is to bring to light a hidden regularity in the matrix $F(p)$ by permuting the basis vectors $\mathbf{u}_k$ and $\mathbf{v}_{k^*}$ of $L(\mathbb{Z}/p\mathbb{Z})$ as follows:

$$\begin{aligned}
\mathbf{u}'_0 &= \mathbf{u}_0 \\
\mathbf{u}'_m &= \mathbf{u}_k \quad \text{with } k = g^m, \qquad m = 1, \ldots, p-1; \\
\mathbf{v}'_0 &= \mathbf{v}_0 \\
\mathbf{v}'_{m^*} &= \mathbf{v}_{k^*} \quad \text{with } k^* = g^{m^*}, \quad m^* = 1, \ldots, p-1;
\end{aligned}$$

where g is a primitive root mod p.

With respect to these new bases, the matrix representing $\bar{F}(p)$ will have the following elements:

$$\begin{aligned}
\text{element } (0,0) &= 1 \\
\text{element } (0, m+1) &= 1 \quad \text{for all } m = 0, \ldots p-2, \\
\text{element } (m^*+1, 0) &= 1 \quad \text{for all } m^* = 0, \ldots, p-2, \\
\text{element } (m^*+1, m+1) &= e\left(\frac{k^*k}{p}\right) \\
&= e(g^{(m^*+m)/p}) \\
&\qquad \text{for all } m^* = 0, \ldots, p-2.
\end{aligned}$$

Thus the 'core' $\bar{C}(p)$ of matrix $\bar{F}(p)$, of size $(p-1) \times (p-1)$, formed by the elements with two nonzero indices, has a so-called *skew-circulant* structure because element (m^*, m) depends only on $m^* + m$. Simplification may now occur because multiplication by $\bar{C}(p)$ is closely related to a *cyclic convolution*. Introducing the notation $C(m) = e(g^{m/p})$ we may write the relation $\mathbf{Y}^* = \bar{F}(p)\mathbf{Y}$ in the permuted bases as

$$Y^*(0) = \sum_k Y(k)$$

$$\begin{aligned} Y^*(m^*+1) &= Y(0) + \sum_{m=0}^{p-2} C(m^*+m)Y(m+1) \\ &= Y(0) + \sum_{m=0}^{p-2} C(m^*-m)Z(m) \\ &= Y(0) + (\mathbf{C} * \mathbf{Z})(m^*), \quad m^* = 0, \ldots, p-2, \end{aligned}$$

where $\mathbf{Z}$ is defined by $Z(m) = Y(p-m-2)$, $m = 0, \ldots, p-2$.

Thus $\mathbf{Y}^*$ may be obtained by cyclic convolution of $\mathbf{C}$ and $\mathbf{Z}$, which may for instance be calculated by

$$\mathbf{C} * \mathbf{Z} = F(p-1)[\bar{F}(p-1)[\mathbf{C}] \times \bar{F}(p-1)[\mathbf{Z}]],$$

where $\times$ denotes the component-wise multiplication of vectors. Since p is odd, $p-1$ is always divisible by 2 and may even be highly composite. In that case, factoring $\bar{F}(p-1)$ by means of the Cooley–Tukey or Good methods leads to an algorithm of complexity $p \log p$ rather than p^2 for $\bar{F}(p)$. An added bonus is that, because $g^{(p-1)/2} = -1$, the elements of $\bar{F}(p-1)[\mathbf{C}]$ can be shown to be either purely real or purely imaginary, which halves the number of real multiplications involved.

1.3.3.2.3.2. N a power of an odd prime

This idea was extended by Winograd (1976, 1978) to the treatment of prime powers $N = p^\nu$, using the cyclic structure of the multiplicative group of units $U(p^\nu)$. The latter consists of all those elements of $\mathbb{Z}/p^\nu\mathbb{Z}$ which are not divisible by p, and thus has $q_\nu = p^{\nu-1}(p-1)$ elements. It is cyclic, and there exist primitive roots g modulo p^ν such that

$$U(p^\nu) = \{1, g, g^2, g^3, \ldots, g^{q_\nu - 1}\}.$$

The $p^{\nu-1}$ elements divisible by p, which are divisors of zero, have to be treated separately just as 0 had to be treated separately for $N = p$.

When $k^* \notin U(p^\nu)$, then $k^* = pk_1^*$ with $k_1^* \in \mathbb{Z}/p^{\nu-1}\mathbb{Z}$. The results $X^*(pk_1^*)$ are p-decimated, hence can be obtained *via* the $p^{\nu-1}$-point DFT of the $p^{\nu-1}$-periodized data $\mathbf{Y}$:

$$X^*(pk_1^*) = \bar{F}(p^{\nu-1})[\mathbf{Y}](k_1^*)$$

with

$$Y(k_1) = \sum_{k_2 \in \mathbb{Z}/p\mathbb{Z}} X(k_1 + p^{\nu-1}k_2).$$

When $k^* \in U(p^\nu)$, then we may write

$$X^*(k^*) = X_0^*(k^*) + X_1^*(k^*),$$

where $\mathbf{X}_0^*$ contains the contributions from $k \notin U(p^\nu)$ and $\mathbf{X}_1^*$ those from $k \in U(p^\nu)$. By a converse of the previous calculation, $\mathbf{X}_0^*$ arises from p-decimated data $\mathbf{Z}$, hence is the $p^{\nu-1}$-periodization of the $p^{\nu-1}$-point DFT of these data:

$$X_0^*(p^{\nu-1}k_1^* + k_2^*) = \bar{F}(p^{\nu-1})[\mathbf{Z}](k_2^*)$$

with

$$Z(k_2) = X(pk_2), \qquad k_2 \in \mathbb{Z}/p^{\nu-1}\mathbb{Z}$$

(the $p^{\nu-1}$-periodicity follows implicit from the fact that the transform on the right-hand side is independent of $k_1^* \in \mathbb{Z}/p\mathbb{Z}$).

Finally, the contribution X_1^* from all $k \in U(p^\nu)$ may be calculated by reindexing by the powers of a primitive root g modulo p^ν, *i.e.* by writing

$$X_1^*(g^{m^*}) = \sum_{m=0}^{q_\nu - 1} X(g^m) e(g^{(m^*+m)/p^\nu})$$

then carrying out the multiplication by the skew-circulant matrix core as a convolution.

Thus the DFT of size p^ν may be reduced to two DFTs of size $p^{\nu-1}$ (dealing, respectively, with p-decimated results and p-decimated data) and a convolution of size $q_\nu = p^{\nu-1}(p-1)$. The latter may be 'diagonalized' into a multiplication by purely real or purely imaginary numbers (because $g^{(q_\nu/2)} = -1$) by two DFTs, whose factoring in turn leads to DFTs of size $p^{\nu-1}$ and $p-1$. This method, applied recursively, allows the complete decomposition of the DFT on p^ν points into arbitrarily small DFTs.

1.3.3.2.3.3. N a power of 2

When $N = 2^\nu$, the same method can be applied, except for a slight modification in the calculation of $\mathbf{X}_1^*$. There is no primitive root modulo 2^ν for $\nu > 2$: the group $U(2^\nu)$ is the direct product of *two* cyclic groups, the first (of order 2) generated by -1, the second (of order $N/4$) generated by 3 or 5. One then uses a representation

$$\begin{aligned} k &= (-1)^{m_1} 5^{m_2} \\ k^* &= (-1)^{m_1^*} 5^{m_2^*} \end{aligned}$$

and the reindexed core matrix gives rise to a two-dimensional convolution. The latter may be carried out by means of two 2D DFTs on $2 \times (N/4)$ points.

1.3.3.2.4. The Winograd algorithms

The cyclic convolutions generated by Rader's multiplicative reindexing may be evaluated more economically than through DFTs if they are re-examined within a new algebraic setting, namely the theory of congruence classes of polynomials [see, for instance, Blahut (1985), Chapter 2; Schroeder (1986), Chapter 24].

The set, denoted $\mathbb{K}[X]$, of polynomials in one variable with coefficients in a given field $\mathbb{K}$ has many of the formal properties of the set $\mathbb{Z}$ of rational integers: it is a *ring* with no zero divisors and has a *Euclidean algorithm* on which a theory of divisibility can be built.

Given a polynomial $P(z)$, then for every $W(z)$ there exist unique polynomials $Q(z)$ and $R(z)$ such that

$$W(z) = P(z)Q(z) + R(z)$$

and

$$\text{degree } (R) < \text{degree } (P).$$

$R(z)$ is called the *residue* of $H(z)$ modulo $P(z)$. Two polynomials $H_1(z)$ and $H_2(z)$ having the same residue modulo $P(z)$ are said to be *congruent* modulo $P(z)$, which is denoted by

$$H_1(z) \equiv H_2(z) \bmod P(z).$$

If $H(z) \equiv 0 \bmod P(z)$, $H(z)$ is said to be *divisible* by $P(z)$. If $H(z)$ only has divisors of degree zero in $\mathbb{K}[X]$, it is said to be *irreducible over* $\mathbb{K}$ (this notion depends on $\mathbb{K}$). Irreducible polynomials play in $\mathbb{K}[X]$ a role analogous to that of prime numbers in $\mathbb{Z}$, and any polynomial over $\mathbb{K}$ has an essentially unique factorization as a product of irreducible polynomials.

There exists a *Chinese remainder theorem* (CRT) for polynomials. Let $P(z) = P_1(z) \ldots P_d(z)$ be factored into a product of pairwise coprime polynomials [*i.e.* $P_i(z)$ and $P_j(z)$ have no common factor for $i \neq j$]. Then the system of congruence equations

$$H(z) \equiv H_j(z) \bmod P_j(z), \quad j = 1, \ldots, d,$$

has a unique solution $H(z)$ modulo $P(z)$. This solution may be constructed by a procedure similar to that used for integers. Let

$$Q_j(z) = P(z)/P_j(z) = \prod_{i \neq j} P_i(z).$$

Then P_j and Q_j are coprime, and the Euclidean algorithm may be used to obtain polynomials $p_j(z)$ and $q_j(z)$ such that

$$p_j(z)P_j(z) + q_j(z)Q_j(z) = 1.$$

With $S_i(z) = q_i(z)Q_i(z)$, the polynomial

$$H(z) = \sum_{i=1}^{d} S_i(z)H_i(z) \bmod P(z)$$

is easily shown to be the desired solution.

As with integers, it can be shown that the 1:1 correspondence between $H(z)$ and $H_j(z)$ sends sums to sums and products to products, *i.e.* establishes a *ring isomorphism*:

$$\mathbb{K}[X] \bmod P \cong (\mathbb{K}[X] \bmod P_1) \times \ldots \times (\mathbb{K}[X] \bmod P_d).$$

These results will now be applied to the efficient calculation of cyclic convolutions. Let $\mathbf{U} = (u_0, u_1, \ldots, u_{N-1})$ and $\mathbf{V} = (v_0, v_1, \ldots, v_{N-1})$ be two vectors of length N, and let $\mathbf{W} = (w_0, w_1, \ldots, w_{N-1})$ be obtained by cyclic convolution of $\mathbf{U}$ and $\mathbf{V}$:

$$w_n = \sum_{m=0}^{N-1} u_m v_{n-m}, \quad n = 0, \ldots, N-1.$$

The very simple but crucial result is that this cyclic convolution may be carried out by *polynomial multiplication modulo* $(z^N - 1)$: if

$$U(z) = \sum_{l=0}^{N-1} u_l z^l$$
$$V(z) = \sum_{m=0}^{N-1} v_m z^m$$
$$W(z) = \sum_{n=0}^{N-1} w_n z^n$$

then the above relation is equivalent to

$$W(z) \equiv U(z)V(z) \bmod (z^N - 1).$$

Now the polynomial $z^N - 1$ can be *factored* over the field of rational numbers into irreducible factors called *cyclotomic polynomials*: if d is the number of divisors of N, including 1 and N, then

$$z^N - 1 = \prod_{i=1}^{d} P_i(z),$$

where the cyclotomics $P_i(z)$ are well known (Nussbaumer, 1981; Schroeder, 1986, Chapter 22). We may now invoke the CRT, and exploit the ring isomorphism it establishes to simplify the calculation of $W(z)$ from $U(z)$ and $V(z)$ as follows:

(i) compute the d residual polynomials

$$U_i(z) \equiv U(z) \bmod P_i(z), \quad i = 1, \ldots, d,$$
$$V_i(z) \equiv V(z) \bmod P_i(z), \quad i = 1, \ldots, d;$$

(ii) compute the d polynomial products

$$W_i(z) \equiv U_i(z)V_i(z) \bmod P_i(z), \quad i = 1, \ldots, d;$$

(iii) use the CRT reconstruction formula just proved to recover $W(z)$ from the $W_i(z)$:

$$W(z) \equiv \sum_{i=1}^{d} S_i(z)W_i(z) \bmod (z^N - 1).$$

When N is not too large, *i.e.* for 'short cyclic convolutions', the $P_i(z)$ are very simple, with coefficients 0 or ± 1, so that (i) only involves a small number of additions. Furthermore, special techniques have been developed to multiply general polynomials modulo cyclotomic polynomials, thus helping keep the number of multiplications in (ii) and (iii) to a minimum. As a result, cyclic convolutions can be calculated rapidly when N is sufficiently composite.

It will be recalled that Rader's multiplicative indexing often gives rise to cyclic convolutions of length $p - 1$ for p an odd prime. Since $p - 1$ is highly composite for all $p \leq 50$ other than 23 and 47, these cyclic convolutions can be performed more efficiently by the above procedure than by DFT.

These combined algorithms are due to Winograd (1977, 1978, 1980), and are known collectively as 'Winograd small FFT algorithms'. Winograd also showed that they can be thought of as bringing the DFT matrix $\mathbf{F}$ to the following 'normal form':

$$\mathbf{F} = \mathbf{CBA},$$

where

$\mathbf{A}$ is an integer matrix with entries 0, ± 1, defining the 'pre-additions',

$\mathbf{B}$ is a diagonal matrix of multiplications,

$\mathbf{C}$ is a matrix with entries 0, ± 1, $\pm i$, defining the 'post-additions'.

The elements on the diagonal of $\mathbf{B}$ can be shown to be either real or pure imaginary, by the same argument as in Section 1.3.3.2.3.1. Matrices $\mathbf{A}$ and $\mathbf{C}$ may be rectangular rather than square, so that intermediate results may require extra storage space.

1.3.3.3. Multidimensional algorithms

From an algorithmic point of view, the distinction between one-dimensional (1D) and multidimensional DFTs is somewhat blurred by the fact that some factoring techniques turn a 1D transform into a multidimensional one. The distinction made here, however, is a practical one and is based on the dimensionality of the indexing sets for data and results. This section will therefore be concerned with the problem of factoring the DFT when the *indexing sets* for the input data and output results are multidimensional.

1.3.3.3.1. The method of successive one-dimensional transforms

The DFT was defined in Section 1.3.2.7.4 in an n-dimensional setting and it was shown that when the decimation matrix $\mathbf{N}$ is diagonal, say $\mathbf{N} = \mathrm{diag}(N^{(1)}, N^{(2)}, \ldots, N^{(n)})$, then $\bar{F}(N)$ has a tensor product structure:

$$\bar{F}(\mathbf{N}) = \bar{F}(N^{(1)}) \otimes \bar{F}(N^{(2)}) \otimes \ldots \otimes \bar{F}(N^{(n)}).$$

This may be rewritten as follows:

$$\begin{aligned}\bar{F}(\mathbf{N}) = {} & [\bar{F}(N^{(1)}) \otimes I_{N^{(2)}} \otimes \ldots \otimes I_{N^{(n)}}] \\ & \times [I_{N^{(1)}} \otimes \bar{F}(N^{(2)}) \otimes \ldots \otimes I_{N^{(n)}}] \\ & \times \ldots \\ & \times [I_{N^{(1)}} \otimes I_{N^{(2)}} \otimes \ldots \otimes \bar{F}(N^{(n)}],\end{aligned}$$

where the I's are identity matrices and $\times$ denotes ordinary matrix multiplication. The matrix within each bracket represents a one-dimensional DFT along one of the n dimensions, the other dimensions being left untransformed. As these matrices commute, the order in which the successive 1D DFTs are performed is immaterial.

This is the most straightforward method for building an n-dimensional algorithm from existing 1D algorithms. It is known in crystallography under the name of 'Beevers–Lipson factorization' (Section 1.3.4.3.1), and in signal processing as the 'row–column method'.

1.3.3.3.2. Multidimensional factorization

Substantial reductions in the arithmetic cost, as well as gains in flexibility, can be obtained if the factoring of the DFT is carried out in several dimensions simultaneously. The presentation given here is a generalization of that of Mersereau & Speake (1981), using the abstract setting established independently by Auslander, Tolimieri & Winograd (1982).

Let us return to the general n-dimensional setting of Section 1.3.2.7.4, where the DFT was defined for an arbitrary decimation matrix $\mathbf{N}$ by the formulae (where $|\mathbf{N}|$ denotes $|\det \mathbf{N}|$):

$$\begin{aligned} F(\mathbf{N}): \quad X(\mathbf{k}) &= \frac{1}{|\mathbf{N}|} \sum_{\mathbf{k}^*} X^*(\mathbf{k}^*) e[-\mathbf{k}^* \cdot (\mathbf{N}^{-1}\mathbf{k})] \\ \bar{F}(\mathbf{N}): \quad X^*(\mathbf{k}^*) &= \sum_{\mathbf{k}} X(\mathbf{k}) e[\mathbf{k}^* \cdot (\mathbf{N}^{-1}\mathbf{k})] \end{aligned}$$

with

$$\mathbf{k} \in \mathbb{Z}^n/\mathbf{N}\mathbb{Z}^n, \quad \mathbf{k}^* \in \mathbb{Z}^n/\mathbf{N}^T\mathbb{Z}^n.$$

1.3.3.3.2.1. Multidimensional Cooley–Tukey factorization

Let us now assume that this decimation can be factored into d successive decimations, *i.e.* that

$$\mathbf{N} = \mathbf{N}_1\mathbf{N}_2 \ldots \mathbf{N}_{d-1}\mathbf{N}_d$$

and hence

$$\mathbf{N}^T = \mathbf{N}_d^T\mathbf{N}_{d-1}^T \ldots \mathbf{N}_2^T\mathbf{N}_1^T.$$

Then the coset decomposition formulae corresponding to these successive decimations (Section 1.3.2.7.1) can be combined as follows:

$$\begin{aligned}\mathbb{Z}^n &= \bigcup_{\mathbf{k}_1} (\mathbf{k}_1 + \mathbf{N}_1\mathbb{Z}^n) \\ &= \bigcup_{\mathbf{k}_1} \left\{ \mathbf{k}_1 + \mathbf{N}_1 \left[\bigcup_{\mathbf{k}_2} (\mathbf{k}_2 + \mathbf{N}_2\mathbb{Z}^n) \right] \right\} \\ &= \ldots \\ &= \bigcup_{\mathbf{k}_1} \ldots \bigcup_{\mathbf{k}_d} (\mathbf{k}_1 + \mathbf{N}_1\mathbf{k}_2 + \ldots + \mathbf{N}_1\mathbf{N}_2 \times \ldots \times \mathbf{N}_{d-1}\mathbf{k}_d + \mathbf{N}\mathbb{Z}^n)\end{aligned}$$

with $\mathbf{k}_j \in \mathbb{Z}^n/\mathbf{N}_j\mathbb{Z}^n$. Therefore, any $\mathbf{k} \in \mathbb{Z}/\mathbf{N}\mathbb{Z}^n$ may be written uniquely as

$$\mathbf{k} = \mathbf{k}_1 + \mathbf{N}_1\mathbf{k}_2 + \ldots + \mathbf{N}_1\mathbf{N}_2 \times \ldots \times \mathbf{N}_{d-1}\mathbf{k}_d.$$

Similarly:

$$\begin{aligned}\mathbb{Z}^n &= \bigcup_{\mathbf{k}_d^*} (\mathbf{k}_d^* + \mathbf{N}_d^T\mathbb{Z}^n) \\ &= \ldots \\ &= \bigcup_{\mathbf{k}_d^*} \ldots \bigcup_{\mathbf{k}_1^*} (\mathbf{k}_d^* + \mathbf{N}_d^T\mathbf{k}_{d-1}^* + \ldots + \mathbf{N}_d^T \times \ldots \times \mathbf{N}_2^T\mathbf{k}_1^* \\ &\quad + \mathbf{N}^T\mathbb{Z}^n)\end{aligned}$$

so that any $\mathbf{k}^* \in \mathbb{Z}^n/\mathbf{N}^T\mathbb{Z}^n$ may be written uniquely as

$$\mathbf{k}^* = \mathbf{k}_d^* + \mathbf{N}_d^T\mathbf{k}_{d-1}^* + \ldots + \mathbf{N}_d^T \times \ldots \times \mathbf{N}_2^T\mathbf{k}_1^*$$

with $\mathbf{k}_j^* \in \mathbb{Z}^n/\mathbf{N}_j^T\mathbb{Z}^n$. These decompositions are the vector analogues of the multi-radix number representation systems used in the Cooley–Tukey factorization.

We may then write the definition of $\bar{F}(\mathbf{N})$ with $d = 2$ factors as

$$\begin{aligned}X^*(\mathbf{k}_2^* + \mathbf{N}_2^T\mathbf{k}_1^*) = {} & \sum_{\mathbf{k}_1} \sum_{\mathbf{k}_2} X(\mathbf{k}_1 + \mathbf{N}_1\mathbf{k}_2) \\ & \times e[(\mathbf{k}_2^{*T} + \mathbf{k}_1^{*T}\mathbf{N}_2)\mathbf{N}_2^{-1}\mathbf{N}_1^{-1}(\mathbf{k}_1 + \mathbf{N}_1\mathbf{k}_2)].\end{aligned}$$

The argument of $e(-)$ may be expanded as

$$\mathbf{k}_2^* \cdot (\mathbf{N}^{-1}\mathbf{k}_1) + \mathbf{k}_1^* \cdot (\mathbf{N}_1^{-1}\mathbf{k}_1) + \mathbf{k}_2^* \cdot (\mathbf{N}_2^{-1}\mathbf{k}_2) + \mathbf{k}_1^* \cdot \mathbf{k}_2.$$

The first summand may be recognized as a twiddle factor, the second and third as the kernels of $\bar{F}(\mathbf{N}_1)$ and $\bar{F}(\mathbf{N}_2)$, respectively, while the fourth is an integer which may be dropped. We are thus led to a 'vector-radix' version of the Cooley–Tukey algorithm, in which the successive decimations may be introduced in all n dimensions simultaneously by general integer matrices. The computation may be decomposed into five stages analogous to those of the one-dimensional algorithm of Section 1.3.3.2.1:

(i) form the $|\mathbf{N}_1|$ vectors $\mathbf{Y}_{\mathbf{k}_1}$ of shape $\mathbf{N}_2$ by

$$Y_{\mathbf{k}_1}(\mathbf{k}_2) = X(\mathbf{k}_1 + \mathbf{N}_1\mathbf{k}_2), \quad \mathbf{k}_1 \in \mathbb{Z}^n/\mathbf{N}_1\mathbb{Z}^n, \quad \mathbf{k}_2 \in \mathbb{Z}^n/\mathbf{N}_2\mathbb{Z}^n;$$

(ii) calculate the $|\mathbf{N}_1|$ transforms $\mathbf{Y}^*_{\mathbf{k}_1}$ on $|\mathbf{N}_2|$ points:

$$Y^*_{\mathbf{k}_1}(\mathbf{k}_2^*) = \sum_{\mathbf{k}_2} e[\mathbf{k}_2^* \cdot (\mathbf{N}_2^{-1}\mathbf{k}_2)] Y_{\mathbf{k}_1}(\mathbf{k}_2), \quad \mathbf{k}_1 \in \mathbb{Z}^n/\mathbf{N}_1\mathbb{Z}^n;$$

(iii) form the $|\mathbf{N}_2|$ vectors $\mathbf{Z}_{\mathbf{k}_2^*}$ of shape $\mathbf{N}_1$ by

$$Z_{\mathbf{k}_2^*}(\mathbf{k}_1) = e[\mathbf{k}_2^* \cdot (\mathbf{N}^{-1}\mathbf{k}_1)] Y^*_{\mathbf{k}_1}(\mathbf{k}_2^*), \quad \mathbf{k}_1 \in \mathbb{Z}^n/\mathbf{N}_1\mathbb{Z}^n, \quad \mathbf{k}_2^* \in \mathbb{Z}^n/\mathbf{N}_2^T\mathbb{Z}^n;$$

(iv) calculate the $|\mathbf{N}_2|$ transforms $\mathbf{Z}^*_{\mathbf{k}_2^*}$ on $|\mathbf{N}_1|$ points:

$$Z^*_{\mathbf{k}_2^*}(\mathbf{k}_1^*) = \sum_{\mathbf{k}_1} e[\mathbf{k}_1^* \cdot (\mathbf{N}_1^{-1}\mathbf{k}_1)] Z_{\mathbf{k}_2^*}(\mathbf{k}_1), \quad \mathbf{k}_2^* \in \mathbb{Z}^n/\mathbf{N}_2^T\mathbb{Z}^n;$$

(v) collect $X^*(\mathbf{k}_2^* + \mathbf{N}_2^T\mathbf{k}_1^*)$ as $Z^*_{\mathbf{k}_2^*}(\mathbf{k}_1^*)$.

The initial $|\mathbf{N}|$-point transform $\bar{F}(\mathbf{N})$ can thus be performed as $|\mathbf{N}_1|$ transforms $\bar{F}(\mathbf{N}_2)$ on $|\mathbf{N}_2|$ points, followed by $|\mathbf{N}_2|$ transforms $\bar{F}(\mathbf{N}_1)$ on $|\mathbf{N}_1|$ points. This process can be applied successively to all d factors. The same decomposition applies to $F(\mathbf{N})$, up to the complex conjugation of twiddle factors, the normalization factor $1/|\mathbf{N}|$ being obtained as the product of the factors $1/|\mathbf{N}_j|$ in the successive partial transforms $F(\mathbf{N}_j)$.

The geometric interpretation of this factorization in terms of partial transforms on translates of sublattices applies in full to this n-dimensional setting; in particular, the twiddle factors are seen to be related to the residual translations which place the sublattices in register within the big lattice. If the intermediate transforms are performed *in place*, then the quantity

$$X^*(\mathbf{k}_d^* + \mathbf{N}_d^T\mathbf{k}_{d-1}^* + \ldots + \mathbf{N}_d^T\mathbf{N}_{d-1}^T \times \ldots \times \mathbf{N}_2^T\mathbf{k}_1^*)$$

will eventually be found at location

$$\mathbf{k}_1^* + \mathbf{N}_1\mathbf{k}_2^* + \ldots + \mathbf{N}_1\mathbf{N}_2 \times \ldots \times \mathbf{N}_{d-1}\mathbf{k}_d^*,$$

so that the final results will have to be *unscrambled* by a process which may be called 'coset reversal', the vector equivalent of digit reversal.

Factoring by 2 in all n dimensions simultaneously, *i.e.* taking $\mathbf{N} = 2\mathbf{M}$, leads to 'n-dimensional butterflies'. Decimation in time corresponds to the choice $\mathbf{N}_1 = 2\mathbf{I}$, $\mathbf{N}_2 = \mathbf{M}$, so that $\mathbf{k}_1 \in \mathbb{Z}^n/2\mathbb{Z}^n$ is an n-dimensional parity class; the calculation then proceeds by

$$\begin{aligned} Y_{\mathbf{k}_1}(\mathbf{k}_2) = X(\mathbf{k}_1 + 2\mathbf{k}_2), \quad \mathbf{k}_1 \in \mathbb{Z}^n/2\mathbb{Z}^n, \quad \mathbf{k}_2 \in \mathbb{Z}^n/\mathbf{M}\mathbb{Z}^n, \\ Y^*_{\mathbf{k}_1} = \bar{F}(\mathbf{M})[\mathbf{Y}_{\mathbf{k}_1}], \quad \mathbf{k}_1 \in \mathbb{Z}^n/2\mathbb{Z}^n; \\ X^*(\mathbf{k}_2^* + \mathbf{M}^T\mathbf{k}_1^*) = \sum_{\mathbf{k}_1 \in \mathbb{Z}^n/2\mathbb{Z}^n} (-1)^{\mathbf{k}_1^* \cdot \mathbf{k}_1} \\ \times e[\mathbf{k}_2^* \cdot (\mathbf{N}^{-1}\mathbf{k}_1)] Y^*_{\mathbf{k}_1}(\mathbf{k}_2^*). \end{aligned}$$

Decimation in frequency corresponds to the choice $\mathbf{N}_1 = \mathbf{M}$, $\mathbf{N}_2 = 2\mathbf{I}$, so that $\mathbf{k}_2 \in \mathbb{Z}^n/2\mathbb{Z}^n$ labels 'octant' blocks of shape $\mathbf{M}$; the calculation then proceeds through the following steps:

$$\begin{aligned} Z_{\mathbf{k}_2^*}(\mathbf{k}_1) = \left[\sum_{\mathbf{k}_2 \in \mathbb{Z}^n/2\mathbb{Z}^n} (-1)^{\mathbf{k}_2^* \cdot \mathbf{k}_2} X(\mathbf{k}_1 + \mathbf{M}\mathbf{k}_2) \right] \\ \times e[\mathbf{k}_2^* \cdot (\mathbf{N}^{-1}\mathbf{k}_1)], \\ \mathbf{Z}^*_{\mathbf{k}_2^*} = \bar{F}(\mathbf{M})[\mathbf{Z}_{\mathbf{k}_2^*}], \\ X^*(\mathbf{k}_2^* + 2\mathbf{k}_1^*) = Z^*_{\mathbf{k}_2^*}(\mathbf{k}_1^*), \end{aligned}$$

i.e. the 2^n parity classes of results, corresponding to the different $\mathbf{k}_2^* \in \mathbb{Z}^n/2\mathbb{Z}^n$, are obtained separately. When the dimension n is 2 and the decimating matrix is diagonal, this analysis reduces to the 'vector radix FFT' algorithms proposed by Rivard (1977) and Harris *et al.* (1977). These lead to substantial reductions in the number M of multiplications compared to the row–column method: M is reduced to $3M/4$ by simultaneous 2×2 factoring, and to $15M/32$ by simultaneous 4×4 factoring.

The use of a nondiagonal decimating matrix may bring savings in computing time if the spectrum of the band-limited function under study is of such a shape as to pack more compactly in a nonrectangular than in a rectangular lattice (Mersereau, 1979). If, for instance, the support K of the spectrum Φ is contained in a sphere, then a decimation matrix producing a close packing of these spheres will yield an aliasing-free DFT algorithm with fewer sample points than the standard algorithm using a rectangular lattice.

1.3.3.3.2.2. Multidimensional prime factor algorithm

Suppose that the decimation matrix $\mathbf{N}$ is diagonal

$$\mathbf{N} = \text{diag } (N^{(1)}, N^{(2)}, \ldots, N^{(n)})$$

and let each diagonal element be written in terms of its prime factors:

$$N^{(i)} = \prod_{j=1}^{m} p_j^{\nu(i,\,j)},$$

where m is the total number of distinct prime factors present in the $N^{(i)}$.

The CRT may be used to turn each 1D transform along dimension i ($i = 1, \ldots, n$) into a multidimensional transform with a separate 'pseudo-dimension' for each distinct prime factor of $N^{(i)}$; the number μ_i, of these pseudo-dimensions is equal to the cardinality of the set:

$$\{j \in \{1, \ldots, m\} | \nu(i, j) > 0 \text{ for some } i\}.$$

The full n-dimensional transform thus becomes μ-dimensional, with $\mu = \sum_{i=1}^{n} \mu_i$.

We may now permute the μ pseudo-dimensions so as to bring into contiguous position those corresponding to the same prime factor p_j; the m resulting groups of pseudo-dimensions are said to define 'p-primary' blocks. The initial transform is now written as a tensor product of m p-primary transforms, where transform j is on

$$p_j^{\nu(1,\,j)} \times p_j^{\nu(2,\,j)} \times \ldots \times p_j^{\nu(n,\,j)}$$

points [by convention, dimension i is not transformed if $\nu(i, j) = 0$]. These p-primary transforms may be computed, for instance, by multidimensional Cooley–Tukey factorization (Section 1.3.3.3.1), which is faster than the straightforward row–column method. The final results may then be obtained by reversing all the permutations used.

The extra gain with respect to the multidimensional Cooley–Tukey method is that *there are no twiddle factors between p-primary pieces corresponding to different primes p*.

The case where **N** is not diagonal has been examined by Guessoum & Mersereau (1986).

1.3.3.3.2.3. Nesting of Winograd small FFTs

Suppose that the CRT has been used as above to map an n-dimensional DFT to a μ-dimensional DFT. For each $\kappa = 1, \ldots, \mu$ [κ runs over those pairs (i, j) such that $\nu(i, j) > 0$], the Rader/Winograd procedure may be applied to put the matrix of the κth 1D DFT in the **CBA** normal form of a Winograd small FFT. The full DFT matrix may then be written, up to permutation of data and results, as

$$\bigotimes_{\kappa=1}^{\mu} (\mathbf{C}_\kappa \mathbf{B}_\kappa \mathbf{A}_\kappa).$$

A well known property of the tensor product of matrices allows this to be rewritten as

$$\left(\bigotimes_{\gamma=1}^{\mu} \mathbf{C}_\gamma\right) \times \left(\bigotimes_{\beta=1}^{\mu} \mathbf{B}_\beta\right) \times \left(\bigotimes_{\alpha=1}^{\mu} \mathbf{A}_\alpha\right)$$

and thus to form a matrix in which the *combined* pre-addition, multiplication and post-addition matrices have been *precomputed*. This procedure, called *nesting*, can be shown to afford a reduction of the arithmetic operation count compared to the row–column method (Morris, 1978).

Clearly, the nesting rearrangement need not be applied to all μ dimensions, but can be restricted to any desired subset of them.

1.3.3.3.2.4. The Nussbaumer–Quandalle algorithm

Nussbaumer's approach views the DFT as the evaluation of certain polynomials constructed from the data (as in Section 1.3.3.2.4). For instance, putting $\omega = e(1/N)$, the 1D N-point DFT

$$X^*(k^*) = \sum_{k=0}^{N-1} X(k)\omega^{k^* k}$$

may be written

$$X^*(k^*) = Q(\omega^{k^*}),$$

where the polynomial Q is defined by

$$Q(z) = \sum_{k=0}^{N-1} X(k) z^k.$$

Let us consider (Nussbaumer & Quandalle, 1979) a 2D transform of size $N \times N$:

$$X^*(k_1^*, k_2^*) = \sum_{k_1=0}^{N-1} \sum_{k_2=0}^{N-1} X(k_1, k_2)\omega^{k_1^* k_1 + k_2^* k_2}.$$

By introduction of the polynomials

$$Q_{k_2}(z) = \sum_{k_1} X(k_1, k_2) z^{k_1}$$

$$R_{k_2^*}(z) = \sum_{k_2} \omega^{k_2^* k_2} Q_{k_2}(z),$$

this may be rewritten:

$$X^*(k_1^*, k_2^*) = R_{k_2^*}(\omega^{k_1^*}) = \sum_{k_2} \omega^{k_2^* k_2} Q_{k_2}(\omega^{k_1^*}).$$

Let us now suppose that k_1^* is coprime to N. Then k_1^* has a unique inverse modulo N (denoted by $1/k_1^*$), so that multiplication by k_1^* simply permutes the elements of $\mathbb{Z}/N\mathbb{Z}$ and hence

$$\sum_{k_2=0}^{N-1} f(k_2) = \sum_{k_2=0}^{N-1} f(k_1^* k_2)$$

for any function f over $\mathbb{Z}/N\mathbb{Z}$. We may thus write:

$$\begin{aligned} X^*(k_1^*, k_2^*) &= \sum_{k_2} \omega^{k_1^* k_2^* k_2} Q_{k_1^* k_2}(\omega^{k_1^*}) \\ &= S_{k_1^* k_2}(\omega^{k_1^*}) \end{aligned}$$

where

$$S_{k^*}(z) = \sum_{k_2} z^{k^* k_2} Q_{k_2}(z).$$

Since only the value of polynomial $S_{k^*}(z)$ at $z = \omega^{k_1^*}$ is involved in the result, the computation of S_{k^*} may be carried out modulo the unique cyclotomic polynomial $P(z)$ such that $P(\omega^{k_1^*}) = 0$. Thus, if we define:

$$T_{k^*}(z) = \sum_{k_2} z^{k^* k_2} Q_{k_2}(z) \bmod P(z)$$

we may write:

$$X^*(k_1^*, k_2^*) = T_{k_1^* k_2^*}(\omega^{k_1^*})$$

or equivalently

$$X^*\left(k_1^*, \frac{k_2^*}{k_1^*}\right) = T_{k_2^*}(\omega^{k_1^*}).$$

For N an odd prime p, all nonzero values of k_1^* are coprime with p so that the $p \times p$-point DFT may be calculated as follows:

(1) form the polynomials

$$T_{k_2^*}(z) = \sum_{k_1} \sum_{k_2} X(k_1, k_2) z^{k_1 + k_2^* k_2} \bmod P(z)$$

for $k_2^* = 0, \ldots, p-1$;

(2) evaluate $T_{k_2^*}(\omega^{k_1^*})$ for $k_1^* = 0, \ldots, p-1$;

(3) put $X^*(k_1^*, k_2^*/k_1^*) = T_{k_2^*}(\omega^{k_1^*})$;

(4) calculate the terms for $k_1^* = 0$ separately by

$$X^*(0, k_2^*) = \sum_{k_2} \left[\sum_{k_1} X(k_1, k_2) \right] \omega^{k_2^* k_2}.$$

Step (1) is a set of p 'polynomial transforms' involving no multiplications; step (2) consists of p DFTs on p points each since if

$$T_{k_2^*}(z) = \sum_{k_1} Y_{k_2^*}(k_1) z^{k_1}$$

then

$$T_{k_2^*}(\omega^{k_1^*}) = \sum_{k_1} Y_{k_2^*}(k_1) \omega^{k_1^* k_1} = Y_{k_2^*}^*(k_1^*);$$

step (3) is a permutation; and step (4) is a p-point DFT. Thus the 2D DFT on $p \times p$ points, which takes $2p$ p-point DFTs by the row–column method, involves only $(p+1)$ p-point DFTs; the other DFTs have been replaced by polynomial transforms involving only additions.

This procedure can be extended to n dimensions, and reduces the number of 1D p-point DFTs from np^{n-1} for the row–column method to $(p^n - 1)/(p-1)$, at the cost of introducing extra additions in the polynomial transforms.

A similar algorithm has been formulated by Auslander *et al.* (1983) in terms of Galois theory.

1.3.3.3.3. Global algorithm design

1.3.3.3.3.1. From local pieces to global algorithms

The mathematical analysis of the structure of DFT computations has brought to light a broad variety of possibilities for reducing or reshaping their arithmetic complexity. All of them are 'analytic' in that they break down large transforms into a succession of smaller ones.

These results may now be considered from the converse 'synthetic' viewpoint as providing a list of procedures for assembling them:

(i) the building blocks are one-dimensional p-point algorithms for p a small prime;

(ii) the low-level connectors are the multiplicative reindexing methods of Rader and Winograd, or the polynomial transform reindexing method of Nussbaumer and Quandalle, which allow the construction of efficient algorithms for larger primes p, for prime powers p^ν, and for p-primary pieces of shape $p^\nu \times \ldots \times p^\nu$;

(iii) the high-level connectors are the additive reindexing scheme of Cooley–Tukey, the Chinese remainder theorem reindexing, and the tensor product construction;

(iv) nesting may be viewed as the 'glue' which seals all elements.

The simplest DFT may then be carried out into a global algorithm in many different ways. The diagrams in Fig. 1.3.3.1 illustrate a few of the options available to compute a 400-point DFT. They may differ greatly in their arithmetic operation counts.

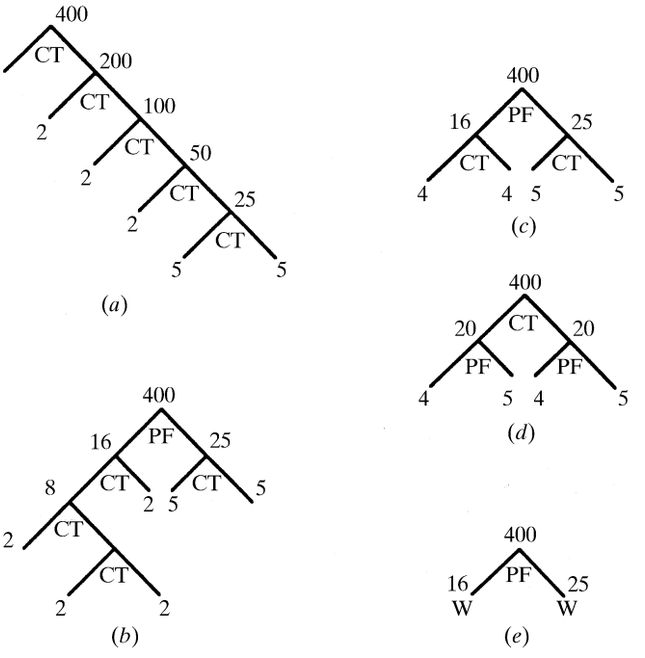

Fig. 1.3.3.1. A few global algorithms for computing a 400-point DFT. CT: Cooley–Tukey factorization. PF: prime factor (or Good) factorization. W: Winograd algorithm.

1.3.3.3.3.2. Computer architecture considerations

To obtain a truly useful measure of the computational complexity of a DFT algorithm, its arithmetic operation count must be tempered by computer architecture considerations. Three main types of trade-offs must be borne in mind:

(i) reductions in floating-point (f.p.) arithmetic count are obtained by reindexing, hence at the cost of an increase in integer arithmetic on addresses, although some shortcuts may be found (Uhrich, 1969; Burrus & Eschenbacher, 1981);

(ii) reduction in the f.p. multiplication count usually leads to a large increase in the f.p. addition count (Morris, 1978);

(iii) nesting can increase execution speed, but causes a loss of modularity and hence complicates program development (Silverman, 1977; Kolba & Parks, 1977).

Many of the mathematical developments above took place in the context of single-processor serial computers, where f.p. addition is substantially cheaper than f.p. multiplication but where integer address arithmetic has to compete with f.p. arithmetic for processor cycles. As a result, the alternatives to the Cooley–Tukey algorithm hardly ever led to particularly favourable trade-offs, thus creating the impression that there was little to gain by switching to more exotic algorithms.

The advent of new machine architectures with vector and/or parallel processing features has greatly altered this picture (Pease, 1968; Korn & Lambiotte, 1979; Fornberg, 1981; Swartzrauber, 1984):

(i) *pipelining* equalizes the cost of f.p. addition and f.p. multiplication, and the ideal 'blend' of the two types of operations depends solely on the number of adder and multiplier units available in each machine;

(ii) integer address arithmetic is delegated to specialized arithmetic and logical units (ALUs) operating concurrently with the f.p. units, so that complex reindexing schemes may be used without loss of overall efficiency.

Another major consideration is that of data flow [see *e.g.* Nawab & McClellan (1979)]. Serial machines only have few registers and few paths connecting them, and allow little or no overlap between computation and data movement. New architectures, on the other hand, comprise banks of vector registers (or 'cache memory') besides the usual internal registers, and dedicated ALUs can service data transfers between several of them simultaneously and concurrently with computation.

In this new context, the devices described in Sections 1.3.3.2 and 1.3.3.3 for altering the balance between the various types of arithmetic operations, and reshaping the data flow during the computation, are invaluable. The field of machine-dependent DFT algorithm design is thriving on them [see *e.g.* Temperton (1983*a*,*b*,*c*, 1985); Agarwal & Cooley (1986, 1987)].

1.3.3.3.3.3. The Johnson–Burrus family of algorithms

In order to explore systematically all possible algorithms for carrying out a given DFT computation, and to pick the one best suited to a given machine, attempts have been made to develop:

(i) a high-level notation of describing all the ingredients of a DFT computation, including data permutation and data flow;

(ii) a formal calculus capable of operating on these descriptions so as to represent all possible reorganizations of the computation;

(iii) an automatic procedure for evaluating the performance of a given algorithm on a specific architecture.

Task (i) can be accomplished by systematic use of a tensor product notation to represent the various stages into which the DFT can be factored (reindexing, small transforms on subsets of indices, twiddle factors, digit-reversal permutations).

Task (ii) may for instance use the Winograd **CBA** normal form for each small transform, then apply the rules governing the rearrangement of tensor product $\bigotimes$ and ordinary product $\times$ operations on matrices. The matching of these rearrangements to the architecture of a vector and/or parallel computer can be formalized algebraically [see *e.g.* Chapter 2 of Tolimieri *et al.* (1989)].

Task (iii) is a complex search which requires techniques such as dynamic programming (Bellman, 1958).

Johnson & Burrus (1983) have proposed and tested such a scheme to identify the optimal trade-offs between prime factor nesting and Winograd nesting of small Winograd transforms. In step (ii), they further decomposed the pre-addition matrix **A** and post-addition matrix **C** into several factors, so that the number of design options available becomes very large: the N-point DFT when N has four factors can be calculated in over 10^{12} distinct ways.

This large family of nested algorithms contains the prime factor algorithm and the Winograd algorithms as particular cases, but usually achieves greater efficiency than either by reducing the f.p. multiplication count while keeping the number of f.p. additions small.

There is little doubt that this systematic approach will be extended so as to incorporate all available methods of restructuring the DFT.

1.3.4. Crystallographic applications of Fourier transforms

1.3.4.1. Introduction

The central role of the Fourier transformation in X-ray crystallography is a consequence of the kinematic approximation used in the description of the scattering of X-rays by a distribution of electrons (Bragg, 1915; Duane, 1925; Havighurst, 1925*a*,*b*; Zachariasen, 1945; James, 1948*a*, Chapters 1 and 2; Lipson & Cochran, 1953, Chapter 1; Bragg, 1975).

Let $\rho(\mathbf{X})$ be the density of electrons in a sample of matter contained in a finite region V which is being illuminated by a parallel monochromatic X-ray beam with wavevector $\mathbf{K}_0$. Then the far-field amplitude scattered in a direction corresponding to wavevector $\mathbf{K} = \mathbf{K}_0 + \mathbf{H}$ is proportional to

$$\begin{aligned} F(\mathbf{H}) &= \int_V \rho(\mathbf{X}) \exp(2\pi i \mathbf{H}\cdot\mathbf{X})\, \mathrm{d}^3\mathbf{X} \\ &= \bar{\mathscr{F}}[\rho](\mathbf{H}) \\ &= \langle \rho_{\mathbf{x}}, \exp(2\pi i \mathbf{H}\cdot\mathbf{X})\rangle. \end{aligned}$$

In certain model calculations, the 'sample' may contain not only volume charges, but also point, line and surface charges. These singularities may be accommodated by letting ρ be a distribution, and writing

$$F(\mathbf{H}) = \bar{\mathscr{F}}[\rho](\mathbf{H}) = \langle \rho_{\mathbf{x}}, \exp(2\pi i \mathbf{H}\cdot\mathbf{X})\rangle.$$

F is still a well behaved function (analytic, by Section 1.3.2.4.2.10) because ρ has been assumed to have compact support.

If the sample is assumed to be an infinite crystal, so that ρ is now a *periodic* distribution, the customary limiting process by which it is shown that F becomes a discrete series of peaks at reciprocal-lattice points (see *e.g.* von Laue, 1936; Ewald, 1940; James, 1948*a* p. 9; Lipson & Taylor, 1958, pp. 14–27; Ewald, 1962, pp. 82–101; Warren, 1969, pp. 27–30) is already subsumed under the treatment of Section 1.3.2.6.

1.3.4.2. Crystallographic Fourier transform theory

1.3.4.2.1. Crystal periodicity

1.3.4.2.1.1. Period lattice, reciprocal lattice and structure factors

Let ρ be the distribution of electrons in a crystal. Then, by definition of a crystal, ρ is Λ-*periodic* for some period lattice Λ (Section 1.3.2.6.5) so that there exists a motif distribution ρ^0 with compact support such that

$$\rho = R * \rho^0,$$

where $R = \sum_{\mathbf{x}\in\Lambda} \delta_{(\mathbf{X})}$. The lattice Λ is usually taken to be the finest for which the above representation holds.

Let Λ have a basis $(\mathbf{a}_1, \mathbf{a}_2, \mathbf{a}_3)$ over the integers, these basis vectors being expressed in terms of a standard orthonormal basis $(\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3)$ as

$$\mathbf{a}_k = \sum_{j=1}^{3} a_{jk}\mathbf{e}_j.$$

Then the matrix

$$\mathbf{A} = \begin{pmatrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ a_{31} & a_{32} & a_{33} \end{pmatrix}$$

is the period matrix of Λ (Section 1.3.2.6.5) with respect to the unit lattice with basis $(\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3)$, and the volume V of the unit cell is given by $V = |\det \mathbf{A}|$.

By Fourier transformation

$$\bar{\mathscr{F}}[\rho] = R^* \times \bar{\mathscr{F}}[\rho^0],$$

where $R^* = \sum_{\mathbf{H}\in\Lambda^*} \delta_{(\mathbf{H})}$ is the lattice distribution associated to the reciprocal lattice Λ^*. The basis vectors $(\mathbf{a}_1^*, \mathbf{a}_2^*, \mathbf{a}_3^*)$ have coordinates in $(\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3)$ given by the columns of $(\mathbf{A}^{-1})^T$, whose expression in terms of the cofactors of **A** (see Section 1.3.2.6.5) gives the familiar formulae involving the cross product of vectors for $n = 3$. The **H**-distribution F of scattered amplitudes may be written

$$F = \bar{\mathscr{F}}[\rho]_{\mathbf{H}} = \sum_{\mathbf{H}\in\Lambda^*} \bar{\mathscr{F}}[\rho^0](\mathbf{H})\delta_{(\mathbf{H})} = \sum_{\mathbf{H}\in\Lambda^*} F_{\mathbf{H}}\delta_{(\mathbf{H})}$$

and is thus a weighted reciprocal-lattice distribution, the weight $F_{\mathbf{H}}$ attached to each node $\mathbf{H} \in \Lambda^*$ being the value at **H** of the transform $\bar{\mathscr{F}}[\rho^0]$ of the motif ρ^0. Taken in conjunction with the assumption that the scattering is elastic, *i.e.* that **H** only changes the direction but not the magnitude of the incident wavevector $\mathbf{K}_0$, this result yields the usual forms (Laue or Bragg) of the

diffraction conditions: $\mathbf{H} \in \Lambda^*$, and simultaneously $\mathbf{H}$ lies on the Ewald sphere.

By the reciprocity theorem, ρ^0 can be recovered if F is known for all $\mathbf{H} \in \Lambda^*$ as follows [Section 1.3.2.6.5, *e.g.* (iv)]:

$$\rho_{\mathbf{x}} = \frac{1}{V} \sum_{\mathbf{H} \in \Lambda^*} F_{\mathbf{H}} \exp(-2\pi i \mathbf{H} \cdot \mathbf{X}).$$

These relations may be rewritten in terms of standard, or 'fractional crystallographic', coordinates by putting

$$\mathbf{X} = \mathbf{A}\mathbf{x}, \quad \mathbf{H} = (\mathbf{A}^{-1})^T \mathbf{h},$$

so that a unit cell of the crystal corresponds to $\mathbf{x} \in \mathbb{R}^3/\mathbb{Z}^3$, and that $\mathbf{h} \in \mathbb{Z}^3$. Defining $\mathscr{p}$ and $\mathscr{p}^0$ by

$$\rho = \frac{1}{V} A^{\#} \mathscr{p}, \quad \rho^0 = \frac{1}{V} A^{\#} \mathscr{p}^0$$

so that

$$\rho(\mathbf{X})\, \mathrm{d}^3\mathbf{X} = \mathscr{p}(\mathbf{x})\, \mathrm{d}^3\mathbf{x}, \quad \rho^0(\mathbf{X})\, \mathrm{d}^3\mathbf{X} = \mathscr{p}^0(\mathbf{x})\, \mathrm{d}^3\mathbf{x},$$

we have

$$\begin{aligned} \bar{\mathscr{F}}[\mathscr{p}]_{\mathbf{h}} &= \sum_{\mathbf{h} \in \mathbb{Z}^3} F(\mathbf{h}) \delta_{(\mathbf{h})}, \\ F(\mathbf{h}) &= \langle \mathscr{p}^0_{\mathbf{x}}, \exp(2\pi i \mathbf{h} \cdot \mathbf{x}) \rangle \\ &= \int_{\mathbb{R}^3/\mathbb{Z}^3} \mathscr{p}^0(\mathbf{x}) \exp(2\pi i \mathbf{h} \cdot \mathbf{x})\, \mathrm{d}^3\mathbf{x} \quad \text{if } \mathscr{p}^0 \in L^1_{\mathrm{loc}}(\mathbb{R}^3/\mathbb{Z}^3), \\ \mathscr{p}_{\mathbf{x}} &= \sum_{\mathbf{h} \in \mathbb{Z}^3} F(\mathbf{h}) \exp(-2\pi i \mathbf{h} \cdot \mathbf{x}). \end{aligned}$$

These formulae are valid for an arbitrary motif distribution $\mathscr{p}^0$, provided the convergence of the Fourier series for $\mathscr{p}$ is considered from the viewpoint of distribution theory (Section 1.3.2.6.10.3).

The experienced crystallographer may notice the absence of the familiar factor $1/V$ from the expression for $\mathscr{p}$ just given. This is because we use the (mathematically) natural unit for $\mathscr{p}$, the *electron per unit cell*, which matches the dimensionless nature of the crystallographic coordinates $\mathbf{x}$ and of the associated volume element $\mathrm{d}^3\mathbf{x}$. The traditional factor $1/V$ was the result of the somewhat inconsistent use of $\mathbf{x}$ as an argument but of $\mathrm{d}^3\mathbf{X}$ as a volume element to obtain ρ in electrons per unit volume (*e.g.* Å^3). A fortunate consequence of the present convention is that nuisance factors of V or $1/V$, which used to abound in convolution or scalar product formulae, are now absent.

It should be noted at this point that the crystallographic terminology regarding $\mathscr{F}$ and $\bar{\mathscr{F}}$ differs from the standard mathematical terminology introduced in Section 1.3.2.4.1 and applied to periodic distributions in Section 1.3.2.6.4: F is the *inverse* Fourier transform of ρ rather than its Fourier transform, and the calculation of ρ is called a Fourier *synthesis* in crystallography even though it is mathematically a Fourier analysis. The origin of this discrepancy may be traced to the fact that the mathematical theory of the Fourier transformation originated with the study of *temporal* periodicity, while crystallography deals with *spatial* periodicity; since the expression for the phase factor of a plane wave is $\exp[2\pi i(\nu t - \mathbf{K} \cdot \mathbf{X})]$, the difference in sign between the contributions from time *versus* spatial displacements makes this conflict unavoidable.

1.3.4.2.1.2. Structure factors in terms of form factors

In many cases, $\mathscr{p}^0$ is a sum of translates of atomic electron-density distributions. Assume there are n distinct chemical types of atoms, with N_j identical isotropic atoms of type j described by an electron distribution $\mathscr{p}_j$ about their centre of mass. According to quantum mechanics each $\mathscr{p}_j$ is a smooth rapidly decreasing function of $\mathbf{x}$, *i.e.* $\mathscr{p}_j \in \mathscr{S}$, hence $\mathscr{p}^0 \in \mathscr{S}$ and (ignoring the effect of thermal agitation)

$$\mathscr{p}^0(\mathbf{x}) = \sum_{j=1}^{n} \left[\sum_{k_j=1}^{N_j} \mathscr{p}_j(\mathbf{x} - \mathbf{x}_{k_j}) \right],$$

which may be written (Section 1.3.2.5.8)

$$\mathscr{p}^0 = \sum_{j=1}^{n} \left[\mathscr{p}_j * \left(\sum_{k_j=1}^{N_j} \delta_{(\mathbf{x}_{k_j})} \right) \right].$$

By Fourier transformation:

$$F(\mathbf{h}) = \sum_{j=1}^{n} \left\{ \bar{\mathscr{F}}[\mathscr{p}_j](\mathbf{h}) \times \left[\sum_{k_j=1}^{N_j} \exp(2\pi i \mathbf{h} \cdot \mathbf{x}_{k_j}) \right] \right\}.$$

Defining the form factor f_j of atom j as a function of $\mathbf{h}$ to be

$$f_j(\mathbf{h}) = \bar{\mathscr{F}}[\mathscr{p}_j](\mathbf{h})$$

we have

$$F(\mathbf{h}) = \sum_{j=1}^{n} f_j(\mathbf{h}) \times \left[\sum_{k_j=1}^{N_j} \exp(2\pi i \mathbf{h} \cdot \mathbf{x}_{k_j}) \right].$$

If $\mathbf{X} = \mathbf{A}\mathbf{x}$ and $\mathbf{H} = (\mathbf{A}^{-1})^T \mathbf{h}$ are the real- and reciprocal-space coordinates in Å and Å^{-1}, and if $\rho_j(\|\mathbf{X}\|)$ is the spherically symmetric electron-density function for atom type j, then

$$f_j(\mathbf{H}) = \int_0^{\infty} 4\pi \|\mathbf{X}\|^2 \rho_j(\|\mathbf{X}\|) \frac{\sin(2\pi \|\mathbf{H}\| \|\mathbf{X}\|)}{2\pi \|\mathbf{H}\| \|\mathbf{X}\|}\, \mathrm{d}\|\mathbf{X}\|.$$

More complex expansions are used for electron-density studies (see Chapter 1.2 in this volume). Anisotropic Gaussian atoms may be dealt with through the formulae given in Section 1.3.2.4.4.2.

1.3.4.2.1.3. Fourier series for the electron density and its summation

The convergence of the Fourier series for $\mathscr{p}$

$$\mathscr{p}(\mathbf{x}) = \sum_{\mathbf{h} \in \mathbb{Z}^3} F(\mathbf{h}) \exp(-2\pi i \mathbf{h} \cdot \mathbf{x})$$

is usually examined from the classical point of view (Section 1.3.2.6.10). The summation of multiple Fourier series meets with considerable difficulties, because there is no natural order in $\mathbb{Z}^n$ to play the role of the natural order in $\mathbb{Z}$ (Ash, 1976). In crystallography, however, the structure factors $F(\mathbf{h})$ are often obtained within spheres $\|\mathbf{H}\| \leq \Delta^{-1}$ for increasing resolution (decreasing Δ). Therefore, successive estimates of $\mathscr{p}$ are most

naturally calculated as the corresponding partial sums (Section 1.3.2.6.10.1):

$$S_\Delta(\rho)(\mathbf{x}) = \sum_{\|(\mathbf{A}^{-1})^T\mathbf{h}\| \le \Delta^{-1}} F(\mathbf{h}) \exp(-2\pi i \mathbf{h}\cdot\mathbf{x}).$$

This may be written

$$S_\Delta(\rho)(\mathbf{x}) = (D_\Delta * \rho)(\mathbf{x}),$$

where D_Δ is the 'spherical Dirichlet kernel'

$$D_\Delta(\mathbf{x}) = \sum_{\|(\mathbf{A}^{-1})^T\mathbf{h}\| \le \Delta^{-1}} \exp(-2\pi i \mathbf{h}\cdot\mathbf{x}).$$

D_Δ exhibits numerous negative ripples around its central peak. Thus the 'series termination errors' incurred by using $S_\Delta(\rho)$ instead of ρ consist of negative ripples around each atom, and may lead to a Gibbs-like phenomenon (Section 1.3.2.6.10.1) near a molecular boundary.

As in one dimension, Cesàro sums (arithmetic means of partial sums) have better convergence properties, as they lead to a convolution by a 'spherical Fejér kernel' which is everywhere positive. Thus Cesàro summation will always produce positive approximations to a positive electron density. Other positive summation kernels were investigated by Pepinsky (1952) and by Waser & Schomaker (1953).

1.3.4.2.1.4. Friedel's law, anomalous scatterers

If the wavelength λ of the incident X-rays is far from any absorption edge of the atoms in the crystal, there is a constant phase shift in the scattering, and the electron density may be considered to be *real-valued*. Then

$$\begin{aligned} F(\mathbf{h}) &= \int_{\mathbb{R}^3/\mathbb{Z}^3} \rho(\mathbf{x}) \exp(2\pi i \mathbf{h}\cdot\mathbf{x})\, \mathrm{d}^3\mathbf{x} \\ &= \overline{\int_{\mathbb{R}^3/\mathbb{Z}^3} \overline{\rho(\mathbf{x})} \exp[2\pi i(-\mathbf{h})\cdot\mathbf{x}]\, \mathrm{d}^3\mathbf{x}} \\ &= \overline{F(-\mathbf{h})} \text{ since } \overline{\rho(\mathbf{x})} = \rho(\mathbf{x}). \end{aligned}$$

Thus if

$$F(\mathbf{h}) = |F(\mathbf{h})| \exp(i\varphi(\mathbf{h})),$$

then

$$|F(-\mathbf{h})| = |F(\mathbf{h})| \quad \text{and} \quad \varphi(-\mathbf{h}) = -\varphi(\mathbf{h}).$$

This is Friedel's law (Friedel, 1913). The set $\{F_\mathbf{h}\}$ of Fourier coefficients is said to have *Hermitian symmetry*.

If λ is close to some absorption edge(s), the proximity to resonance induces an extra phase shift, whose effect may be represented by letting $\rho(\mathbf{x})$ take on *complex values*. Let

$$\rho(\mathbf{x}) = \rho^{\mathrm{R}}(\mathbf{x}) + i\rho^{\mathrm{I}}(\mathbf{x})$$

and correspondingly, by termwise Fourier transformation

$$F(\mathbf{h}) = F^{\mathrm{R}}(\mathbf{h}) + iF^{\mathrm{I}}(\mathbf{h}).$$

Since $\rho^{\mathrm{R}}(\mathbf{x})$ and $\rho^{\mathrm{I}}(\mathbf{x})$ are both real, $F^{\mathrm{R}}(\mathbf{h})$ and $F^{\mathrm{I}}(\mathbf{h})$ are both Hermitian symmetric, hence

$$F(-\mathbf{h}) = \overline{F^{\mathrm{R}}(\mathbf{h})} + \overline{iF^{\mathrm{I}}(\mathbf{h})},$$

while

$$\overline{F(\mathbf{h})} = \overline{F^{\mathrm{R}}(\mathbf{h})} - \overline{iF^{\mathrm{I}}(\mathbf{h})}.$$

Thus $F(-\mathbf{h}) \neq \overline{F(\mathbf{h})}$, so that Friedel's law is violated. The components $F^{\mathrm{R}}(\mathbf{h})$ and $F^{\mathrm{I}}(\mathbf{h})$, which do obey Friedel's law, may be expressed as:

$$\begin{aligned} F^{\mathrm{R}}(\mathbf{h}) &= \tfrac{1}{2}[F(\mathbf{h}) + \overline{F(-\mathbf{h})}], \\ F^{\mathrm{I}}(\mathbf{h}) &= \frac{1}{2i}[F(\mathbf{h}) - \overline{F(-\mathbf{h})}]. \end{aligned}$$

1.3.4.2.1.5. Parseval's identity and other L^2 theorems

By Section 1.3.2.4.3.3 and Section 1.3.2.6.10.2,

$$\sum_{\mathbf{h}\in\mathbb{Z}^3} |F(\mathbf{h})|^2 = \int_{\mathbb{R}^3/\mathbb{Z}^3} |\rho(\mathbf{x})|^2\, \mathrm{d}^3\mathbf{x} = V \int_{\mathbb{R}^3/\Lambda} |\rho(\mathbf{X})|^2\, \mathrm{d}^3\mathbf{X}.$$

Usually $\rho(\mathbf{x})$ is real and positive, hence $|\rho(\mathbf{x})| = \rho(\mathbf{x})$, but the identity remains valid even when $\rho(\mathbf{x})$ is made complex-valued by the presence of anomalous scatterers.

If $\{G_\mathbf{h}\}$ is the collection of structure factors belonging to another electron density $\sigma = A^{\#}\sigma$ with the same period lattice as ρ, then

$$\begin{aligned} \sum_{\mathbf{h}\in\mathbb{Z}^3} \overline{F(\mathbf{h})} G(\mathbf{h}) &= \int_{\mathbb{R}^3/\mathbb{Z}^3} \overline{\rho(\mathbf{x})}\sigma(\mathbf{x})\, \mathrm{d}^3\mathbf{x} \\ &= V \int_{\mathbb{R}^3/\Lambda} \rho(\mathbf{X})\sigma(\mathbf{X})\, \mathrm{d}^3\mathbf{X}. \end{aligned}$$

Thus, norms and inner products may be evaluated either from structure factors or from 'maps'.

1.3.4.2.1.6. Convolution, correlation and Patterson function

Let $\rho = r * \rho^0$ and $\sigma = r * \sigma^0$ be two electron densities referred to crystallographic coordinates, with structure factors $\{F_\mathbf{h}\}_{\mathbf{h}\in\mathbb{Z}^3}$ and $\{G_\mathbf{h}\}_{\mathbf{h}\in\mathbb{Z}^3}$, so that

$$\begin{aligned} \rho_\mathbf{x} &= \sum_{\mathbf{h}\in\mathbb{Z}^3} F(\mathbf{h}) \exp(-2\pi i \mathbf{h}\cdot\mathbf{x}), \\ \sigma_\mathbf{x} &= \sum_{\mathbf{h}\in\mathbb{Z}^3} G(\mathbf{h}) \exp(-2\pi i \mathbf{h}\cdot\mathbf{x}). \end{aligned}$$

The distribution $\omega = r * (\rho^0 * \sigma^0)$ is well defined, since the generalized support condition (Section 1.3.2.3.9.7) is satisfied. The forward version of the convolution theorem implies that if

$$\omega_\mathbf{x} = \sum_{\mathbf{h}\in\mathbb{Z}^3} W(\mathbf{h}) \exp(-2\pi i \mathbf{h}\cdot\mathbf{x}),$$

then

$$W(\mathbf{h}) = F(\mathbf{h})G(\mathbf{h}).$$

If either $\mathscr{p}^0$ or $\mathscr{o}^0$ is infinitely differentiable, then the distribution $\psi = \mathscr{p} \times \mathscr{o}$ exists, and if we analyse it as

$$\psi_{\mathbf{x}} = \sum_{\mathbf{h}\in\mathbb{Z}^3} Y(\mathbf{h}) \exp(-2\pi i \mathbf{h}\cdot\mathbf{x}),$$

then the backward version of the convolution theorem reads:

$$Y(\mathbf{h}) = \sum_{\mathbf{k}\in\mathbb{Z}^3} F(\mathbf{h})G(\mathbf{h}-\mathbf{k}).$$

The *cross correlation* $\kappa[\mathscr{p},\mathscr{o}]$ between $\mathscr{p}$ and $\mathscr{o}$ is the $\mathbb{Z}^3$-periodic distribution defined by:

$$\kappa = \check{\mathscr{p}}^0 * \mathscr{o}.$$

If $\mathscr{p}^0$ and $\mathscr{o}^0$ are locally integrable,

$$\begin{aligned}\kappa[\mathscr{p},\mathscr{o}](\mathbf{t}) &= \int_{\mathbb{R}^3} \mathscr{p}^0(\mathbf{x})\mathscr{o}(\mathbf{x}+\mathbf{t})\,\mathrm{d}^3\mathbf{x} \\ &= \int_{\mathbb{R}^3/\mathbb{Z}^3} \mathscr{p}(\mathbf{x})\mathscr{o}(\mathbf{x}+\mathbf{t})\,\mathrm{d}^3\mathbf{x}.\end{aligned}$$

Let

$$\kappa(\mathbf{t}) = \sum_{\mathbf{h}\in\mathbb{Z}^3} K(\mathbf{h}) \exp(-2\pi i \mathbf{h}\cdot\mathbf{t}).$$

The combined use of the shift property and of the forward convolution theorem then gives immediately:

$$K(\mathbf{h}) = \overline{F(\mathbf{h})}G(\mathbf{h});$$

hence the Fourier series representation of $\kappa[\mathscr{p},\mathscr{o}]$:

$$\kappa[\mathscr{p},\mathscr{o}](\mathbf{t}) = \sum_{\mathbf{h}\in\mathbb{Z}^3} \overline{F(\mathbf{h})}G(\mathbf{h}) \exp(-2\pi i \mathbf{h}\cdot\mathbf{t}).$$

Clearly, $\kappa[\mathscr{p},\mathscr{o}] = (\kappa[\mathscr{o},\mathscr{p}])\check{}$, as shown by the fact that permuting F and G changes $K(\mathbf{h})$ into its complex conjugate.

The *auto-correlation* of $\mathscr{p}$ is defined as $\kappa[\mathscr{p},\mathscr{p}]$ and is called the *Patterson function* of $\mathscr{p}$. If $\mathscr{p}$ consists of point atoms, *i.e.*

$$\mathscr{p}^0 = \sum_{j=1}^{N} Z_j \delta_{(\mathbf{x}_j)},$$

then

$$\kappa[\mathscr{p},\mathscr{p}] = r * \left[\sum_{j=1}^{N}\sum_{k=1}^{N} Z_j Z_k \delta_{(\mathbf{x}_j-\mathbf{x}_k)}\right]$$

contains information about interatomic vectors. It has the Fourier series representation

$$\kappa[\mathscr{p},\mathscr{p}](\mathbf{t}) = \sum_{\mathbf{h}\in\mathbb{Z}^3} |F(\mathbf{h})|^2 \exp(-2\pi i \mathbf{h}\cdot\mathbf{t}),$$

and is therefore calculable from the diffraction intensities alone. It was first proposed by Patterson (1934, 1935*a*,*b*) as an extension to crystals of the radially averaged correlation function used by Warren & Gingrich (1934) in the study of powders.

1.3.4.2.1.7. Sampling theorems, continuous transforms, interpolation

Shannon's sampling and interpolation theorem (Section 1.3.2.7.1) takes two different forms, according to whether the property of finite bandwidth is assumed in real space or in reciprocal space.

(1) The most usual setting is in reciprocal space (see Sayre, 1952*c*). Only a finite number of diffraction intensities can be recorded and phased, and for physical reasons the cutoff criterion is the resolution $\Delta = 1/\|\mathbf{H}\|_{\max}$. Electron-density maps are thus calculated as partial sums (Section 1.3.4.2.1.3), which may be written in Cartesian coordinates as

$$S_\Delta(\rho)(\mathbf{X}) = \sum_{\mathbf{H}\in\Lambda^*,\ \|\mathbf{H}\|\le\Delta^{-1}} F(\mathbf{H}) \exp(-2\pi i \mathbf{H}\cdot\mathbf{X}).$$

$S_\Delta(\rho)$ is band-limited, the support of its spectrum being contained in the solid sphere Σ_Δ defined by $\|\mathbf{H}\| \le \Delta^{-1}$. Let χ_Δ be the indicator function of Σ_Δ. The transform of the normalized version of χ_Δ is (see below, Section 1.3.4.4.3.5)

$$\begin{aligned}I_\Delta(\mathbf{X}) &= \frac{3\Delta^3}{4\pi}\mathscr{F}[\chi_\Delta](\mathbf{X}) \\ &= \frac{3}{u^3}(\sin u - u\cos u) \quad \text{where } u = 2\pi\frac{\|\mathbf{X}\|}{\Delta}.\end{aligned}$$

By Shannon's theorem, it suffices to calculate $S_\Delta(\rho)$ on an integral subdivision Γ of the period lattice Λ such that the sampling criterion is satisfied (*i.e.* that the translates of Σ_Δ by vectors of Γ^* do not overlap). Values of $S_\Delta(\rho)$ may then be calculated at an arbitrary point $\mathbf{X}$ by the interpolation formula:

$$S_\Delta(\rho)(\mathbf{X}) = \sum_{\mathbf{Y}\in\Gamma} I_\Delta(\mathbf{X}-\mathbf{Y}) S_\Delta(\rho)(\mathbf{Y}).$$

(2) The reverse situation occurs whenever the support of the motif $\mathscr{p}^0$ does not fill the whole unit cell, *i.e.* whenever there exists a region M (the 'molecular envelope'), strictly smaller than the unit cell, such that the translates of M by vectors of r do not overlap and that

$$\chi_M \times \mathscr{p}^0 = \mathscr{p}^0.$$

It then follows that $\mathscr{p} = r * (\chi_M \times \mathscr{p})$. Defining the 'interference function' G as the normalized indicator function of M according to

$$G(\boldsymbol{\eta}) = \frac{1}{\mathrm{vol}(M)}\bar{\mathscr{F}}[\chi_M](\boldsymbol{\eta})$$

we may invoke Shannon's theorem to calculate the value $\bar{\mathscr{F}}[\mathscr{p}^0](\boldsymbol{\xi})$ at an arbitrary point $\boldsymbol{\xi}$ of reciprocal space from its sample values $F(\mathbf{h}) = \bar{\mathscr{F}}[\mathscr{p}^0](\mathbf{h})$ at points of the reciprocal lattice as

$$\bar{\mathscr{F}}[\mathscr{p}^0](\boldsymbol{\xi}) = \sum_{\mathbf{h}\in\mathbb{Z}^3} \mathbf{G}(\boldsymbol{\xi}-\mathbf{h})F(\mathbf{h}).$$

This aspect of Shannon's theorem constitutes the mathematical basis of phasing methods based on geometric redundancies created by solvent regions and/or noncrystallographic symmetries (Bricogne, 1974). The connection between Shannon's theorem and the phase problem was first noticed by Sayre (1952*b*). He pointed out that the Patterson function of ρ, written as $\kappa[\rho, \rho] = r * (\check{\rho}^0 * \rho^0)$, may be viewed as consisting of a motif $\kappa^0 = \check{\rho}^0 * \rho^0$ (containing all the internal interatomic vectors) which is periodized by convolution with r. As the translates of κ^0 by vectors of $\mathbb{Z}^3$ *do* overlap, the sample values of the intensities $|F(\mathbf{h})|^2$ at nodes of the reciprocal lattice do not provide enough data to interpolate intensities $|F(\boldsymbol{\xi})|^2$ at arbitrary points of reciprocal space. Thus the loss of phase is intimately related to the impossibility of intensity interpolation, implying in return that any indication of intensity values attached to nonintegral points of the reciprocal lattice is a potential source of phase information.

1.3.4.2.1.8. Sections and projections

It was shown at the end of Section 1.3.2.5.8 that the convolution theorem establishes, under appropriate assumptions, a duality between sectioning a smooth function (viewed as a multiplication by a δ-function in the sectioning coordinate) and projecting its transform (viewed as a convolution with the function **1** everywhere equal to 1 as a function of the projection coordinate). This duality follows from the fact that $\mathcal{F}$ and $\bar{\mathcal{F}}$ map $\mathbf{1}_{x_i}$ to δ_{x_i} and δ_{x_i} to $\mathbf{1}_{x_i}$ (Section 1.3.2.5.6), and from the tensor product property (Section 1.3.2.5.5).

In the case of periodic distributions, projection and section must be performed with respect to directions or subspaces which are integral with respect to the period lattice if the result is to be periodic; furthermore, projections must be performed only on the contents of *one* repeating unit along the direction of projection, or else the result would diverge. The same relations then hold between principal central sections and projections of the electron density and the dual principal central projections and sections of the weighted reciprocal lattice, *e.g.*

$$\begin{aligned}
\rho(x_1, 0, 0) &\leftrightarrow \sum_{h_1, h_2} F(h_1, h_2, h_3), \\
\rho(x_1, x_2, 0) &\leftrightarrow \sum_{h_3} F(h_1, h_2, h_3), \\
\rho_{1,2}(x_3) = \int_{\mathbb{R}^2/\mathbb{Z}^2} \rho(x_1, x_2, x_3)\, \mathrm{d}x_1\, \mathrm{d}x_2 &\leftrightarrow F(0, 0, h_3), \\
\rho_1(x_2, x_3) = \int_{\mathbb{R}/\mathbb{Z}} \rho(x_1, x_2, x_3)\, \mathrm{d}x_1 &\leftrightarrow F(0, h_2, h_3)
\end{aligned}$$

etc.

When the sections are principal but not central, it suffices to use the shift property of Section 1.3.2.5.5. When the sections or projections are not principal, they can be made principal by changing to new primitive bases B and B^* for Λ and Λ^*, respectively, the transition matrices $\mathbf{P}$ and $\mathbf{P}^*$ to these new bases being related by $\mathbf{P}^* = (\mathbf{P}^{-1})^T$ in order to preserve duality. This change of basis must be such that one of these matrices (say, $\mathbf{P}$) should have a given integer vector $\mathbf{u}$ as its first column, $\mathbf{u}$ being related to the line or plane defining the section or projection of interest.

The problem of constructing a matrix $\mathbf{P}$ given $\mathbf{u}$ received an erroneous solution in Volume II of *International Tables* (Patterson, 1959), which was subsequently corrected in 1962. Unfortunately, the solution proposed there is complicated and does not suggest a general approach to the problem. It therefore seems worthwhile to record here an effective procedure which solves this problem in any dimension n (Watson, 1970).

Let

$$\mathbf{u} = \begin{pmatrix} u_1 \\ \vdots \\ u_n \end{pmatrix}$$

be a primitive integral vector, *i.e.* g.c.d. $(u_1, \ldots, u_n) = 1$. Then an $n \times n$ integral matrix $\mathbf{P}$ with $\det \mathbf{P} = 1$ having $\mathbf{u}$ as its first column can be constructed by induction as follows. For $n = 1$ the result is trivial. For $n = 2$ it can be solved by means of the Euclidean algorithm, which yields z_1, z_2 such that $u_1 z_2 - u_2 z_1 = 1$, so that we may take

$$\mathbf{P} = \begin{pmatrix} u_1 & z_1 \\ u_2 & z_2 \end{pmatrix}.$$

Note that, if

$$\mathbf{z} = \begin{pmatrix} z_1 \\ z_2 \end{pmatrix}$$

is a solution, then $\mathbf{z} + m\mathbf{u}$ is another solution for any $m \in \mathbb{Z}$. For $n \geq 3$, write

$$\mathbf{u} = \begin{pmatrix} u_1 \\ d\mathbf{z} \end{pmatrix}$$

with $d =$ g.c.d. $(u_2, \ldots, u_n)$ so that both

$$\mathbf{z} = \begin{pmatrix} z_2 \\ \vdots \\ z_n \end{pmatrix} \quad \text{and} \quad \begin{pmatrix} u_1 \\ d \end{pmatrix}$$

are primitive. By the inductive hypothesis there is an integral 2×2 matrix $\mathbf{V}$ with

$$\begin{pmatrix} u_1 \\ d \end{pmatrix}$$

as its first column, and an integral $(n-1) \times (n-1)$ matrix $\mathbf{Z}$ with $\mathbf{z}$ as its first column, with $\det \mathbf{V} = 1$ and $\det \mathbf{Z} = 1$.

Now put

$$\mathbf{P} = \begin{pmatrix} 1 & \\ & \mathbf{Z} \end{pmatrix} \begin{pmatrix} \mathbf{V} & \\ & \mathbf{I}_{n-2} \end{pmatrix},$$

i.e.

$$\mathbf{P} = \begin{pmatrix} 1 & 0 & 0 & . & 0 \\ 0 & z_2 & * & . & * \\ 0 & z_3 & * & . & * \\ . & . & . & . & . \\ 0 & z_n & * & . & * \end{pmatrix} \begin{pmatrix} u_1 & * & 0 & . & 0 \\ d & * & 0 & . & 0 \\ 0 & 0 & 1 & . & 0 \\ . & . & . & . & . \\ 0 & 0 & 0 & . & 1 \end{pmatrix}.$$

The first column of $\mathbf{P}$ is

$$\begin{pmatrix} u_1 \\ dz_2 \\ . \\ . \\ dz_n \end{pmatrix} = \mathbf{u},$$

and its determinant is 1, QED.

The incremental step from dimension $n-1$ to dimension n is the construction of 2×2 matrix $\mathbf{V}$, for which there exist infinitely many solutions labelled by an integer m_{n-1}. Therefore, the collection of matrices $\mathbf{P}$ which solve the problem is labelled by $n-1$ arbitrary integers $(m_1, m_2, \ldots, m_{n-1})$. This freedom can be used to adjust the shape of the basis B.

Once $\mathbf{P}$ has been chosen, the calculation of general sections and projections is transformed into that of *principal* sections and projections by the changes of coordinates:

$$\mathbf{x} = \mathbf{P}\mathbf{x}', \qquad \mathbf{h} = \mathbf{P}^*\mathbf{h}',$$

and an appeal to the tensor product property.

Booth (1945*a*) made use of the convolution theorem to form the Fourier coefficients of 'bounded projections', which provided a compromise between 2D and 3D Fourier syntheses. If it is desired to compute the projection on the (x, y) plane of the electron density lying between the planes $z = z_1$ and $z = z_2$, which may be written as

$$[\rho \times (\mathbf{1}_x \otimes \mathbf{1}_y \otimes \chi_{[z_1, z_2]})] * (\delta_x \otimes \delta_y \otimes \mathbf{1}_z).$$

The transform is then

$$[F * (\delta_h \otimes \delta_k \otimes \bar{\mathscr{F}}[\chi_{[z_1, z_2]}])] \times (\mathbf{1}_h \otimes \mathbf{1}_k \otimes \delta_l),$$

giving for coefficient (h, k):

$$\sum_{l \in \mathbb{Z}} F(h, k, l) \exp\{2\pi i l[(z_1 + z_2)/2]\} \times \frac{\sin \pi l(z_1 - z_2)}{\pi l}.$$

1.3.4.2.1.9. Differential syntheses

Another particular instance of the convolution theorem is the duality between differentiation and multiplication by a monomial (Sections 1.3.2.4.2.8, 1.3.2.5.8).

In the present context, this result may be written

$$\bar{\mathscr{F}}\left[\frac{\partial^{m_1+m_2+m_3}\rho}{\partial X_1^{m_1}\partial X_2^{m_2}\partial X_3^{m_3}}\right](\mathbf{H}) = (-2\pi i)^{m_1+m_2+m_3} H_1^{m_1} H_2^{m_2} H_3^{m_3} F(\mathbf{A}^T\mathbf{H})$$

in Cartesian coordinates, and

$$\bar{\mathscr{F}}\left[\frac{\partial^{m_1+m_2+m_3}\rho}{\partial x_1^{m_1}\partial x_2^{m_2}\partial x_3^{m_3}}\right](\mathbf{h}) = (-2\pi i)^{m_1+m_2+m_3} h_1^{m_1} h_2^{m_2} h_3^{m_3} F(\mathbf{h})$$

in crystallographic coordinates.

A particular case of the first formula is

$$-4\pi^2 \sum_{\mathbf{H} \in \Lambda^*} \|\mathbf{H}\|^2 F(\mathbf{A}^T\mathbf{H}) \exp(-2\pi i \mathbf{H} \cdot \mathbf{X}) = \Delta\rho(\mathbf{X}),$$

where

$$\Delta\rho = \sum_{j=1}^{3} \frac{\partial^2 \rho}{\partial X_j^2}$$

is the Laplacian of ρ.

The second formula has been used with $|\mathbf{m}| = 1$ or 2 to compute 'differential syntheses' and refine the location of maxima (or other stationary points) in electron-density maps. Indeed, the values at $\mathbf{x}$ of the gradient vector $\nabla\rho$ and Hessian matrix $(\nabla\nabla^T)\rho$ are readily obtained as

$$(\nabla\rho)(\mathbf{x}) = \sum_{\mathbf{h} \in \mathbb{Z}^3} (-2\pi i \mathbf{h}) F(\mathbf{h}) \exp(-2\pi i \mathbf{h} \cdot \mathbf{x}),$$
$$[(\nabla\nabla^T)\rho](\mathbf{x}) = \sum_{\mathbf{h} \in \mathbb{Z}^3} (-4\pi^2 \mathbf{h}\mathbf{h}^T) F(\mathbf{h}) \exp(-2\pi i \mathbf{h} \cdot \mathbf{x}),$$

and a step of Newton iteration towards the nearest stationary point of ρ will proceed by

$$\mathbf{x} \longmapsto \mathbf{x} - \{[(\nabla\nabla^T)\rho](\mathbf{x})\}^{-1}(\nabla\rho)(\mathbf{x}).$$

The modern use of Fourier transforms to speed up the computation of derivatives for model refinement will be described in Section 1.3.4.4.7.

The converse property is also useful: it relates the derivatives of the continuous transform $\bar{\mathscr{F}}[\rho^0]$ to the moments of ρ^0:

$$\frac{\partial^{m_1+m_2+m_3}\bar{\mathscr{F}}[\rho^0]}{\partial X_1^{m_1}\partial X_2^{m_2}\partial X_3^{m_3}}(\mathbf{H}) = \bar{\mathscr{F}}[(2\pi i)^{m_1+m_2+m_3} X_1^{m_1} X_2^{m_2} X_3^{m_3} \rho_{\mathbf{x}}^0](\mathbf{H}).$$

For $|\mathbf{m}| = 2$ and $\mathbf{H} = \mathbf{0}$, this identity gives the well known relation between the Hessian matrix of the transform $\bar{\mathscr{F}}[\rho^0]$ at the origin of reciprocal space and the inertia tensor of the motif ρ^0. This is a particular case of the moment-generating properties of $\bar{\mathscr{F}}$, which will be further developed in Section 1.3.4.5.2.

1.3.4.2.1.10. Toeplitz forms, determinantal inequalities and Szegö's theorem

The classical results presented in Section 1.3.2.6.9 can be readily generalized to the case of triple Fourier series; no new concept is needed, only an obvious extension of the notation.

Let ρ be real-valued, so that Friedel's law holds and $F(-\mathbf{h}) = \overline{F(\mathbf{h})}$. Let H be a finite set of indices comprising the origin: $\mathsf{H} = \{\mathbf{h}_0 = \mathbf{0}, \mathbf{h}_1, \ldots, \mathbf{h}_n\}$. Then the Hermitian form in $n+1$ complex variables

$$T_{\mathsf{H}}[\rho](\mathbf{u}) = \sum_{j,\,k=0}^{n} F(\mathbf{h}_j - \mathbf{h}_k)\overline{u_j}u_k$$

is called the Toeplitz form of order H associated to ρ. By the convolution theorem and Parseval's identity,

$$T_{\mathsf{H}}[\rho](\mathbf{u}) = \int_{\mathbb{R}^3/\mathbb{Z}^3} \rho(\mathbf{x}) \left| \sum_{j=0}^{n} u_j \exp(2\pi i \mathbf{h}_j \cdot \mathbf{x}) \right|^2 \mathrm{d}^3\mathbf{x}.$$

If ρ is almost everywhere non-negative, then for all H the forms $T_{\mathsf{H}}[\rho]$ are positive semi-definite and therefore all Toeplitz determinants $D_{\mathsf{H}}[\rho]$ are non-negative, where

$$D_{\mathsf{H}}[\mathscr{P}] = \det\{[F(\mathbf{h}_j - \mathbf{h}_k)]\}.$$

The Toeplitz–Carathéodory–Herglotz theorem given in Section 1.3.2.6.9.2 states that the converse is true: if $D_{\mathsf{H}}[\rho] \geq 0$ for all H, then $\mathscr{P}$ is almost everywhere non-negative. This result is known in the crystallographic literature through the papers of Karle & Hauptman (1950), MacGillavry (1950), and Goedkoop (1950), following previous work by Harker & Kasper (1948) and Gillis (1948*a*,*b*).

Szegö's study of the asymptotic distribution of the eigenvalues of Toeplitz forms as their order tends to infinity remains valid. Some precautions are needed, however, to define the notion of a sequence (H_k) of finite subsets of indices tending to infinity: it suffices that the H_k should consist essentially of the reciprocal-lattice points $\mathbf{h}$ contained within a domain of the form $k\Omega$ (k-fold dilation of Ω) where Ω is a convex domain in $\mathbb{R}^3$ containing the origin (Widom, 1960). Under these circumstances, the eigenvalues $\lambda_\nu^{(n)}$ of the Toeplitz forms $T_{\mathsf{H}_k}[\mathscr{P}]$ become equidistributed with the sample values $\mathscr{P}_\nu^{(n)}$ of $\mathscr{P}$ on a grid satisfying the Shannon sampling criterion for the data in H_k (*cf.* Section 1.3.2.6.9.3).

A particular consequence of this equidistribution is that the geometric means of the $\lambda_\nu^{(n)}$ and of the $\mathscr{P}_\nu^{(n)}$ are equal, and hence as in Section 1.3.2.6.9.4

$$\lim_{k\to\infty}\{D_{\mathsf{H}_k}[\mathscr{P}]\}^{1/|\mathsf{H}_k|} = \exp\left\{\int_{\mathbb{R}^3/\mathbb{Z}^3} \log \mathscr{P}(\mathbf{x})\, \mathrm{d}^3\mathbf{x}\right\},$$

where $|\mathsf{H}_k|$ denotes the number of reflections in H_k. Complementary terms giving a better comparison of the two sides were obtained by Widom (1960, 1975) and Linnik (1975).

This formula played an important role in the solution of the 2D Ising model by Onsager (1944) (see Montroll *et al.*, 1963). It is also encountered in phasing methods involving the 'Burg entropy' (Britten & Collins, 1982; Narayan & Nityananda, 1982; Bricogne, 1982, 1984, 1988).

1.3.4.2.2. Crystal symmetry

1.3.4.2.2.1. Crystallographic groups

The description of a crystal given so far has dealt only with its invariance under the action of the (discrete Abelian) group of translations by vectors of its period lattice Λ.

Let the crystal now be embedded in Euclidean 3-space, so that it may be acted upon by the group $M(3)$ of rigid (*i.e.* distance-preserving) motions of that space. The group $M(3)$ contains a normal subgroup $T(3)$ of translations, and the quotient group $M(3)/T(3)$ may be identified with the 3-dimensional orthogonal group $O(3)$. The period lattice Λ of a crystal is a discrete uniform subgroup of $T(3)$.

The possible invariance properties of a crystal under the action of $M(3)$ are captured by the following definition: a *crystallographic group* is a subgroup Γ of $M(3)$ if

(i) $\Gamma \cap T(3) = \Lambda$, a period lattice and a normal subgroup of Γ;

(ii) the factor group $G = \Gamma/\Lambda$ is finite.

The two properties are not independent: by a theorem of Bieberbach (1911), they follow from the assumption that Λ is a discrete subgroup of $M(3)$ which operates without accumulation point and with a compact fundamental domain (see Auslander, 1965). These two assumptions imply that G acts on Λ through an integral representation, and this observation leads to a complete enumeration of all distinct Γ's. The mathematical theory of these groups is still an active research topic (see, for instance, Farkas, 1981), and has applications to Riemannian geometry (Wolf, 1967).

This classification of crystallographic groups is described elsewhere in these *Tables* (Wondratschek, 2005), but it will be surveyed briefly in Section 1.3.4.2.2.3 for the purpose of establishing further terminology and notation, after recalling basic notions and results concerning groups and group actions in Section 1.3.4.2.2.2.

1.3.4.2.2.2. Groups and group actions

The books by Hall (1959) and Scott (1964) are recommended as reference works on group theory.

(*a*) *Left and right actions*

Let G be a group with identity element e, and let X be a set. An *action* of G on X is a mapping from $G \times X$ to X with the property that, if $g\,x$ denotes the image of (g, x), then

(i) $(g_1g_2)x = g_1(g_2x)$ for all $g_1, g_2 \in G$ and all $x \in X$,

(ii) $ex = x$ for all $x \in X$.

An element g of G thus induces a mapping T_g of X into itself defined by $T_g(x) = gx$, with the 'representation property':

(iii) $T_{g_1g_2} = T_{g_1}T_{g_2}$ for all $g_1, g_2 \in G$.

Since G is a group, every g has an inverse g^{-1}; hence every mapping T_g has an inverse $T_{g^{-1}}$, so that each T_g is a permutation of X.

Strictly speaking, what has just been defined is a *left* action. A *right* action of G on X is defined similarly as a mapping $(g, x) \longmapsto xg$ such that

(i′) $x(g_1g_2) = (xg_1)g_2$ for all $g_1, g_2 \in G$ and all $x \in X$,

(ii′) $xe = x$ for all $x \in X$.

The mapping T'_g defined by $T'_g(x) = xg$ then has the 'right-representation' property:

(iii′) $T'_{g_1g_2} = T'_{g_2}T'_{g_1}$ for all $g_1, g_2 \in G$.

The essential difference between left and right actions is of course not whether the elements of G are written on the left or right of those of X: it lies in the difference between (iii) and (iii′). In a left action the product g_1g_2 in G operates on $x \in X$ by g_2 operating first, then g_1 operating on the result; in a right action, g_1 operates first, then g_2. This distinction will be of importance in Sections 1.3.4.2.2.4 and 1.3.4.2.2.5. In the sequel, we will use left actions unless otherwise stated.

(*b*) *Orbits and isotropy subgroups*

Let x be a fixed element of X. Two fundamental entities are associated to x:

(1) the subset of G consisting of all g such that $gx = x$ is a subgroup of G, called the *isotropy subgroup* of x and denoted G_x;

(2) the subset of X consisting of all elements gx with g running through G is called the *orbit* of x under G and is denoted Gx.

Through these definitions, the action of G on X can be related to the internal structure of G, as follows. Let G/G_x denote the collection of distinct left cosets of G_x in G, *i.e.* of distinct subsets of G of the form gG_x. Let $|G|$, $|G_x|$, $|Gx|$ and $|G/G_x|$ denote the numbers of elements in the corresponding sets. The number $|G/G_x|$ of distinct cosets of G_x in G is also denoted $[G : G_x]$ and is called the *index* of G_x in G; by Lagrange's theorem

$$[G : G_x] = |G/G_x| = \frac{|G|}{|G_x|}.$$

Now if g_1 and g_2 are in the same coset of G_x, then $g_2 = g_1 g'$ with $g' \in G_x$, and hence $g_1 x = g_2 x$; the converse is obviously true. Therefore, the mapping from cosets to orbit elements

$$gG_x \longmapsto gx$$

establishes a one-to-one correspondence between the distinct left cosets of G_x in G and the elements of the orbit of x under G. It follows that the number of distinct elements in the orbit of x is equal to the index of G_x in G:

$$|Gx| = [G : G_x] = \frac{|G|}{|G_x|},$$

and that the elements of the orbit of x may be listed without repetition in the form

$$Gx = \{\gamma x | \gamma \in G/G_x\}.$$

Similar definitions may be given for a right action of G on X. The set of distinct right cosets $G_x g$ in G, denoted $G_x\backslash G$, is then in one-to-one correspondence with the distinct elements in the orbit xG of x.

(*c*) *Fundamental domain and orbit decomposition*

The group properties of G imply that two orbits under G are either disjoint or equal. The set X may thus be written as the *disjoint* union

$$X = \bigcup_{i \in I} Gx_i,$$

where the x_i are elements of distinct orbits and I is an indexing set labelling them. The subset $D = \{x_i\}_{i \in I}$ is said to constitute a *fundamental domain* (mathematical terminology) or an *asymmetric unit* (crystallographic terminology) for the action of G on X: it contains one representative x_i of each distinct orbit. Clearly, other fundamental domains may be obtained by choosing different representatives for these orbits.

If X is finite and if f is an arbitrary complex-valued function over X, the 'integral' of f over X may be written as a sum of integrals over the distinct orbits, yielding the *orbit decomposition formula*:

$$\sum_{x \in X} f(x) = \sum_{i \in I} \left(\sum_{y_i \in Gx_i} f(y_i) \right) = \sum_{i \in I} \left(\sum_{\gamma_i \in G/G_{x_i}} f(\gamma_i x_i) \right)$$
$$= \sum_{i \in I} \frac{1}{|G_{x_i}|} \left(\sum_{g_i \in G} f(g_i x_i) \right).$$

In particular, taking $f(x) = 1$ for all x and denoting by $|X|$ the number of elements of X:

$$|X| = \sum_{i \in I} |Gx_i| = \sum_{i \in I} |G/G_{x_i}| = \sum_{i \in I} \frac{|G|}{|G_{x_i}|}.$$

(*d*) *Conjugation, normal subgroups, semi-direct products*

A group G acts on itself by *conjugation*, *i.e.* by associating to $g \in G$ the mapping C_g defined by

$$C_g(h) = ghg^{-1}.$$

Indeed, $C_g(hk) = C_g(h)C_g(k)$ and $[C_g(h)]^{-1} = C_{g^{-1}}(h)$. In particular, C_g operates on the set of subgroups of G, two subgroups H and K being called conjugate if $H = C_g(K)$ for some $g \in G$; for example, it is easily checked that $G_{gx} = C_g(G_x)$. The orbits under this action are the *conjugacy classes* of subgroups of G, and the isotropy subgroup of H under this action is called the *normalizer* of H in G.

If $\{H\}$ is a one-element orbit, H is called a *self-conjugate* or *normal* subgroup of G; the cosets of H in G then form a group G/H called the *factor group* of G by H.

Let G and H be two groups, and suppose that G acts on H by *automorphisms* of H, *i.e.* in such a way that

$$g(h_1 h_2) = g(h_1)g(h_2)$$
$$g(e_H) = e_H \qquad \text{(where } e_H \text{ is the identity element of } H\text{)}.$$
$$g(h^{-1}) = (g(h))^{-1}$$

Then the symbols $[g, h]$ with $g \in G$, $h \in H$ form a group K under the product rule:

$$[g_1, h_1][g_2, h_2] = [g_1 g_2, h_1 g_1(h_2)]$$

{associativity checks; $[e_G, e_H]$ is the identity; $[g, h]$ has inverse $[g^{-1}, g^{-1}(h^{-1})]$}. The group K is called the *semi-direct product* of H by G, denoted $K = H \rtimes G$.

The elements $[g, e_H]$ form a subgroup of K isomorphic to G, the elements $[e_G, h]$ form a normal subgroup of K isomorphic to H, and the action of G on H may be represented as an action by conjugation in the sense that

$$C_{[g, e_H]}([e_G, h]) = [e_G, g(h)].$$

A familiar example of semi-direct product is provided by the group of Euclidean motions $M(3)$ (Section 1.3.4.2.2.1). An element S of $M(3)$ may be written $S = [R, t]$ with $R \in O(3)$, the orthogonal group, and $t \in T(3)$, the translation group, and the product law

$$[R_1, t_1][R_2, t_2] = [R_1 R_2, t_1 + R_1(t_2)]$$

shows that $M(3) = T(3) \rtimes O(3)$ with $O(3)$ acting on $T(3)$ by rotating the translation vectors.

(*e*) *Associated actions in function spaces*

For every left action T_g of G in X, there is an associated left action $T_g^{\#}$ of G on the space $L(X)$ of complex-valued functions over X, defined by 'change of variable' (Section 1.3.2.3.9.5):

$$[T_g^{\#} f](x) = f((T_g)^{-1} x) = f(g^{-1} x).$$

Indeed for any g_1, g_2 in G,

$$[T_{g_1}^{\#}[T_{g_2}^{\#} f]](x) = [T_{g_2}^{\#} f]((T_{g_1})^{-1} x) = f[T_{g_2}^{-1} T_{g_1}^{-1} x]$$
$$= f((T_{g_1} T_{g_2})^{-1} x);$$

since $T_{g_1} T_{g_2} = T_{g_1 g_2}$, it follows that

$$T^{\#}_{g_1} T^{\#}_{g_2} = T^{\#}_{g_1 g_2}.$$

It is clear that the change of variable must involve the action of g^{-1} (not g) if $T^{\#}$ is to define a *left* action; using g instead would yield a *right* action.

The linear representation operators $T^{\#}_g$ on $L(X)$ provide the most natural instrument for stating and exploiting symmetry properties which a function may possess with respect to the action of G. Thus a function $f \in L(X)$ will be called *G-invariant* if $f(gx) = f(x)$ for all $g \in G$ and all $x \in X$. The value $f(x)$ then depends on x only through its orbit $G\,x$, and f is uniquely defined once it is specified on a fundamental domain $D = \{x_i\}_{i \in I}$; its integral over X is then a weighted sum of its values in D:

$$\sum_{x \in X} f(x) = \sum_{i \in I} [G : G_{x_i}] f(x_i).$$

The G-invariance of f may be written:

$$T^{\#}_g f = f \quad \text{for all } g \in G.$$

Thus f is invariant under each $T^{\#}_g$, which obviously implies that f is invariant under the linear operator in $L(X)$

$$A_G = \frac{1}{|G|} \sum_{g \in G} T^{\#}_g,$$

which averages an arbitrary function by the action of G. Conversely, if $A_G f = f$, then

$$T^{\#}_{g_0} f = T^{\#}_{g_0}(A_G f) = (T^{\#}_{g_0} A_G) f = A_G f = f \quad \text{for all } g_0 \in G,$$

so that the two statements of the G-invariance of f are equivalent. The identity

$$T^{\#}_{g_0} A_G = A_G \quad \text{for all } g_0 \in G$$

is easily proved by observing that the map $g \longmapsto g_0 g$ (g_0 being any element of G) is a one-to-one map from G into itself, so that

$$\sum_{g \in G} T^{\#}_g = \sum_{g \in G} T^{\#}_{g_0 g}$$

as these sums differ only by the order of the terms. The same identity implies that A_G is a *projector*:

$$(A_G)^2 = A_G,$$

and hence that its eigenvalues are either 0 or 1. In summary, we may say that the invariance of f under G is equivalent to f being an eigenfunction of the associated projector A_G for eigenvalue 1.

(f) *Orbit exchange*

One final result about group actions which will be used repeatedly later is concerned with the case when X has the structure of a Cartesian product:

$$X = X_1 \times X_2 \times \ldots \times X_n$$

and when G acts *diagonally* on X, *i.e.* acts on each X_j separately:

$$gx = g(x_1, x_2, \ldots, x_n) = (gx_1, gx_2, \ldots, gx_n).$$

Then complete sets (but not usually minimal sets) of representatives of the distinct orbits for the action of G in X may be obtained in the form

$$D_k = X_1 \times \ldots \times X_{k-1} \times \{x^{(k)}_{i_k}\}_{i_k \in I_k} \times X_{k+1} \times \ldots \times X_n$$

for each $k = 1, 2, \ldots, n$, *i.e.* by taking a fundamental domain in X_k and all the elements in X_j with $j \neq k$. The action of G on each D_k does indeed generate the whole of X: given an arbitrary element $y = (y_1, y_2, \ldots, y_n)$ of X, there is an index $i_k \in I_k$ such that $y_k \in G x^{(k)}_{i_k}$ and a coset of $G_{x^{(k)}_{i_k}}$ in G such that $y_k = \gamma x^{(k)}_{i_k}$ for any representative γ of that coset; then

$$y = \gamma(\gamma^{-1} y_1, \ldots, \gamma^{-1} y_{k-1}, x^{(k)}_{i_k}, \gamma^{-1} y_{k+1}, \ldots, \gamma^{-1} y_n)$$

which is of the form $y = \gamma d_k$ with $d_k \in D_k$.

The various D_k are related in a simple manner by 'transposition' or 'orbit exchange' (the latter name is due to J. W. Cooley). For instance, D_j may be obtained from $D_k (j \neq k)$ as follows: for each $y_j \in X_j$ there exists $g(y_j) \in G$ and $i_j(y_j) \in I_j$ such that $y_j = g(y_j) x^{(j)}_{i_j(y_j)}$; therefore

$$D_j = \bigcup_{y_j \in X_j} [g(y_j)]^{-1} D_k,$$

since the fundamental domain of X_k is thus expanded to the whole of X_k, while X_j is reduced to its fundamental domain. In other words: orbits are simultaneously collapsed in the jth factor and expanded in the kth.

When G operates without fixed points in each X_k (*i.e.* $G_{x_k} = \{e\}$ for all $x_k \in X_k$), then each D_k is a fundamental domain for the action of G in X. The existence of fixed points in some or all of the X_k complicates the situation in that for each k and each $x_k \in X_k$ such that $G_{x_k} \neq \{e\}$ the action of G/G_{x_k} on the other factors must be examined. Shenefelt (1988) has made a systematic study of orbit exchange for space group $P622$ and its subgroups.

Orbit exchange will be encountered, in a great diversity of forms, as the basic mechanism by which intermediate results may be rearranged between the successive stages of the computation of crystallographic Fourier transforms (Section 1.3.4.3).

1.3.4.2.2.3. Classification of crystallographic groups

Let Γ be a crystallographic group, Λ the normal subgroup of its lattice translations, and G the finite factor group Γ/Λ. Then G acts on Λ by conjugation [Section 1.3.4.2.2.2(d)] and this action, being a mapping of a lattice into itself, is representable by matrices with integer entries.

The classification of crystallographic groups proceeds from this observation in the following three steps:

Step 1: find all possible finite abstract groups G which can be represented by 3×3 integer matrices.

Step 2: for each such G find all its inequivalent representations by 3×3 integer matrices, equivalence being defined by a change of primitive lattice basis (*i.e.* conjugation by a 3×3 integer matrix with determinant ± 1).

Step 3: for each G and each equivalence class of integral representations of G, find all inequivalent extensions of the action of G from Λ to $T(3)$, equivalence being defined by an affine coordinate change [*i.e.* conjugation by an element of $A(3)$].

Step 1 leads to the following groups, listed in association with the crystal system to which they later give rise:

$\mathbb{Z}/2\mathbb{Z}$	monoclinic
$\mathbb{Z}/2\mathbb{Z} \oplus \mathbb{Z}/2\mathbb{Z}$	orthorhombic
$\mathbb{Z}/3\mathbb{Z}, (\mathbb{Z}/3\mathbb{Z}) \ltimes\{\alpha\}$	trigonal
$\mathbb{Z}/4\mathbb{Z}, (\mathbb{Z}/4\mathbb{Z}) \ltimes\{\alpha\}$	tetragonal
$\mathbb{Z}/6\mathbb{Z}, (\mathbb{Z}/6\mathbb{Z}) \ltimes\{\alpha\}$	hexagonal
$(\mathbb{Z}/2\mathbb{Z} \oplus \mathbb{Z}/2\mathbb{Z}) \ltimes\{S_3\}$	cubic

and the extension of these groups by a centre of inversion. In this list $\ltimes$ denotes a semi-direct product [Section 1.3.4.2.2.2(d)], α denotes the automorphism $g \longmapsto g^{-1}$, and S_3 (the group of permutations on three letters) operates by permuting the copies of $\mathbb{Z}/2\mathbb{Z}$ (using the subgroup A_3 of cyclic permutations gives the tetrahedral subsystem).

Step 2 leads to a list of 73 equivalence classes called *arithmetic classes* of representations $g \longmapsto \mathbf{R}_g$, where $\mathbf{R}_g$ is a 3×3 integer matrix, with $\mathbf{R}_{g_1 g_2} = \mathbf{R}_{g_1}\mathbf{R}_{g_2}$ and $\mathbf{R}_e = \mathbf{I}_3$. This enumeration is more familiar if equivalence is relaxed so as to allow conjugation by *rational* 3×3 matrices with determinant ± 1: this leads to the 32 crystal classes. The difference between an arithmetic class and its rational class resides in the choice of a lattice mode (P, $A/B/C$, I, F or R). Arithmetic classes always refer to a primitive lattice, but may use inequivalent integral representations for a given geometric symmetry element; while crystallographers prefer to change over to a nonprimitive lattice, if necessary, in order to preserve the same integral representation for a given geometric symmetry element. The matrices $\mathbf{P}$ and $\mathbf{Q} = \mathbf{P}^{-1}$ describing the changes of basis between primitive and centred lattices are listed in Table 5.1.3.1 and illustrated in Figs. 5.1.3.2 to 5.1.3.8, pp. 80–85, of Volume A of *International Tables* (Arnold, 2005).

Step 3 gives rise to a system of congruences for the systems of nonprimitive translations $\{\mathbf{t}_g\}_{g\in G}$ which may be associated to the matrices $\{\mathbf{R}_g\}_{g\in G}$ of a given arithmetic class, namely:

$$\mathbf{t}_{g_1 g_2} \equiv \mathbf{R}_{g_1}\mathbf{t}_{g_2} + \mathbf{t}_{g_1} \bmod \Lambda,$$

first derived by Frobenius (1911). If equivalence under the action of $A(3)$ is taken into account, 219 classes are found. If equivalence is defined with respect to the action of the subgroup $A^+(3)$ of $A(3)$ consisting only of transformations with determinant +1, then 230 classes called *space-group types* are obtained. In particular, associating to each of the 73 arithmetic classes a trivial set of nonprimitive translations ($\mathbf{t}_g = \mathbf{0}$ for all $g \in G$) yields the 73 symmorphic space groups. This third step may also be treated as an abstract problem concerning group extensions, using cohomological methods [Ascher & Janner (1965); see Janssen (1973) for a summary]; the connection with Frobenius's approach, as generalized by Zassenhaus (1948), is examined in Ascher & Janner (1968).

The finiteness of the number of space-group types in dimension 3 was shown by Bieberbach (1912) to be the case in arbitrary dimension. The reader interested in N-dimensional space-group theory for $N > 3$ may consult Brown (1969), Brown *et al.* (1978), Schwarzenberger (1980) and Engel (1986). The standard reference for integral representation theory is Curtis & Reiner (1962).

All three-dimensional space groups G have the property of being *solvable*, *i.e.* that there exists a chain of subgroups

$$G = G_r > G_{r-1} > \ldots > G_1 > G_0 = \{e\},$$

where each G_{i-1} is a normal subgroup of G_1 and the factor group G_i/G_{i-1} is a *cyclic* group of some order m_i ($1 \le i \le r$). This property may be established by inspection, or deduced from a famous theorem of Burnside [see Burnside (1911), pp. 322–323] according to which any group G such that $|G| = p^\alpha q^\beta$, with p and q distinct primes, is solvable; in the case at hand, $p = 2$ and $q = 3$. The whole classification of 3D space groups can be performed swiftly by a judicious use of the solvability property (L. Auslander, personal communication).

Solvability facilitates the indexing of elements of G in terms of generators and relations (Coxeter & Moser, 1972; Magnus *et al.*, 1976) for the purpose of calculation. By definition of solvability, elements $g_1, g_2, \ldots, g_r$ may be chosen in such a way that the cyclic factor group G_i/G_{i-1} is generated by the coset $g_i G_{i-1}$. The set $\{g_1, g_2, \ldots, g_r\}$ is then a system of generators for G such that the defining relations [see Brown *et al.* (1978), pp. 26–27] have the particularly simple form

$$\begin{aligned} g_1^{m_1} &= e, \\ g_i^{m_i} &= g_{i-1}^{a(i,i-1)} g_{i-2}^{a(i,i-2)} \ldots g_1^{a(i,1)} && \text{for } 2 \le i \le r, \\ g_i^{-1} g_j^{-1} g_i g_j &= g_{j-1}^{b(i,j,j-1)} g_{j-2}^{b(i,j,j-2)} \ldots g_1^{b(i,j,1)} && \text{for } 1 \le i < j \le r, \end{aligned}$$

with $0 \le a(i,h) < m_h$ and $0 \le b(i,j,h) < m_h$. Each element g of G may then be obtained uniquely as an 'ordered word':

$$g = g_r^{k_r} g_{r-1}^{k_{r-1}} \ldots g_1^{k_1},$$

with $0 \le k_i < m_i$ for all $i = 1, \ldots, r$, using the algorithm of Jürgensen (1970). Such generating sets and defining relations are tabulated in Brown *et al.* (1978, pp. 61–76). An alternative list is given in Janssen (1973, Table 4.3, pp. 121–123, and Appendix D, pp. 262–271).

1.3.4.2.2.4. Crystallographic group action in real space

The action of a crystallographic group Γ may be written in terms of standard coordinates in $\mathbb{R}^3/\mathbb{Z}^3$ as

$$(g, \mathbf{x}) \longmapsto S_g(\mathbf{x}) = \mathbf{R}_g\mathbf{x} + \mathbf{t}_g \bmod \Lambda, \quad g \in G,$$

with

$$S_{g_1 g_2} = S_{g_1} S_{g_2}.$$

An important characteristic of the representation $\theta : g \longmapsto S_g$ is its *reducibility*, *i.e.* whether or not it has invariant subspaces other than $\{\mathbf{0}\}$ and the whole of $\mathbb{R}^3/\mathbb{Z}^3$. For triclinic, monoclinic and orthorhombic space groups, θ is reducible to a direct sum of three one-dimensional representations:

$$\mathbf{R}_g = \begin{pmatrix} \mathbf{R}_g^{(1)} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{R}_g^{(2)} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{R}_g^{(3)} \end{pmatrix};$$

for trigonal, tetragonal and hexagonal groups, it is reducible to a direct sum of two representations, of dimension 2 and 1, respectively; while for tetrahedral and cubic groups, it is irreducible.

By Schur's lemma (see *e.g.* Ledermann, 1987), any matrix which commutes with all the matrices $\mathbf{R}_g$ for $g \in G$ must be a scalar multiple of the identity in each invariant subspace.

In the reducible cases, the reductions involve changes of basis which will be *rational*, not integral, for those arithmetic classes corresponding to nonprimitive lattices. Thus the simplification of having maximally reduced representation has as its counterpart the use of nonprimitive lattices.

The notions of orbit, isotropy subgroup and fundamental domain (or asymmetric unit) for the action of G on $\mathbb{R}^3/\mathbb{Z}^3$ are inherited directly from the general setting of Section 1.3.4.2.2.2. Points $\mathbf{x}$ for which $G_{\mathbf{x}} \neq \{e\}$ are called *special positions*, and the various types of isotropy subgroups which may be encountered in crystallographic groups have been labelled by means of Wyckoff symbols. The representation operators $S_g^{\#}$ in $L(\mathbb{R}^3/\mathbb{Z}^3)$ have the form:

$$[S_g^{\#} f](\mathbf{x}) = f\,[S_g^{-1}(\mathbf{x})] = f\,[\mathbf{R}_g^{-1}(\mathbf{x} - \mathbf{t}_g)].$$

The operators $R_g^{\#}$ associated to the purely rotational part of each transformation S_g will also be used. Note the relation: $S_g^{\#} = \tau_{\mathbf{t}_g} R_g^{\#}$.

Let a crystal structure be described by the list of the atoms in its unit cell, indexed by $k \in K$. Let the electron-density distribution about the centre of mass of atom k be described by ρ_k with respect to the standard coordinates $\mathbf{x}$. Then the motif ρ^0 may be written as a sum of translates:

$$\rho^0 = \sum_{k \in K} \tau_{\mathbf{x}_k} \rho_k$$

and the crystal electron density is $\rho = r^* \rho^0$.

Suppose that ρ is invariant under Γ. If $\mathbf{x}_{k_1}$ and $\mathbf{x}_{k_2}$ are in the same orbit, say $\mathbf{x}_{k_2} = S_g(\mathbf{x}_{k_1})$, then

$$\tau_{\mathbf{x}_{k_2}} \rho_{k_2} = S_g^{\#}(\tau_{\mathbf{x}_{k_1}} \rho_{k_1}).$$

Therefore if $\mathbf{x}_k$ is a special position and thus $G_{\mathbf{x}_k} \neq \{e\}$, then

$$S_g^{\#}(\tau_{\mathbf{x}_k} \rho_k) = \tau_{\mathbf{x}_k} \rho_k \quad \text{for all } g \in G_{\mathbf{x}_k}.$$

This identity implies that

$$\mathbf{R}_g \mathbf{x}_k + \mathbf{t}_g \equiv \mathbf{x}_k \bmod \Lambda$$

(the special position condition), and that

$$\rho_k = R_g^{\#} \rho_k,$$

i.e. that ρ_k must be invariant by the pure rotational part of $G_{\mathbf{x}_k}$. Trueblood (1956) investigated the consequences of this invariance on the thermal vibration tensor of an atom in a special position (see Section 1.3.4.2.2.6 below).

Let J be a subset of K such that $\{\mathbf{x}_j\}_{j \in J}$ contains exactly one atom from each orbit. An orbit decomposition yields an expression for ρ^0 in terms of symmetry-unique atoms:

$$\rho^0 = \sum_{j \in J} \left(\sum_{\gamma_j \in G/G_{\mathbf{x}_j}} S_{\gamma_j}^{\#}(\tau_{\mathbf{x}_j} \rho_j) \right)$$

or equivalently

$$\rho^0(\mathbf{x}) = \sum_{j \in J} \left\{ \sum_{\gamma_j \in G/G_{\mathbf{x}_j}} \rho_j[\mathbf{R}_{\gamma_j}^{-1}(\mathbf{x} - \mathbf{t}_{\gamma_j}) - \mathbf{x}_j] \right\}.$$

If the atoms are assumed to be Gaussian, write

$$\rho_j(\mathbf{X}) = \frac{Z_j}{|\det \pi \mathbf{U}_j|^{1/2}} \times \exp(-\tfrac{1}{2}\mathbf{X}^T \mathbf{U}_j^{-1} \mathbf{X}) \text{ in Cartesian Å coordinates,}$$

where Z_j is the total number of electrons, and where the matrix $\mathbf{U}_j$ combines the Gaussian spread of the electrons in atom j at rest with the covariance matrix of the random positional fluctuations of atom j caused by thermal agitation.

In crystallographic coordinates:

$$\rho_j(\mathbf{x}) = \frac{Z_j}{|\det \pi \mathbf{Q}_j|^{1/2}} \times \exp(-\tfrac{1}{2}\mathbf{x}^T \mathbf{Q}_j^{-1} \mathbf{x}) \text{ with } \mathbf{Q}_j = \mathbf{A}^{-1} \mathbf{U}_j (\mathbf{A}^{-1})^T.$$

If atom k is in a special position $\mathbf{x}_k$, then the matrix $\mathbf{Q}_k$ must satisfy the identity

$$\mathbf{R}_g \mathbf{Q}_k \mathbf{R}_g^{-1} = \mathbf{Q}_k$$

for all g in the isotropy subgroup of $\mathbf{x}_k$. This condition may also be written in Cartesian coordinates as

$$\mathbf{T}_g \mathbf{U}_k \mathbf{T}_g^{-1} = \mathbf{U}_k,$$

where

$$\mathbf{T}_g = \mathbf{A} \mathbf{R}_g \mathbf{A}^{-1}.$$

This is a condensed form of the symmetry properties derived by Trueblood (1956).

1.3.4.2.2.5. Crystallographic group action in reciprocal space

An elementary discussion of this topic may be found in Chapter 1.4 of this volume.

Having established that the symmetry of a crystal may be most conveniently stated and handled *via* the left representation $g \longmapsto S_g^{\#}$ of G given by its action on electron-density distributions, it is natural to transpose this action by the identity of Section 1.3.2.5.5:

$$\bar{\mathscr{F}}[S_g^{\#} T]_{\xi} = \bar{\mathscr{F}}[\tau_{\mathbf{t}_g}(R_g^{\#} T)]_{\xi} = \exp(2\pi i \boldsymbol{\xi} \cdot \mathbf{t}_g)[(\mathbf{R}_g^{-1})^{T\#} \bar{\mathscr{F}}[T]]_{\xi}$$

for any tempered distribution T, *i.e.*

$$\bar{\mathscr{F}}[S_g^{\#} T](\boldsymbol{\xi}) = \exp(2\pi i \boldsymbol{\xi} \cdot \mathbf{t}_g) \bar{\mathscr{F}}[T](\mathbf{R}_g^T \boldsymbol{\xi})$$

whenever the transforms are functions.

Putting $T = \rho$, a $\mathbb{Z}^3$-periodic distribution, this relation defines a left action S_g^* of G on $L(\mathbb{Z}^3)$ given by

$$(S_g^* F)(\mathbf{h}) = \exp(2\pi i \boldsymbol{\xi} \cdot \mathbf{t}_g) F(\mathbf{R}_g^T \mathbf{h})$$

which is conjugate to the action $S_g^{\#}$ in the sense that

$$\bar{\mathscr{F}}[S_g^{\#} \rho] = S_g^* \bar{\mathscr{F}}[\rho], \quad \textit{i.e. } S_g^* = \bar{\mathscr{F}} S_g^{\#} \bar{\mathscr{F}}.$$

The identity $S_g^{\#}\wp = \wp$ expressing the G-invariance of $\wp$ is then equivalent to the identity $S_g^* F = F$ between its structure factors, *i.e.* (Waser, 1955*a*)

$$F(\mathbf{h}) = \exp(2\pi i \mathbf{h}\cdot\mathbf{t}_g) F(\mathbf{R}_g^T \mathbf{h}).$$

If G is made to act on $\mathbb{Z}^3$ *via*

$$\theta^* : \quad (g, \mathbf{h}) \longmapsto (\mathbf{R}_g^{-1})^T \mathbf{h},$$

the usual notions of orbit, isotropy subgroup (denoted $G_{\mathbf{h}}$) and fundamental domain may be attached to this action. The above relation then shows that the spectrum $\{F(\mathbf{h})\}_{\mathbf{h}\in\mathbb{Z}^3}$ is entirely known if it is specified on a fundamental domain D^* containing one reciprocal-lattice point from each orbit of this action.

A reflection $\mathbf{h}$ is called *special* if $G_{\mathbf{h}} \neq \{e\}$. Then for any $g \in G_{\mathbf{h}}$ we have $\mathbf{R}_g^T \mathbf{h} = \mathbf{h}$, and hence

$$F(\mathbf{h}) = \exp(2\pi i \mathbf{h}\cdot\mathbf{t}_g) F(\mathbf{h}),$$

implying that $F(\mathbf{h}) = 0$ unless $\mathbf{h}\cdot\mathbf{t}_g \equiv 0 \bmod 1$. Special reflections $\mathbf{h}$ for which $\mathbf{h}\cdot\mathbf{t}_g \not\equiv 0 \bmod 1$ for some $g \in G_{\mathbf{h}}$ are thus *systematically absent*. This phenomenon is an instance of the duality between periodization and decimation of Section 1.3.2.7.2: if $\mathbf{t}_g \neq \mathbf{0}$, the projection of $\wp$ on the direction of $\mathbf{h}$ has period $(\mathbf{t}_g\cdot\mathbf{h})/(\mathbf{h}\cdot\mathbf{h}) < 1$, hence its transform (which is the portion of F supported by the central line through $\mathbf{h}$) will be decimated, giving rise to the above condition.

A reflection $\mathbf{h}$ is called *centric* if $G\mathbf{h} = G(-\mathbf{h})$, *i.e.* if the orbit of $\mathbf{h}$ contains $-\mathbf{h}$. Then $\mathbf{R}_\gamma^T \mathbf{h} = -\mathbf{h}$ for some coset γ in $G/G_{\mathbf{h}}$, so that the following relation must hold:

$$|F(\mathbf{h})| \exp(i\varphi_{\mathbf{h}}) = \exp(2\pi i \mathbf{h}\cdot\mathbf{t}_\gamma) |F(-\mathbf{h})| \exp(i\varphi_{-\mathbf{h}}).$$

In the absence of dispersion, Friedel's law gives rise to the *phase restriction*:

$$\varphi_{\mathbf{h}} \equiv \pi \mathbf{h}\cdot\mathbf{t}_\gamma \bmod \pi.$$

The value of the restricted phase is independent of the choice of coset representative γ. Indeed, if γ' is another choice, then $\gamma' = g\gamma$ with $g \in G_{\mathbf{h}}$ and by the Frobenius congruences $\mathbf{t}_{\gamma'} = \mathbf{R}_g \mathbf{t}_\gamma + \mathbf{t}_g$, so that

$$\mathbf{h}\cdot\mathbf{t}_{\gamma'} \equiv (\mathbf{R}_g^T \mathbf{h})\cdot\mathbf{t}_\gamma + \mathbf{h}\cdot\mathbf{t}_g \bmod 1.$$

Since $g \in G_{\mathbf{h}}$, $\mathbf{R}_g^T \mathbf{h} = \mathbf{h}$ and $\mathbf{h}\cdot\mathbf{t}_g \equiv 0 \bmod 1$ if $\mathbf{h}$ is not a systematic absence: thus

$$\pi \mathbf{h}\cdot\mathbf{t}_\gamma \equiv \pi \mathbf{h}\cdot\mathbf{t}_{\gamma'} \bmod \pi.$$

The treatment of centred lattices may be viewed as another instance of the duality between periodization and decimation (Section 1.3.2.7.2): the periodization of the electron density by the nonprimitive lattice translations has as its counterpart in reciprocal space the decimation of the transform by the 'reflection conditions' describing the allowed reflections, the decimation and periodization matrices being each other's contragredient.

The reader may consult the papers by Bienenstock & Ewald (1962) and Wells (1965) for earlier approaches to this material.

1.3.4.2.2.6. Structure-factor calculation

Structure factors may be calculated from a list of symmetry-unique atoms by Fourier transformation of the orbit decomposition formula for the motif $\wp^0$ given in Section 1.3.4.2.2.4:

$$\begin{aligned}
F(\mathbf{h}) &= \bar{\mathscr{F}}[\wp^0](\mathbf{h}) \\
&= \bar{\mathscr{F}}\left[\sum_{j\in J}\left(\sum_{\gamma_j\in G/G_{\mathbf{x}_j}} S_{\gamma_j}^{\#}(\tau_{\mathbf{x}_j}\wp_j)\right)\right](\mathbf{h}) \\
&= \sum_{j\in J}\sum_{\gamma_j\in G/G_{\mathbf{x}_j}} \bar{\mathscr{F}}[\tau_{\mathbf{t}_{\gamma_j}} \mathbf{R}_{\gamma_j}^{\#} \tau_{\mathbf{x}_j}\wp_j](\mathbf{h}) \\
&= \sum_{j\in J}\sum_{\gamma_j\in G/G_{\mathbf{x}_j}} \exp(2\pi i \mathbf{h}\cdot\mathbf{t}_{\gamma_j}) \\
&\quad \times [(\mathbf{R}_{\gamma_j}^{-1})^{T\#}[\exp(2\pi i \boldsymbol{\xi}\cdot\mathbf{x}_j)\bar{\mathscr{F}}[\wp_j]_\xi]](\mathbf{h}) \\
&= \sum_{j\in J}\sum_{\gamma_j\in G/G_{\mathbf{x}_j}} \exp(2\pi i \mathbf{h}\cdot\mathbf{t}_{\gamma_j}) \\
&\quad \times \exp[2\pi i (\mathbf{R}_{\gamma_j}^T \mathbf{h})\cdot\mathbf{x}_j]\bar{\mathscr{F}}[\wp_j](\mathbf{R}_{\gamma_j}^T \mathbf{h});
\end{aligned}$$

i.e. finally:

$$F(\mathbf{h}) = \sum_{j\in J}\sum_{\gamma_j\in G/G_{\mathbf{x}_j}} \exp\{2\pi i \mathbf{h}\cdot[S_{\gamma_j}(\mathbf{x}_j)]\}\bar{\mathscr{F}}[\wp_j](\mathbf{R}_{\gamma_j}^T \mathbf{h}).$$

In the case of Gaussian atoms, the atomic transforms are

$$\bar{\mathscr{F}}[\wp_j](\mathbf{h}) = Z_j \exp[-\tfrac{1}{2}\mathbf{h}^T(4\pi^2\mathbf{Q}_j)\mathbf{h}]$$

or equivalently

$$\bar{\mathscr{F}}[\rho_j](\mathbf{H}) = Z_j \exp[-\tfrac{1}{2}\mathbf{H}^T(4\pi^2\mathbf{U}_j)\mathbf{H}].$$

Two common forms of equivalent temperature factors (incorporating both atomic form and thermal motion) are

(i) isotropic B:

$$\bar{\mathscr{F}}[\wp_j](\mathbf{h}) = Z_j \exp(-\tfrac{1}{4}B_j \mathbf{H}^T\mathbf{H}),$$

so that $\mathbf{U}_j = (B_j/8\pi^2)\mathbf{I}$, or $\mathbf{Q}_j = (B_j/8\pi^2)\mathbf{A}^{-1}(\mathbf{A}^{-1})^T$;

(ii) anisotropic β's:

$$\bar{\mathscr{F}}[\wp_j](\mathbf{h}) = Z_j \exp(-\mathbf{h}^T\boldsymbol{\beta}_j\mathbf{h}),$$

so that $\boldsymbol{\beta}_j = 2\pi^2\mathbf{Q}_j = 2\pi^2\mathbf{A}^{-1}\mathbf{U}_j(\mathbf{A}^{-1})^T$, or $\mathbf{U}_j = (1/2\pi^2)\mathbf{A}\beta_j\mathbf{A}^T$.

In the first case, $\bar{\mathscr{F}}[\wp_j](\mathbf{R}_{\gamma_j}^T\mathbf{h})$ does not depend on γ_j, and therefore:

$$\begin{aligned}
F(\mathbf{h}) &= \sum_{j\in J} Z_j \exp\{-\tfrac{1}{4}B_j \mathbf{h}^T[\mathbf{A}^{-1}(\mathbf{A}^{-1})^T]\mathbf{h}\} \\
&\quad \times \sum_{\gamma_j\in G/G_{\mathbf{x}_j}} \exp\{2\pi i \mathbf{h}\cdot[S_{\gamma_j}(\mathbf{x}_j)]\}.
\end{aligned}$$

In the second case, however, no such simplification can occur:

$$\begin{aligned}
F(\mathbf{h}) &= \sum_{j\in J} Z_j \sum_{\gamma_j\in G/G_{\mathbf{x}_j}} \exp[-\mathbf{h}^T(\mathbf{R}_{\gamma_j}\boldsymbol{\beta}_j\mathbf{R}_{\gamma_j}^T)\mathbf{h}] \\
&\quad \times \exp\{2\pi i \mathbf{h}\cdot[S_{\gamma_j}(\mathbf{x}_j)]\}.
\end{aligned}$$

These formulae, or special cases of them, were derived by Rollett & Davies (1955), Waser (1955*b*), and Trueblood (1956).

The computation of structure factors by applying the discrete Fourier transform to a set of electron-density values calculated on a grid will be examined in Section 1.3.4.4.5.

1.3.4.2.2.7. Electron-density calculations

A formula for the Fourier synthesis of electron-density maps from symmetry-unique structure factors is readily obtained by orbit decomposition:

$$\begin{aligned}\rho(\mathbf{x}) &= \sum_{\mathbf{h}\in\mathbb{Z}^3} F(\mathbf{h})\exp(-2\pi i\mathbf{h}\cdot\mathbf{x}) \\ &= \sum_{l\in L}\left[\sum_{\gamma_l\in G/G_{\mathbf{h}_l}} F(\mathbf{R}_{\gamma_l}^T\mathbf{h}_l)\exp[-2\pi i(\mathbf{R}_{\gamma_l}^T\mathbf{h}_l)\cdot\mathbf{x}]\right] \\ &= \sum_{l\in L} F(\mathbf{h}_l)\left[\sum_{\gamma_l\in G/G_{\mathbf{h}_l}}\exp\{-2\pi i\mathbf{h}_l\cdot[S_{\gamma_l}(\mathbf{x})]\}\right],\end{aligned}$$

where L is a subset of $\mathbb{Z}^3$ such that $\{\mathbf{h}_l\}_{l\in L}$ contains exactly one point of each orbit for the action $\theta^*:(g,\mathbf{h})\longmapsto(\mathbf{R}_g^{-1})^T\mathbf{h}$ of G on $\mathbb{Z}^3$. The physical electron density per cubic ångström is then

$$\rho(\mathbf{X}) = \frac{1}{V}\rho(\mathbf{A}\mathbf{x})$$

with V in Å^3.

In the absence of anomalous scatterers in the crystal and of a centre of inversion $-\mathbf{I}$ in Γ, the spectrum $\{F(\mathbf{h})\}_{\mathbf{h}\in\mathbb{Z}^3}$ has an extra symmetry, namely the Hermitian symmetry expressing Friedel's law (Section 1.3.4.2.1.4). The action of a centre of inversion may be added to that of Γ to obtain further simplification in the above formula: under this extra action, an orbit $G\mathbf{h}_l$ with $\mathbf{h}_l\neq\mathbf{0}$ is either mapped into itself or into the disjoint orbit $G(-\mathbf{h}_l)$; the terms corresponding to $+\mathbf{h}_l$ and $-\mathbf{h}_l$ may then be grouped *within* the common orbit in the first case, and *between* the two orbits in the second case.

Case 1: $G(-\mathbf{h}_l)=G\mathbf{h}_l$, $\mathbf{h}_l$ is *centric*. The cosets in $G/G_{\mathbf{h}_l}$ may be partitioned into two disjoint classes by picking one coset in each of the two-coset orbits of the action of $-\mathbf{I}$. Let $(G/G_{\mathbf{h}_l})^+$ denote one such class: then the *reduced orbit*

$$\{\mathbf{R}_{\gamma_l}^T\mathbf{h}_l|\gamma_l\in(G/G_{\mathbf{h}_l})^+\}$$

contains exactly once the Friedel-unique half of the full orbit $G\mathbf{h}_l$, and thus

$$|(G/G_{\mathbf{h}_l})^+| = \tfrac{1}{2}|G/G_{\mathbf{h}_l}|.$$

Grouping the summands for $+\mathbf{h}_l$ and $-\mathbf{h}_l$ yields a real-valued summand

$$2F(\mathbf{h}_l)\sum_{\gamma_l\in(G/G_{\mathbf{h}_l})^+}\cos[2\pi\mathbf{h}_l\cdot[S_{\gamma_l}(\mathbf{x})]-\varphi_{\mathbf{h}l}].$$

Case 2: $G(-\mathbf{h}_l)\neq G\mathbf{h}_l$, $\mathbf{h}_l$ is *acentric*. The two orbits are then disjoint, and the summands corresponding to $+\mathbf{h}_l$ and $-\mathbf{h}_l$ may be grouped together into a single real-valued summand

$$2F(\mathbf{h}_l)\sum_{\gamma_l\in G/G_{\mathbf{h}_l}}\cos[2\pi\mathbf{h}_l\cdot[S_{\gamma_l}(\mathbf{x})]-\varphi_{\mathbf{h}_l}].$$

In order to reindex the collection of all summands of ρ, put

$$L = L_c\cup L_a,$$

where L_c labels the Friedel-unique centric reflections in L and L_a the acentric ones, and let L_a^+ stand for a subset of L_a containing a unique element of each pair $\{+\mathbf{h}_l,-\mathbf{h}_l\}$ for $l\in L_a$. Then

$$\begin{aligned}\rho(\mathbf{x}) &= F(\mathbf{0}) \\ &\quad+\sum_{c\in L_c}\left[2F(\mathbf{h}_c)\sum_{\gamma_c\in(G/G_{\mathbf{h}_c})^+}\cos[2\pi\mathbf{h}_c\cdot[S_{\gamma_c}(\mathbf{x})]-\varphi_{\mathbf{h}_c}]\right] \\ &\quad+\sum_{a\in L_a^+}\left[2F(\mathbf{h}_a)\sum_{\gamma_a\in G/G_{\mathbf{h}_a}}\cos[2\pi\mathbf{h}_a\cdot[S_{\gamma_a}(\mathbf{x})]-\varphi_{\mathbf{h}_a}]\right].\end{aligned}$$

1.3.4.2.2.8. Parseval's theorem with crystallographic symmetry

The general statement of Parseval's theorem given in Section 1.3.4.2.1.5 may be rewritten in terms of symmetry-unique structure factors and electron densities by means of orbit decomposition.

In reciprocal space,

$$\sum_{\mathbf{h}\in\mathbb{Z}^3}\overline{F_1(\mathbf{h})}F_2(\mathbf{h}) = \sum_{l\in L}\sum_{\gamma_l\in G/G_{\mathbf{h}_l}}\overline{F_1(\mathbf{R}_{\gamma_l}^T\mathbf{h}_l)}F_2(\mathbf{R}_{\gamma_l}^T\mathbf{h}_l);$$

for each l, the summands corresponding to the various γ_l are equal, so that the left-hand side is equal to

$$\begin{aligned}&F_1(\mathbf{0})F_2(\mathbf{0}) \\ &\quad+\sum_{c\in L_c}2|(G/G_{\mathbf{h}_c})^+|\|F_1(\mathbf{h}_c)\|F_2(\mathbf{h}_c)|\cos[\varphi_1(\mathbf{h}_c)-\varphi_2(\mathbf{h}_c)] \\ &\quad+\sum_{a\in L_a^+}2|G/G_{\mathbf{h}_a}\|F_1(\mathbf{h}_a)\|F_2(\mathbf{h}_a)|\cos[\varphi_1(\mathbf{h}_a)-\varphi_2(\mathbf{h}_a)].\end{aligned}$$

In real space, the triple integral may be rewritten as

$$\int_{\mathbb{R}^3/\mathbb{Z}^3}\overline{\rho_1(\mathbf{x})}\rho_2(\mathbf{x})\,\mathrm{d}^3\mathbf{x} = |G|\int_D\overline{\rho_1(\mathbf{x})}\rho_2(\mathbf{x})\,\mathrm{d}^3\mathbf{x}$$

(where D is the asymmetric unit) if ρ_1 and ρ_2 are smooth densities, since the set of special positions has measure zero. If, however, the integral is approximated as a sum over a G-invariant grid defined by decimation matrix $\mathbf{N}$, special positions on this grid must be taken into account:

$$\begin{aligned}&\frac{1}{|\mathbf{N}|}\sum_{\mathbf{k}\in\mathbb{Z}^3/\mathbf{N}\mathbb{Z}^3}\overline{\rho_1(\mathbf{x})}\rho_2(\mathbf{x}) \\ &\quad=\frac{1}{|\mathbf{N}|}\sum_{\mathbf{x}\in D}[G:G_{\mathbf{x}}]\overline{\rho_1(\mathbf{x})}\rho_2(\mathbf{x}) \\ &\quad=\frac{|G|}{|\mathbf{N}|}\sum_{\mathbf{x}\in D}\frac{1}{|G_{\mathbf{x}}|}\overline{\rho_1(\mathbf{x})}\rho_2(\mathbf{x}),\end{aligned}$$

where the discrete asymmetric unit D contains exactly one point in each orbit of G in $\mathbb{Z}^3/\mathbf{N}\mathbb{Z}^3$.

1.3.4.2.2.9. Convolution theorems with crystallographic symmetry

The standard convolution theorems derived in the absence of symmetry are readily seen to follow from simple properties of functions $e^{\pm}(\mathbf{h},\mathbf{x}) = \exp(\pm 2\pi i \mathbf{h}\cdot\mathbf{x})$ (denoted simply e in formulae which are valid for both signs), namely:

$$\text{(i)} \qquad e(\mathbf{h},\mathbf{x}) \times e(\mathbf{k},\mathbf{x}) = e(\mathbf{h}+\mathbf{k},\mathbf{x}),$$
$$\text{(ii)} \qquad e(\mathbf{h},\mathbf{x}) \times e(\mathbf{h},\mathbf{y}) = e(\mathbf{h},\mathbf{x}+\mathbf{y}).$$

These relations imply that the families of functions

$$\{\mathbf{x} \longmapsto e(\mathbf{h},\mathbf{x})\}_{\mathbf{h}\in\mathbb{Z}^3} \qquad \text{in real space}$$

and

$$\{\mathbf{h} \longmapsto e(\mathbf{h},\mathbf{x})\}_{\mathbf{x}\in\mathbb{R}^3/\mathbb{Z}^3} \qquad \text{in reciprocal space}$$

both generate an *algebra* of functions, *i.e.* a vector space endowed with an internal multiplication, since (i) and (ii) show how to 'linearize products'.

Friedel's law (when applicable) on the one hand, and the Fourier relation between intensities and the Patterson function on the other hand, both follow from the property

$$\text{(iii)} \qquad \overline{e(\mathbf{h},\mathbf{x})} = e(-\mathbf{h},\mathbf{x}) = e(\mathbf{h},-\mathbf{x}).$$

When crystallographic symmetry is present, the convolution theorems remain valid in their original form if written out in terms of 'expanded' data, but acquire a different form when rewritten in terms of symmetry-unique data only. This rewriting is made possible by the extra relation (Section 1.3.4.2.2.5)

$$\text{(iv)} \qquad S^{\#}_{g^{-1}} e(\mathbf{h},\mathbf{x}) \equiv e[\mathbf{h}, S_g(\mathbf{x})] = e(\mathbf{h},\mathbf{t}_g) e(\mathbf{R}_g^T\mathbf{h},\mathbf{x})$$

or equivalently

$$\text{(iv}') \qquad S^{\#}_{g} e(\mathbf{h},\mathbf{x}) \equiv e[\mathbf{h}, S_g^{-1}(\mathbf{x})] = e[(-\mathbf{R}_g^{-1})^T\mathbf{h},\mathbf{t}_g] e[(\mathbf{R}_g^{-1})^T\mathbf{h},\mathbf{x}].$$

The kernels of symmetrized Fourier transforms are not the functions e but rather the symmetrized sums

$$\Xi^{\pm}(\mathbf{h},\mathbf{x}) = \sum_{g\in G} e^{\pm}[\mathbf{h}, S_g(\mathbf{x})] = \sum_{g\in G} e^{\pm}[\mathbf{h}, S_g^{-1}(\mathbf{x})]$$

for which the linearization formulae are readily obtained using (i), (ii) and (iv) as

$$\text{(i)}_G \qquad \Xi^{\pm}(\mathbf{h},\mathbf{x})\Xi^{\pm}(\mathbf{k},\mathbf{x}) = \sum_{g\in G} e^{\pm}(\mathbf{k},\mathbf{t}_g)\Xi^{\pm}(\mathbf{h}+\mathbf{R}_g^T\mathbf{k},\mathbf{x}),$$
$$\text{(ii)}_G \qquad \Xi^{\pm}(\mathbf{h},\mathbf{x})\Xi^{\pm}(\mathbf{h},\mathbf{y}) = \sum_{g\in G} \Xi^{\pm}[\mathbf{h},\mathbf{x}+S_g(\mathbf{y})],$$

where the choice of sign in $\pm$ must be the same throughout each formula.

Formulae $(\text{i})_G$ defining the 'structure-factor algebra' associated to G were derived by Bertaut (1955*c*, 1956*b*,*c*, 1959*a*,*b*) and Bertaut & Waser (1957) in another context.

The forward convolution theorem (in discrete form) then follows. Let

$$F_1(\mathbf{h}) = \sum_{\mathbf{y}\in D} \frac{1}{|G_{\mathbf{y}}|} \rho_1(\mathbf{y})\Xi^{+}(\mathbf{h},\mathbf{y}),$$
$$F_2(\mathbf{h}) = \sum_{\mathbf{z}\in D} \frac{1}{|G_{\mathbf{z}}|} \rho_2(\mathbf{z})\Xi^{+}(\mathbf{h},\mathbf{z}),$$

then

$$F_1(\mathbf{h})F_2(\mathbf{h}) = \sum_{\mathbf{x}\in D} \frac{1}{|G_{\mathbf{x}}|} \sigma(\mathbf{x})\Xi^{+}(\mathbf{h},\mathbf{x})$$

with

$$\sigma(\mathbf{x}) = \frac{1}{|\mathbf{N}|} \sum_{\mathbf{z}\in D} \sum_{g\in G} \frac{|G_{\mathbf{x}}|}{|G_{\mathbf{x}-S_g(\mathbf{z})}| \times |G_{\mathbf{z}}|} \rho_1[\mathbf{x}-S_g(\mathbf{z})]\rho_2(\mathbf{z}).$$

The backward convolution theorem is derived similarly. Let

$$\rho_1(\mathbf{x}) = \sum_{\mathbf{k}\in D^*} \frac{1}{|G_{\mathbf{k}}|} F_1(\mathbf{k})\Xi^{-}(\mathbf{k},\mathbf{x}),$$
$$\rho_2(\mathbf{x}) = \sum_{\mathbf{l}\in D^*} \frac{1}{|G_{\mathbf{l}}|} F_2(\mathbf{l})\Xi^{-}(\mathbf{l},\mathbf{x}),$$

then

$$\rho_1(\mathbf{x})\rho_2(\mathbf{x}) = \sum_{\mathbf{h}\in D^*} \frac{1}{|G_{\mathbf{h}}|} F(\mathbf{h})\Xi^{-}(\mathbf{h},\mathbf{x})$$

with

$$F(\mathbf{h}) = \sum_{\mathbf{l}\in D^*} \sum_{g\in G} \frac{|G_{\mathbf{h}}|}{|G_{\mathbf{h}-\mathbf{R}_g^T(\mathbf{l})}| \times |G_{\mathbf{l}}|} e^{-}(\mathbf{l},\mathbf{t}_g) F_1(\mathbf{h}-\mathbf{R}_g^T\mathbf{l}) F_2(\mathbf{l}).$$

Both formulae are simply orbit decompositions of their symmetry-free counterparts.

1.3.4.2.2.10. Correlation and Patterson functions

Consider two model electron densities ρ_1 and ρ_2 with the same period lattice $\mathbb{Z}^3$ and the same space group G. Write their motifs in terms of atomic electron densities (Section 1.3.4.2.2.4) as

$$\rho_1^0 = \sum_{j_1\in J_1} \left(\sum_{\gamma_{j_1}\in G/G^{(1)}_{\mathbf{x}_{j_1}}} S^{\#}_{\gamma_{j_1}} (\tau_{\mathbf{x}^{(1)}_{j_1}} \rho^{(1)}_{j_1}) \right),$$
$$\rho_2^0 = \sum_{j_2\in J_2} \left(\sum_{\gamma_{j_2}\in G/G^{(2)}_{\mathbf{x}_{j_2}}} S^{\#}_{\gamma_{j_2}} (\tau_{\mathbf{x}^{(2)}_{j_2}} \rho^{(2)}_{j_2}) \right),$$

where J_1 and J_2 label the symmetry-unique atoms placed at positions $\{\mathbf{x}^{(1)}_{j_1}\}_{j_1\in J_1}$ and $\{\mathbf{x}^{(2)}_{j_2}\}_{j_2\in J_2}$, respectively.

To calculate the correlation between ρ_1 and ρ_2 we need the following preliminary formulae, which are easily established: if $S(\mathbf{x}) = \mathbf{R}\mathbf{x}+\mathbf{t}$ and f is an arbitrary function on $\mathbb{R}^3$, then

$$(R^{\#}f)\check{} = R^{\#}\check{f}, \quad (\tau_{\mathbf{x}}f)\check{} = \tau_{-\mathbf{x}}\check{f}, \quad R^{\#}(\tau_{\mathbf{x}}f) = \tau_{\mathbf{R}\mathbf{x}}f,$$

hence

$$S^{\#}(\tau_{\mathbf{x}} f) = \tau_{S(\mathbf{x})} R^{\#} f \quad \text{and} \quad [S^{\#}(\tau_{\mathbf{x}} f)]^{\check{}} = \tau_{-S(\mathbf{x})} R^{\#} \check{f};$$

and

$$S_1^{\#} f_1 * S_2^{\#} f_2 = S_1^{\#}[f_1 * (S_1^{-1} S_2)^{\#} f_2] = S_2^{\#}[(S_2^{-1} S_1)^{\#} f_1 * f_2].$$

The cross correlation $\check{\mathscr{P}}_1^0 * \mathscr{P}_2^0$ between motifs is therefore

$$\begin{aligned}\check{\mathscr{P}}_1^0 * \mathscr{P}_2^0 &= \sum_{j_1}\sum_{j_2}\sum_{\gamma_{j_1}}\sum_{\gamma_{j_2}} [S^{\#}_{\gamma_{j_1}}(\tau_{\mathbf{x}_{j_1}^{(1)}} \mathscr{P}_{j_1}^{(1)})]^{\check{}} * [S^{\#}_{\gamma_{j_2}}(\tau_{\mathbf{x}_{j_2}^{(2)}} \mathscr{P}_{j_2}^{(2)})] \\ &= \sum_{j_1}\sum_{j_2}\sum_{\gamma_{j_1}}\sum_{\gamma_{j_2}} \tau_{S_{\gamma_{j_2}}(\mathbf{x}_{j_2}^{(2)}) - S_{\gamma_{j_1}}(\mathbf{x}_{j_1}^{(1)})} [(R^{\#}_{\gamma_{j_1}} \check{\mathscr{P}}_{j_1}^{(1)}) * (R^{\#}_{\gamma_{j_2}} \mathscr{P}_{j_2}^{(2)})]\end{aligned}$$

which contains a peak of shape $(R^{\#}_{\gamma_{j_1}} \check{\mathscr{P}}_{j_1}^{(1)}) * (R^{\#}_{\gamma_{j_2}} \mathscr{P}_{j_2}^{(2)})$ at the interatomic vector $S_{\gamma_{j_2}}(\mathbf{x}_{j_2}^{(2)}) - S_{\gamma_{j_1}}(\mathbf{x}_{j_1}^{(1)})$ for each $j_1 \in J_1$, $j_2 \in J_2$, $\gamma_{j_1} \in G/G_{\mathbf{x}_{j_1}^{(1)}}$, $\gamma_{j_2} \in G/G_{\mathbf{x}_{j_2}^{(2)}}$.

The cross-correlation $r * \check{\mathscr{P}}^0 * \mathscr{P}^0$ between the original electron densities is then obtained by further periodizing by $\mathbb{Z}^3$.

Note that these expressions are valid for any choice of 'atomic' density functions $\mathscr{P}_{j_1}^{(1)}$ and $\mathscr{P}_{j_2}^{(2)}$, which may be taken as molecular fragments if desired (see Section 1.3.4.4.8).

If G contains elements g such that $\mathbf{R}_g$ has an eigenspace E_1 with eigenvalue 1 and an invariant complementary subspace E_2, while $\mathbf{t}_g$ has a nonzero component $\mathbf{t}_g^{(1)}$ in E_1, then the Patterson function $r * \check{\mathscr{P}}^0 * \mathscr{P}^0$ will contain *Harker peaks* (Harker, 1936) of the form

$$S_g(\mathbf{x}) - \mathbf{x} = \mathbf{t}_g^{(1)} \oplus (S_g^{(2)}(\mathbf{x}) - \mathbf{x})$$

[where $S_g^{(s)}$ represent the action of g in E_2] in the translate of E_1 by $\mathbf{t}_g^{(1)}$.

1.3.4.3. Crystallographic discrete Fourier transform algorithms

1.3.4.3.1. Historical introduction

In 1929, W. L. Bragg demonstrated the practical usefulness of the Fourier transform relation between electron density and structure factors by determining the structure of diopside from three principal projections calculated numerically by 2D Fourier summation (Bragg, 1929). It was immediately realized that the systematic use of this powerful method, and of its extension to three dimensions, would entail considerable amounts of numerical computation which had to be organized efficiently. As no other branch of applied science had yet needed this type of computation, crystallographers had to invent their own techniques.

The first step was taken by Beevers & Lipson (1934) who pointed out that a 2D summation could be factored into successive 1D summations. This is essentially the tensor product property of the Fourier transform (Sections 1.3.2.4.2.4, 1.3.3.3.1), although its aspect is rendered somewhat complicated by the use of sines and cosines instead of complex exponentials. Computation is economized to the extent that the cost of an $N \times N$ transform grows with N as $2N^3$ rather than N^4. Generalization to 3D is immediate, reducing computation size from N^6 to $3N^4$ for an $N \times N \times N$ transform. The complication introduced by using expressions in terms of sines and cosines is turned to advantage when symmetry is present, as certain families of terms are systematically absent or are simply related to each other; multiplicity corrections must, however, be introduced. The necessary information was tabulated for each space group by Lonsdale (1936), and was later incorporated into Volume I of *International Tables*.

The second step was taken by Beevers & Lipson (1936) and Lipson & Beevers (1936) in the form of the invention of the 'Beevers–Lipson strips', a practical device which was to assist a whole generation of crystallographers in the numerical computation of crystallographic Fourier sums. The strips comprise a set of 'cosine strips' tabulating the functions

$$A \cos\left(\frac{2\pi hm}{60}\right) \ (A = 1, 2, \ldots, 99;\ h = 1, 2, \ldots, 99)$$

and a set of 'sine strips' tabulating the functions

$$B \sin\left(\frac{2\pi hm}{60}\right) \ (B = 1, 2, \ldots, 99;\ h = 1, 2, \ldots, 99)$$

for the 16 arguments $m = 0, 1, \ldots, 15$. Function values are rounded to the nearest integer, and those for other arguments m may be obtained by using the symmetry properties of the sine and cosine functions. A Fourier summation of the form

$$Y(m) = \sum_{j=1}^{n} \left[A_j \cos\left(\frac{2\pi h_j m}{60}\right) + B_j \sin\left(\frac{2\pi h_j m}{60}\right) \right]$$

is then performed by selecting the n cosine strips labelled (A_j, h_j) and the n sine strips labelled (B_j, h_j), placing them in register, and adding the tabulated values columnwise. The number 60 was chosen as the l.c.m. of 12 (itself the l.c.m. of the orders of all possible nonprimitive translations) and of 10 (for decimal convenience). The limited accuracy imposed by the two-digit tabulation was later improved by Robertson's sorting board (Robertson, 1936*a*,*b*) or by the use of separate strips for each decimal digit of the amplitude (Booth, 1948*b*), which allowed three-digit tabulation while keeping the set of strips within manageable size. Cochran (1948*a*) found that, for most structures under study at the time, the numerical inaccuracies of the method were less than the level of error in the experimental data. The sampling rate was subsequently increased from 60 to 120 (Beevers, 1952) to cope with larger unit cells.

Further gains in speed and accuracy were sought through the construction of special-purpose mechanical, electro-mechanical, electronic or optical devices. Two striking examples are the mechanical computer RUFUS built by Robertson (1954, 1955, 1961) on the principle of previous strip methods (see also Robertson, 1932) and the electronic analogue computer X-RAC built by Pepinsky, capable of real-time calculation and display of 2D and 3D Fourier syntheses (Pepinsky, 1947; Pepinsky & Sayre, 1948; Pepinsky *et al.*, 1961; see also Suryan, 1957). The optical methods of Lipson & Taylor (1951, 1958) also deserve mention. Many other ingenious devices were invented, whose descriptions may be found in Booth (1948*b*), Niggli (1961) and Lipson & Cochran (1968).

Later, commercial punched-card machines were programmed to carry out Fourier summations or structure-factor calculations (Shaffer *et al.*, 1946*a*,*b*; Cox *et al.*, 1947, 1949; Cox & Jeffrey, 1949; Donohue & Schomaker, 1949; Grems & Kasper, 1949; Hodgson *et al.*, 1949; Greenhalgh & Jeffrey, 1950; Kitz & Marchington, 1953).

The modern era of digital electronic computation of Fourier series was initiated by the work of Bennett & Kendrew (1952), Mayer & Trueblood (1953), Ahmed & Cruickshank (1953*b*), Sparks *et al.* (1956) and Fowweather (1955). Their Fourier-synthesis programs used Beevers–Lipson factorization, the program by Sparks *et al.* being the first 3D Fourier program useable for all space groups (although these were treated as $P1$ or $P\bar{1}$ by data expansion). Ahmed & Barnes (1958) then proposed a

general programming technique to allow full use of symmetry elements (orthorhombic or lower) in the 3D Beevers–Lipson factorization process, including multiplicity corrections. Their method was later adopted by Shoemaker & Sly (1961), and by crystallographic program writers at large.

The discovery of the FFT algorithm by Cooley & Tukey in 1965, which instantly transformed electrical engineering and several other disciplines, paradoxically failed to have an immediate impact on crystallographic computing. A plausible explanation is that the calculation of large 3D Fourier maps was a relatively infrequent task which was not thought to constitute a bottleneck, as crystallographers had learned to settle most structural questions by means of cheaper 2D sections or projections. It is significant in this respect that the first use of the FFT in crystallography by Barrett & Zwick (1971) should have occurred as part of an iterative scheme for improving protein phases by density modification in real space, which required a much greater number of Fourier transformations than any previous method. Independently, Bondot (1971) had attracted attention to the merits of the FFT algorithm.

The FFT program used by Barrett & Zwick had been written for signal-processing applications. It was restricted to sampling rates of the form 2^n, and was not designed to take advantage of crystallographic symmetry at any stage of the calculation; Bantz & Zwick (1974) later improved this situation somewhat.

It was the work of Ten Eyck (1973) and Immirzi (1973, 1976) which led to the general adoption of the FFT in crystallographic computing. Immirzi treated all space groups as $P1$ by data expansion. Ten Eyck based his program on a versatile multi-radix FFT routine (Gentleman & Sande, 1966) coupled with a flexible indexing scheme for dealing efficiently with multidimensional transforms. He also addressed the problems of incorporating symmetry elements of order 2 into the factorization of 1D transforms, and of transposing intermediate results by other symmetry elements. He was thus able to show that in a large number of space groups (including the 74 space groups having orthorhombic or lower symmetry) it is possible to calculate only the unique results from the unique data within the logic of the FFT algorithm. Ten Eyck wrote and circulated a package of programs for computing Fourier maps and re-analysing them into structure factors in some simple space groups ($P1$, $P\bar{1}$, $P2$, $P2/m$, $P2_1$, $P222$, $P2_12_12_1$, $Pmmm$). This package was later augmented by a handful of new space-group-specific programs contributed by other crystallographers ($P2_12_12$, $I222$, $P3_121$, $P4_12_12$). The writing of such programs is an undertaking of substantial complexity, which has deterred all but the bravest: the usual practice is now to expand data for a high-symmetry space group to the largest subgroup for which a specific FFT program exists in the package, rather than attempt to write a new program. Attempts have been made to introduce more modern approaches to the calculation of crystallographic Fourier transforms (Auslander, Feig & Winograd, 1982; Auslander & Shenefelt, 1987; Auslander *et al.*, 1988) but have not gone beyond the stage of preliminary studies.

The task of fully exploiting the FFT algorithm in crystallographic computations is therefore still unfinished, and it is the purpose of this section to provide a systematic treatment such as that (say) of Ahmed & Barnes (1958) for the Beevers–Lipson algorithm.

Ten Eyck's approach, based on the reducibility of certain space groups, is extended by the derivation of a universal transposition formula for intermediate results. It is then shown that space groups which are not completely reducible may nevertheless be treated by three-dimensional Cooley–Tukey factorization in such a way that their symmetry may be fully exploited, whatever the shape of their asymmetric unit. Finally, new factorization methods with built-in symmetries are presented. The unifying concept throughout this presentation is that of 'group action' on indexing sets, and of 'orbit exchange' when this action has a composite structure; it affords new ways of rationalizing the use of symmetry, or of improving computational speed, or both.

1.3.4.3.2. Defining relations and symmetry considerations

A finite set of reflections $\{F_{\mathbf{h}_l}\}_{l\in L}$ can be periodized without aliasing by the translations of a suitable sublattice $\mathbf{N}^T\Lambda^*$ of the reciprocal lattice Λ^*; the converse operation in real space is the sampling of ρ at points $\mathbf{X}$ of a grid of the form $\mathbf{N}^{-1}\Lambda$ (Section 1.3.2.7.3). In standard coordinates, $\{F_{\mathbf{h}_l}\}_{l\in L}$ is periodized by $\mathbf{N}^T\mathbb{Z}^3$, and $\mathscr{P}$ is sampled at points $\mathbf{x}\in\mathbf{N}^{-1}\mathbb{Z}^3$.

In the absence of symmetry, the unique data are

– the $F_{\mathbf{h}}$ indexed by $\mathbf{h}\in\mathbb{Z}^3/\mathbf{N}^T\mathbb{Z}^3$ in reciprocal space;

– the $\mathscr{P}_{\mathbf{x}}$ indexed by $\mathbf{x}\in(\mathbf{N}^{-1}\mathbb{Z}^3)/\mathbb{Z}^3$; or equivalently the $\mathscr{P}_{\mathbf{m}}$ indexed by $\mathbf{m}\in\mathbb{Z}^3/\mathbf{N}\mathbb{Z}^3$, where $\mathbf{x}=\mathbf{N}^{-1}\mathbf{m}$.

They are connected by the ordinary DFT relations:

$$F_{\mathbf{h}}=\frac{1}{|\det\mathbf{N}|}\sum_{\mathbf{x}\in(\mathbf{N}^{-1}\mathbb{Z}^3)/\mathbb{Z}^3}\mathscr{P}_{\mathbf{x}}\exp(2\pi i\mathbf{h}\cdot\mathbf{x})$$

or

$$F_{\mathbf{h}}=\frac{1}{|\det\mathbf{N}|}\sum_{\mathbf{m}\in\mathbb{Z}^3/\mathbf{N}\mathbb{Z}^3}\mathscr{P}_{\mathbf{m}}\exp[2\pi i\mathbf{h}\cdot(\mathbf{N}^{-1}\mathbf{m})]$$

and

$$\mathscr{P}_{\mathbf{x}}=\sum_{\mathbf{h}=\mathbb{Z}^3/\mathbf{N}^T\mathbb{Z}^3}F_{\mathbf{h}}\exp(-2\pi i\mathbf{h}\cdot\mathbf{x})$$

or

$$\mathscr{P}_{\mathbf{m}}=\sum_{\mathbf{h}\in\mathbb{Z}^3/\mathbf{N}^T\mathbb{Z}^3}F_{\mathbf{h}}\exp[-2\pi i\mathbf{h}\cdot(\mathbf{N}^{-1}\mathbf{m})].$$

In the presence of symmetry, the unique data are

– $\{\mathscr{P}_{\mathbf{x}}\}_{\mathbf{x}\in D}$ or $\{\mathscr{P}_{\mathbf{m}}\}_{\mathbf{m}\in D}$ in real space (by abuse of notation, D will denote an asymmetric unit for $\mathbf{x}$ or for $\mathbf{m}$ indifferently);

– $\{F_{\mathbf{h}}\}_{\mathbf{h}\in D^*}$ in reciprocal space.

The previous summations may then be subjected to orbital decomposition, to yield the following 'crystallographic DFT' (CDFT) defining relations:

$$\begin{aligned}F_{\mathbf{h}}&=\frac{1}{|\det\mathbf{N}|}\sum_{\mathbf{x}\in D}\mathscr{P}_{\mathbf{x}}\left[\sum_{\gamma\in G/G_{\mathbf{x}}}\exp\{2\pi i\mathbf{h}\cdot[S_\gamma(\mathbf{x})]\}\right]\\&=\frac{1}{|\det\mathbf{N}|}\sum_{\mathbf{x}\in D}\mathscr{P}_{\mathbf{x}}\left[\frac{1}{|G_{\mathbf{x}}|}\sum_{g\in G}\exp\{2\pi i\mathbf{h}\cdot[S_g(\mathbf{x})]\}\right],\\\mathscr{P}_{\mathbf{x}}&=\sum_{\mathbf{h}\in D^*}F_{\mathbf{h}}\left[\sum_{\gamma\in G/G_{\mathbf{h}}}\exp\{-2\pi i\mathbf{h}\cdot[S_\gamma(\mathbf{x})]\}\right]\\&=\sum_{\mathbf{h}\in D^*}F_{\mathbf{h}}\left[\frac{1}{|G_{\mathbf{h}}|}\sum_{g\in G}\exp\{-2\pi i\mathbf{h}\cdot[S_g(\mathbf{x})]\}\right],\end{aligned}$$

with the obvious alternatives in terms of $\mathscr{P}_{\mathbf{m}}$, $\mathbf{m}=\mathbf{N}\mathbf{x}$. Our problem is to evaluate the CDFT for a given space group as efficiently as possible, in spite of the fact that the group action has spoilt the simple tensor-product structure of the ordinary three-dimensional DFT (Section 1.3.3.3.1).

Two procedures are available to carry out the 3D summations involved as a succession of smaller summations:

(1) *decomposition* into successive transforms of *fewer dimensions* but on the *same number of points* along these dimensions. This possibility depends on the reducibility of the space group, as defined in Section 1.3.4.2.2.4, and simply invokes the tensor product property of the DFT;

(2) *factorization* of the transform into transforms of the *same number of dimensions* as the original one, but on *fewer points* along each dimension. This possibility depends on the arithmetic factorability of the decimation matrix **N**, as described in Section 1.3.3.3.2.

Clearly, a symmetry expansion to the largest fully reducible subgroup of the space group will give maximal decomposability, but will require computing more than the unique results from more than the unique data. Economy will follow from factoring the transforms in the subspaces within which the space group acts irreducibly.

For irreducible subspaces of dimension 1, the group action is readily incorporated into the factorization of the transform, as first shown by Ten Eyck (1973).

For irreducible subspaces of dimension 2 or 3, the ease of incorporation of symmetry into the factorization depends on the type of factorization method used. The multidimensional Cooley–Tukey method (Section 1.3.3.3.1) is rather complicated; the multidimensional Good method (Section 1.3.3.3.2.2) is somewhat simpler; and the Rader/Winograd factorization admits a generalization, based on the arithmetic of certain rings of *algebraic* integers, which accommodates 2D crystallographic symmetries in a most powerful and pleasing fashion.

At each stage of the calculation, it is necessary to keep track of the definition of the asymmetric unit and of the symmetry properties of the numbers being manipulated. This requirement applies not only to the initial data and to the final results, where these are familiar; but also to all the intermediate quantities produced by partial transforms (on subsets of factors, or subsets of dimensions, or both), where they are less familiar. Here, the general formalism of transposition (or 'orbit exchange') described in Section 1.3.4.2.2.2 plays a central role.

1.3.4.3.3. Interaction between symmetry and decomposition

Suppose that the space-group action is reducible, *i.e.* that for each $g \in G$

$$\mathbf{R}_g = \begin{pmatrix} \mathbf{R}'_g & \mathbf{0} \\ \mathbf{0} & \mathbf{R}''_g \end{pmatrix}, \qquad \mathbf{t}_g = \begin{pmatrix} \mathbf{t}'_g \\ \mathbf{t}''_g \end{pmatrix};$$

by Schur's lemma, the decimation matrix must then be of the form

$$\mathbf{N} = \begin{pmatrix} \mathbf{N}' & \mathbf{0} \\ \mathbf{0} & \mathbf{N}'' \end{pmatrix}$$

if it is to commute with all the $\mathbf{R}_g$.

Putting

$$\mathbf{x} = \begin{pmatrix} \mathbf{x}' \\ \mathbf{x}'' \end{pmatrix} \quad \text{and} \quad \mathbf{h} = \begin{pmatrix} \mathbf{h}' \\ \mathbf{h}'' \end{pmatrix},$$

we may define

$$S'_g(\mathbf{x}') = \mathbf{R}'_g\mathbf{x}' + \mathbf{t}'_g,$$
$$S''_g(\mathbf{x}'') = \mathbf{R}''_g\mathbf{x}'' + \mathbf{t}''_g,$$

and write $S_g = S'_g \oplus S''_g$ (direct sum) as a shorthand for

$$S_g(\mathbf{x}) = \begin{pmatrix} S'_g(\mathbf{x}') \\ S''_g(\mathbf{x}'') \end{pmatrix}.$$

We may also define the representation operators $S'^{\#}_g$ and $S''^{\#}_g$ acting on functions of $\mathbf{x}'$ and $\mathbf{x}''$, respectively (as in Section 1.3.4.2.2.4), and the operators S'^{*}_g and S''^{*}_g acting on functions of $\mathbf{h}'$ and $\mathbf{h}''$, respectively (as in Section 1.3.4.2.2.5). Then we may write

$$S^{\#}_g = (S'_g)^{\#} \oplus (S''_g)^{\#}$$

and

$$S^{*}_g = (S'_g)^{*} \oplus (S''_g)^{*}$$

in the sense that g acts on $f(\mathbf{x}) \equiv f(\mathbf{x}', \mathbf{x}'')$ by

$$(S^{\#}_g f)(\mathbf{x}', \mathbf{x}'') = f[(S'_g)^{-1}(\mathbf{x}'), (S''_g)^{-1}(\mathbf{x}'')]$$

and on $\Phi(\mathbf{h}) \equiv \Phi(\mathbf{h}', \mathbf{h}'')$ by

$$(S^{*}_g \Phi)(\mathbf{h}', \mathbf{h}'') = \exp(2\pi i \mathbf{h}' \cdot \mathbf{t}'_g) \exp(2\pi i \mathbf{h}'' \cdot \mathbf{t}''_g) \times \Phi[\mathbf{R}'^{T}_g \mathbf{h}', \mathbf{R}''^{T}_g \mathbf{h}''].$$

Thus equipped we may now derive concisely a general identity describing the symmetry properties of intermediate quantities of the form

$$T(\mathbf{x}', \mathbf{h}'') = \sum_{\mathbf{h}'} F(\mathbf{h}', \mathbf{h}'') \exp(-2\pi i \mathbf{h}' \cdot \mathbf{x}') = \frac{1}{|\det \mathbf{N}'|} \sum_{\mathbf{x}''} \rho(\mathbf{x}', \mathbf{x}'') \exp(+2\pi i \mathbf{h}'' \cdot \mathbf{x}''),$$

which arise through partial transformation of F on $\mathbf{h}'$ or of ρ on $\mathbf{x}''$. The action of $g \in G$ on these quantities will be

(i) through $(S'_g)^{\#}$ on the function $\mathbf{x}' \longmapsto T(\mathbf{x}', \mathbf{h}'')$,

(ii) through $(S''_g)^{*}$ on the function $\mathbf{h}'' \longmapsto T(\mathbf{x}', \mathbf{h}'')$,

and hence the symmetry properties of T are expressed by the identity

$$T = [(S'_g)^{\#} \oplus (S''_g)^{*}]T.$$

Applying this relation not to T but to $[(S'_{g^{-1}})^{\#} \oplus (S''_e)^{*}]T$ gives

$$[(S'_{g^{-1}})^{\#} \oplus (S''_e)^{*}]T = [(S'_e)^{\#} \oplus (S''_g)^{*}]T,$$

i.e.

$$\boxed{T(S'_g(\mathbf{x}'), \mathbf{h}'') = \exp(2\pi i \mathbf{h}'' \cdot \mathbf{t}''_g) T(\mathbf{x}', \mathbf{R}''^{T}_g \mathbf{h}'').}$$

If the unique $F(\mathbf{h}) \equiv F(\mathbf{h}', \mathbf{h}'')$ were initially indexed by

$$(\text{all } \mathbf{h}') \times (\text{unique } \mathbf{h}'')$$

(see Section 1.3.4.2.2.2), this formula allows the reindexing of the intermediate results $T(\mathbf{x}', \mathbf{h}'')$ from the initial form

$$(\text{all } \mathbf{x}') \times (\text{unique } \mathbf{h}'')$$

to the final form

$$(\text{unique } \mathbf{x}') \times (\text{all } \mathbf{h}''),$$

on which the second transform (on $\mathbf{h}''$) may now be performed, giving the final results $\mathscr{P}(\mathbf{x}', \mathbf{x}'')$ indexed by

$$(\text{unique } \mathbf{x}') \times (\text{all } \mathbf{x}''),$$

which is an asymmetric unit. An analogous interpretation holds if one is going from $\mathscr{P}$ to F.

The above formula solves the general problem of transposing from one invariant subspace to another, and is the main device for decomposing the CDFT. Particular instances of this formula were derived and used by Ten Eyck (1973); it is useful for orthorhombic groups, and for dihedral groups containing screw axes n_m with g.c.d. $(m, n) = 1$. For comparison with later uses of orbit exchange, it should be noted that the type of intermediate results just dealt with is obtained after transforming on *all* factors in *one* summand.

A central piece of information for driving such a decomposition is the definition of the full asymmetric unit in terms of the asymmetric units in the invariant subspaces. As indicated at the end of Section 1.3.4.2.2.2, this is straightforward when G acts without fixed points, but becomes more involved if fixed points do exist. To this day, no systematic 'calculus of asymmetric units' exists which can automatically generate a complete description of the asymmetric unit of an arbitrary space group in a form suitable for directing the orbit exchange process, although Shenefelt (1988) has outlined a procedure for dealing with space group $P622$ and its subgroups. The asymmetric unit definitions given in Volume A of *International Tables* are incomplete in this respect, in that they do not specify the possible residual symmetries which may exist on the boundaries of the domains.

1.3.4.3.4. Interaction between symmetry and factorization

Methods for factoring the DFT in the absence of symmetry were examined in Sections 1.3.3.2 and 1.3.3.3. They are based on the observation that the finite sets which index both data and results are endowed with certain algebraic structures (*e.g.* are Abelian groups, or rings), and that subsets of indices may be found which are not merely subsets but *substructures* (*e.g.* subgroups or subrings). Summation over these substructures leads to partial transforms, and the way in which substructures fit into the global structure indicates how to reassemble the partial results into the final results. As a rule, the richer the algebraic structure which is identified in the indexing set, the more powerful the factoring method.

The ability of a given factoring method to accommodate crystallographic symmetry will thus be determined by the extent to which the crystallographic group action respects (or fails to respect) the partitioning of the index set into the substructures pertaining to that method. This remark justifies trying to gain an overall view of the algebraic structures involved, and of the possibilities of a crystallographic group acting 'naturally' on them.

The index sets $\{\mathbf{m}|\mathbf{m} \in \mathbb{Z}^3/\mathbf{N}\mathbb{Z}^3\}$ and $\{\mathbf{h}|\mathbf{h} \in \mathbb{Z}^3/\mathbf{N}^T\mathbb{Z}^3\}$ are finite Abelian groups under component-wise addition. If an iterated addition is viewed as an action of an integer scalar $n \in \mathbb{Z}$ *via*

$$\begin{aligned} n\mathbf{h} &= \mathbf{h} + \mathbf{h} + \ldots + \mathbf{h} && (n \text{ times}) && \text{for } n > 0, \\ &= \mathbf{0} && && \text{for } n = 0, \\ &= -(\mathbf{h} + \mathbf{h} + \ldots + \mathbf{h}) && (|n| \text{ times}) && \text{for } n < 0, \end{aligned}$$

then an Abelian group becomes a *module* over the ring $\mathbb{Z}$ (or, for short, a $\mathbb{Z}$-module), a module being analogous to a vector space but with scalars drawn from a ring rather than a field. The left actions of a crystallographic group G by

$$g: \quad \mathbf{m} \longmapsto \mathbf{R}_g\mathbf{m} + \mathbf{N}\mathbf{t}_g \mod \mathbf{N}\mathbb{Z}^3$$

and by

$$g: \quad \mathbf{h} \longmapsto (\mathbf{R}_g^{-1})^T\mathbf{h} \mod \mathbf{N}^T\mathbb{Z}^3$$

can be combined with this $\mathbb{Z}$ action as follows:

$$\begin{aligned} \textstyle\sum_{g\in G} n_g g: &\quad \mathbf{m} \longmapsto \textstyle\sum_{g\in G} n_g(\mathbf{R}_g\mathbf{m} + \mathbf{N}\mathbf{t}_g) && \mod \mathbf{N}\mathbb{Z}^3, \\ \textstyle\sum_{g\in G} n_g g: &\quad \mathbf{h} \longmapsto \textstyle\sum_{g\in G} n_g[(\mathbf{R}_g^{-1})^T\mathbf{h}] && \mod \mathbf{N}^T\mathbb{Z}^3. \end{aligned}$$

This provides a left action, on the indexing sets, of the set

$$\mathbb{Z}G = \left\{ \sum_{g\in G} n_g g \middle| n_g \in \mathbb{Z} \text{ for each } g \in G \right\}$$

of symbolic linear combinations of elements of G with integral coefficients. If addition and multiplication are defined in $\mathbb{Z}G$ by

$$\left(\sum_{g_1\in G} a_{g_1} g_1\right) + \left(\sum_{g_2\in G} b_{g_2} g_2\right) = \sum_{g\in G} (a_g + b_g) g$$

and

$$\left(\sum_{g_1\in G} a_{g_1} g_1\right) \times \left(\sum_{g_2\in G} b_{g_2} g_2\right) = \sum_{g\in G} c_g g,$$

with

$$c_g = \sum_{g'\in G} a_{g'} b_{(g')^{-1}g},$$

then $\mathbb{Z}G$ is a *ring*, and the action defined above makes the indexing sets into $\mathbb{Z}G$*-modules*. The ring $\mathbb{Z}G$ is called the *integral group ring* of G (Curtis & Reiner, 1962, p. 44).

From the algebraic standpoint, therefore, the interaction between symmetry and factorization can be expected to be favourable whenever the indexing sets of partial transforms are $\mathbb{Z}G$-submodules of the main $\mathbb{Z}G$-modules.

1.3.4.3.4.1. Multidimensional Cooley–Tukey factorization

Suppose, as in Section 1.3.3.3.2.1, that the decimation matrix $\mathbf{N}$ may be factored as $\mathbf{N}_1\mathbf{N}_2$. Then any grid point index $\mathbf{m} \in \mathbb{Z}^3/\mathbf{N}\mathbb{Z}^3$ in real space may be written

$$\mathbf{m} = \mathbf{m}_1 + \mathbf{N}_1\mathbf{m}_2$$

with $\mathbf{m}_1 \in \mathbb{Z}^3/\mathbf{N}_1\mathbb{Z}^3$ and $\mathbf{m}_2 \in \mathbb{Z}^3/\mathbf{N}_2\mathbb{Z}^3$ determined by

$$\begin{aligned} \mathbf{m}_1 &= \mathbf{m} && \mod \mathbf{N}_1\mathbb{Z}^3, \\ \mathbf{m}_2 &= \mathbf{N}_1^{-1}(\mathbf{m} - \mathbf{m}_1) && \mod \mathbf{N}_2\mathbb{Z}^3. \end{aligned}$$

These relations establish a one-to-one correspondence $\mathbf{m} \leftrightarrow (\mathbf{m}_1, \mathbf{m}_2)$ between $I = \mathbb{Z}^3/\mathbf{N}\mathbb{Z}^3$ and the Cartesian product $I_1 \times I_2$ of $I_1 = \mathbb{Z}^3/\mathbf{N}_1\mathbb{Z}^3$ and $I_2 = \mathbb{Z}^3/\mathbf{N}_2\mathbb{Z}^3$, and hence $I \cong I_1 \times I_2$ as a set. However $I \ncong I_1 \times I_2$ as an Abelian group, since in general $\mathbf{m} + \mathbf{m}' \not\leftrightarrow (\mathbf{m}_1 + \mathbf{m}_1', \mathbf{m}_2 + \mathbf{m}_2')$ because there can be a 'carry' from the addition of the first components into the second components; therefore, $I \ncong I_1 \times I_2$ as a $\mathbb{Z}G$-module, which shows that the incorporation of symmetry into the Cooley–Tukey algorithm is not a trivial matter.

Let $g \in G$ act on I through

$$g: \quad \mathbf{m} \longmapsto S_g(\mathbf{m}) = \mathbf{R}_g\mathbf{m} + \mathbf{N}\mathbf{t}_g \bmod \mathbf{N}\mathbb{Z}^3$$

and suppose that $\mathbf{N}$ 'integerizes' all the nonprimitive translations $\mathbf{t}_g$ so that we may write

$$\mathbf{N}\mathbf{t}_g = \mathbf{t}_g^{(1)} + \mathbf{N}_1\mathbf{t}_g^{(2)},$$

with $\mathbf{t}_g^{(1)} \in I_1$ and $\mathbf{t}_g^{(2)} \in I_2$ determined as above. Suppose further that $\mathbf{N}$, $\mathbf{N}_1$ and $\mathbf{N}_2$ commute with $\mathbf{R}_g$ for all $g \in G$, *i.e.* (by Schur's lemma, Section 1.3.4.2.2.4) that these matrices are integer multiples of the identity in each G-invariant subspace. The action of g on $\mathbf{m} = \mathbf{N}\mathbf{x} \bmod \mathbf{N}\mathbb{Z}^3$ leads to

$$\begin{aligned} S_g(\mathbf{m}) &= \mathbf{N}[\mathbf{R}_g(\mathbf{N}^{-1}\mathbf{m}) + \mathbf{N}\mathbf{t}_g] && \bmod \mathbf{N}\mathbb{Z}^3 \\ &= \mathbf{N}\mathbf{R}_g\mathbf{N}^{-1}(\mathbf{m}_1 + \mathbf{N}_1\mathbf{m}_2) + \mathbf{t}_g^{(1)} + \mathbf{N}_1\mathbf{t}_g^{(2)} && \bmod \mathbf{N}\mathbb{Z}^3 \\ &= \mathbf{R}_g\mathbf{m}_1 + \mathbf{t}_g^{(1)} + \mathbf{N}_1(\mathbf{R}_g\mathbf{m}_2 + \mathbf{t}_g^{(2)}) && \bmod \mathbf{N}\mathbb{Z}^3, \end{aligned}$$

which we may decompose as

$$S_g(\mathbf{m}) = [S_g(\mathbf{m})]_1 + \mathbf{N}_1[S_g(\mathbf{m})]_2$$

with

$$[S_g(\mathbf{m})]_1 \equiv S_g(\mathbf{m}) \qquad \bmod \mathbf{N}_1\mathbb{Z}^3$$

and

$$[S_g(\mathbf{m})]_2 \equiv \mathbf{N}_1^{-1}\{S_g(\mathbf{m}) - [S_g(\mathbf{m})]_1\} \qquad \bmod \mathbf{N}_2\mathbb{Z}^3.$$

Introducing the notation

$$\begin{aligned} S_g^{(1)}(\mathbf{m}_1) &= \mathbf{R}_g\mathbf{m}_1 + \mathbf{t}_g^{(1)} \bmod \mathbf{N}_1\mathbb{Z}^3, \\ S_g^{(2)}(\mathbf{m}_2) &= \mathbf{R}_g\mathbf{m}_2 + \mathbf{t}_g^{(2)} \bmod \mathbf{N}_2\mathbb{Z}^3, \end{aligned}$$

the two components of $S_g(\mathbf{m})$ may be written

$$\begin{aligned} [S_g(\mathbf{m})]_1 &= S_g^{(1)}(\mathbf{m}_1), \\ [S_g(\mathbf{m})]_2 &= S_g^{(2)}(\mathbf{m}_2) + \boldsymbol{\mu}_2(g, \mathbf{m}_1) \bmod \mathbf{N}_2\mathbb{Z}^3, \end{aligned}$$

with

$$\boldsymbol{\mu}_2(g, \mathbf{m}_1) = \mathbf{N}_1^{-1}\{(\mathbf{R}_g\mathbf{m}_1 + \mathbf{t}_g^{(1)}) - [S_g(\mathbf{m}_1)]_1\} \bmod \mathbf{N}_2\mathbb{Z}^3.$$

The term $\boldsymbol{\mu}_2$ is the geometric equivalent of a *carry* or *borrow*: it arises because $\mathbf{R}_g\mathbf{m}_1 + \mathbf{t}_g^{(1)}$, calculated as a vector in $\mathbb{Z}^3/\mathbf{N}\mathbb{Z}^3$, may be outside the unit cell $\mathbf{N}_1[0, 1]^3$, and may need to be brought back into it by a 'large' translation with a nonzero component in the $\mathbf{m}_2$ space; equivalently, the action of g may need to be applied around different permissible origins for different values of $\mathbf{m}_1$, so as to map the unit cell into itself without any recourse to lattice translations. [Readers familiar with the cohomology of groups (see *e.g.* Hall, 1959; MacLane, 1963) will recognize $\boldsymbol{\mu}_2$ as the cocycle of the extension of $\mathbb{Z}$ G-modules described by the exact sequence $0 \to I_2 \to I \to I_1 \to 0$.]

Thus G acts on I in a rather complicated fashion: although $g \longmapsto S_g^{(1)}$ does define a left action in I_1 alone, no action can be defined in I_2 alone because $\boldsymbol{\mu}_2$ depends on $\mathbf{m}_1$. However, because S_g, $S_g^{(1)}$ and $S_g^{(2)}$ *are* left actions, it follows that $\boldsymbol{\mu}_2$ satisfies the identity

$$\boldsymbol{\mu}_2(gg', \mathbf{m}_1) = S_g^{(2)}[\boldsymbol{\mu}_2(g', \mathbf{m}_1)] + \boldsymbol{\mu}_2[g, S_g^{(1)}(\mathbf{m}_1)] \qquad \bmod \mathbf{N}_2\mathbb{Z}^3$$

for all g, g' in G and all $\mathbf{m}_1$ in I_1. In particular, $\boldsymbol{\mu}_2(\mathrm{e}, \mathbf{m}_1) = \mathbf{0}$ for all $\mathbf{m}_1$, and

$$\boldsymbol{\mu}_2(g^{-1}, \mathbf{m}_1) = -S_{g^{-1}}^{(2)}\{\boldsymbol{\mu}_2[g, S_{g^{-1}}^{(1)}(\mathbf{m}_1)]\} \bmod \mathbf{N}_2\mathbb{Z}^3.$$

This action will now be used to achieve optimal use of symmetry in the multidimensional Cooley–Tukey algorithm of Section 1.3.3.3.2.1. Let us form an array Y according to

$$Y(\mathbf{m}_1, \mathbf{m}_2) = \rho(\mathbf{m}_1 + \mathbf{N}_1\mathbf{m}_2)$$

for *all* $\mathbf{m}_2 \in I_2$ but only for the *unique* $\mathbf{m}_1$ under the action $S_g^{(1)}$ of G in I_1. Except in special cases which will be examined later, these vectors contain essentially an asymmetric unit of electron-density data, up to some redundancies on boundaries. We may then compute the partial transform on $\mathbf{m}_2$:

$$Y^*(\mathbf{m}_1, \mathbf{h}_2) = \frac{1}{|\det \mathbf{N}_2|} \sum_{\mathbf{m}_2 \in I_2} Y(\mathbf{m}_1, \mathbf{m}_2) e[\mathbf{h}_2 \cdot (\mathbf{N}_2^{-1}\mathbf{m}_2)].$$

Using the symmetry of ρ in the form $\rho = S_g^{\#}\rho$ yields by the procedure of Section 1.3.3.3.2 the transposition formula

$$\begin{aligned} Y^*(S_g^{(1)}(\mathbf{m}_1), \mathbf{h}_2) = e\{\mathbf{h}_2 \cdot [\mathbf{N}_2^{-1}(\mathbf{t}_g^{(2)} + \boldsymbol{\mu}_2(g, \mathbf{m}_1))]\} \\ \times Y^*(\mathbf{m}_1, [\mathbf{R}_g^{(2)}]^T\mathbf{h}_2). \end{aligned}$$

By means of this identity we can transpose intermediate results Y^* initially indexed by

$$(\text{unique } \mathbf{m}_1) \times (\text{all } \mathbf{h}_2),$$

so as to have them indexed by

$$(\text{all } \mathbf{m}_1) \times (\text{unique } \mathbf{h}_2).$$

We may then apply twiddle factors to get

$$Z(\mathbf{m}_1, \mathbf{h}_2) = e[\mathbf{h}_2 \cdot (\mathbf{N}^{-1}\mathbf{m}_1)] Y^*(\mathbf{m}_1, \mathbf{h}_2)$$

and carry out the second transform

$$Z^*(\mathbf{h}_1, \mathbf{h}_2) = \frac{1}{|\det \mathbf{N}_1|} \sum_{\mathbf{m}_1 \in I_1} Z(\mathbf{m}_1, \mathbf{h}_2) e[\mathbf{h}_1 \cdot (\mathbf{N}_1^{-1}\mathbf{m}_1)].$$

The final results are indexed by

$$(\text{all } \mathbf{h}_1) \times (\text{unique } \mathbf{h}_2),$$

which yield essentially an asymmetric unit of structure factors after unscrambling by:

$$F(\mathbf{h}_2 + \mathbf{N}_2^T\mathbf{h}_1) = Z^*(\mathbf{h}_1, \mathbf{h}_2).$$

The transposition formula above applies to intermediate results when going backwards from F to $\not\rho$, provided these results are considered *after* the twiddle-factor stage. A transposition formula applicable *before* that stage can be obtained by characterizing the action of G on $\mathbf{h}$ (including the effects of periodization by $\mathbf{N}^T\mathbb{Z}^3$) in a manner similar to that used for $\mathbf{m}$.

Let

$$\mathbf{h} = \mathbf{h}_2 + \mathbf{N}_2^T\mathbf{h}_1,$$

with

$$\begin{aligned} \mathbf{h}_2 &= \mathbf{h} && \bmod \mathbf{N}_2^T\mathbb{Z}^3, \\ \mathbf{h}_1 &= (\mathbf{N}_2^{-1})^T(\mathbf{h} - \mathbf{h}_2) && \bmod \mathbf{N}_1^T\mathbb{Z}^3. \end{aligned}$$

We may then write

$$\mathbf{R}_g^T\mathbf{h} = [\mathbf{R}_g^T\mathbf{h}]_2 + \mathbf{N}_2^T[\mathbf{R}_g^T\mathbf{h}]_1,$$

with

$$\begin{aligned} [\mathbf{R}_g^T\mathbf{h}]_2 &= [\mathbf{R}_g^{(2)}]^T\mathbf{h}_2 && \bmod \mathbf{N}_2^T\mathbb{Z}^3, \\ [\mathbf{R}_g^T\mathbf{h}]_1 &= [\mathbf{R}_g^{(1)}]^T\mathbf{h}_1 + \boldsymbol{\eta}_1(g, \mathbf{h}_2) && \bmod \mathbf{N}_1^T\mathbb{Z}^3. \end{aligned}$$

Here $[\mathbf{R}_g^{(2)}]^T$, $[\mathbf{R}_g^{(1)}]^T$ and $\boldsymbol{\eta}_1$ are defined by

$$\begin{aligned} [\mathbf{R}_g^{(2)}]^T\mathbf{h}_2 &= \mathbf{R}_g^T\mathbf{h} && \bmod \mathbf{N}_2^T\mathbb{Z}^3, \\ [\mathbf{R}_g^{(1)}]^T\mathbf{h}_1 &= \mathbf{R}_g^T\mathbf{h} && \bmod \mathbf{N}_1^T\mathbb{Z}^3 \end{aligned}$$

and

$$\boldsymbol{\eta}_1(g, \mathbf{h}_2) = (\mathbf{N}_2^{-1})^T(\mathbf{R}_g^T\mathbf{h}_2 - [\mathbf{R}_g^{(2)}]^T\mathbf{h}_2) \bmod \mathbf{N}_1^T\mathbb{Z}^3.$$

Let us then form an array Z^* according to

$$Z^*(\mathbf{h}_1', \mathbf{h}_2') = F(\mathbf{h}_2' + \mathbf{N}_2^T\mathbf{h}_1')$$

for *all* $\mathbf{h}_1'$ but only for the *unique* $\mathbf{h}_2'$ under the action of G in $\mathbb{Z}^3/\mathbf{N}_2^T\mathbb{Z}^3$, and transform on $\mathbf{h}_1'$ to obtain

$$Z(\mathbf{m}_1, \mathbf{h}_2) = \sum_{\mathbf{h}_1' \in \mathbb{Z}^3/\mathbf{N}_1^T\mathbb{Z}^3} Z^*(\mathbf{h}_1', \mathbf{h}_2') e[-\mathbf{h}_1' \cdot (\mathbf{N}_1^{-1}\mathbf{m}_1)].$$

Putting $\mathbf{h}' = \mathbf{R}_g^T\mathbf{h}$ and using the symmetry of F in the form

$$F(\mathbf{h}') = F(\mathbf{h}) \exp(-2\pi i \mathbf{h} \cdot \mathbf{t}_g),$$

where

$$\begin{aligned} \mathbf{h} \cdot \mathbf{t}_g &= (\mathbf{h}_2^T + \mathbf{h}_1^T\mathbf{N}_2)(\mathbf{N}_2^{-1}\mathbf{N}_1^{-1})(\mathbf{t}_g^{(1)} + \mathbf{N}_1\mathbf{t}_g^{(2)}) \\ &\equiv \mathbf{h}_2 \cdot \mathbf{t}_g + \mathbf{h}_2 \cdot (\mathbf{N}_1^{-1}\mathbf{t}_g^{(1)}) \bmod 1 \end{aligned}$$

yields by a straightforward rearrangement

$$\begin{aligned} Z(\mathbf{m}_1, [\mathbf{R}_g^{(2)}]^T\mathbf{h}_2) = e[-\{\mathbf{h}_2 \cdot \mathbf{t}_g + \boldsymbol{\eta}_1(g, \mathbf{h}_2) \cdot (\mathbf{N}_1^{-1}\mathbf{m}_1)\}] \\ \times Z\{S_g^{(1)}(\mathbf{m}_1), \mathbf{h}_2\}. \end{aligned}$$

This formula allows the transposition of intermediate results Z from an indexing by

$$(\text{all } \mathbf{m}_1) \times (\text{unique } \mathbf{h}_2)$$

to an indexing by

$$(\text{unique } \mathbf{m}_1) \times (\text{all } \mathbf{h}_2).$$

We may then apply the twiddle factors to obtain

$$Y^*(\mathbf{m}_1, \mathbf{h}_2) = e[-\mathbf{h}_2 \cdot (\mathbf{N}^{-1}\mathbf{m}_1)]Z(\mathbf{m}_1, \mathbf{h}_2)$$

and carry out the second transform on $\mathbf{h}_2$

$$Y(\mathbf{m}_1, \mathbf{m}_2) = \sum_{\mathbf{h}_2 \in \mathbb{Z}^3/\mathbf{N}_2^T\mathbb{Z}^3} Y^*(\mathbf{m}_1, \mathbf{h}_2) e[-\mathbf{h}_2 \cdot (\mathbf{N}_2^{-1}\mathbf{m}_2)].$$

The results, indexed by

$$(\text{unique } \mathbf{m}_1) \times (\text{all } \mathbf{m}_2)$$

yield essentially an asymmetric unit of electron densities by the rearrangement

$$\not\rho(\mathbf{m}_1 + \mathbf{N}_1\mathbf{m}_2) = Y(\mathbf{m}_1, \mathbf{m}_2).$$

The equivalence of the two transposition formulae up to the intervening twiddle factors is readily established, using the relation

$$\mathbf{h}_2 \cdot [\mathbf{N}_2^{-1}\boldsymbol{\mu}_2(g, \mathbf{m}_1)] = \boldsymbol{\eta}_1(g, \mathbf{h}_2) \cdot (\mathbf{N}_1^{-1}\mathbf{m}_1) \bmod 1$$

which is itself a straightforward consequence of the identity

$$\mathbf{h} \cdot [\mathbf{N}^{-1}S_g(\mathbf{m})] = \mathbf{h} \cdot \mathbf{t}_g + (\mathbf{R}_g^T\mathbf{h}) \cdot (\mathbf{N}^{-1}\mathbf{m}).$$

To complete the characterization of the effect of symmetry on the Cooley–Tukey factorization, and of the economy of computation it allows, it remains to consider the possibility that some values of $\mathbf{m}_1$ may be invariant under some transformations $g \in G$ under the action $\mathbf{m}_1 \longmapsto S_g^{(1)}(\mathbf{m}_1)$.

Suppose that $\mathbf{m}_1$ has a nontrivial isotropy subgroup $G_{\mathbf{m}_1}$, and let $g \in G_{\mathbf{m}_1}$. Then each subarray $Y_{\mathbf{m}_1}$ defined by

$$Y_{\mathbf{m}_1}(\mathbf{m}_2) = Y(\mathbf{m}_1, \mathbf{m}_2) = \rho(\mathbf{m}_1 + \mathbf{N}_1\mathbf{m}_2)$$

satisfies the identity

$$Y_{\mathbf{m}_1}(\mathbf{m}_2) = Y_{S_g^{(1)}(\mathbf{m}_1)}[S_g^{(2)}(\mathbf{m}_2) + \boldsymbol{\mu}_2(g, \mathbf{m}_1)]$$
$$= Y_{\mathbf{m}_1}[S_g^{(2)}(\mathbf{m}_2) + \boldsymbol{\mu}_2(g, \mathbf{m}_1)]$$

so that the data for the transform on $\mathbf{m}_2$ have residual symmetry properties. In this case the identity satisfied by $\boldsymbol{\mu}_2$ simplifies to

$$\boldsymbol{\mu}_2(gg', \mathbf{m}_1) = S_g^{(2)}[\boldsymbol{\mu}_2(g', \mathbf{m}_1)] + \boldsymbol{\mu}_2(g, \mathbf{m}_1) \bmod \mathbf{N}_2\mathbb{Z}^3,$$

which shows that the mapping $g \longmapsto \boldsymbol{\mu}_2(g, \mathbf{m}_1)$ satisfies the Frobenius congruences (Section 1.3.4.2.2.3). Thus the internal symmetry of subarray $Y_{\mathbf{m}_1}$ with respect to the action of G on $\mathbf{m}_2$ is given by $G_{\mathbf{m}_1}$ acting on $\mathbb{Z}^3/\mathbf{N}_2\mathbb{Z}^3$ *via*

$$\mathbf{m}_2 \longmapsto S_g^{(2)}(\mathbf{m}_2) + \boldsymbol{\mu}_2(g, \mathbf{m}_1) \bmod \mathbf{N}_2\mathbb{Z}^3.$$

The transform on $\mathbf{m}_2$ needs only be performed for one out of $[G : G_{\mathbf{m}_1}]$ distinct arrays $Y_{\mathbf{m}_1}$ (results for the others being obtainable by the transposition formula), and this transforms is $G_{\mathbf{m}_1}$-symmetric. In other words, the following cases occur:

(i) $G_{\mathbf{m}_1} = \{e\}$ — maximum saving in computation (by $|G|$); $\mathbf{m}_2$-transform has no symmetry.

(ii) $G_{\mathbf{m}_1} = G' < G$ — saving in computation by a factor of $[G : G']$; $\mathbf{m}_2$-transform is G'-symmetric.

(iii) $G_{\mathbf{m}_1} = G$ — no saving in computation; $\mathbf{m}_2$-transform is G-symmetric.

The symmetry properties of the $\mathbf{m}_2$-transform may themselves be exploited in a similar way if $\mathbf{N}_2$ can be factored as a product of smaller decimation matrices; otherwise, an appropriate symmetrized DFT routine may be provided, using for instance the idea of 'multiplexing/demultiplexing' (Section 1.3.4.3.5). We thus have a recursive *descent procedure*, in which the deeper stages of the recursion deal with transforms on *fewer points*, or of *lower symmetry* (usually both).

The same analysis applies to the $\mathbf{h}_1$-transforms on the subarrays $Z^*_{\mathbf{h}_2}$, and leads to a similar descent procedure.

In conclusion, crystallographic symmetry can be fully exploited to reduce the amount of computation to the minimum required to obtain the unique results from the unique data. No such analysis was so far available in cases where the asymmetric units in real and reciprocal space are not parallelepipeds. An example of this procedure will be given in Section 1.3.4.3.6.5.

1.3.4.3.4.2. Multidimensional Good factorization

This procedure was described in Section 1.3.3.3.2.2. The main difference with the Cooley–Tukey factorization is that if $\mathbf{N} = \mathbf{N}_1\mathbf{N}_2 \ldots \mathbf{N}_{d-1}\mathbf{N}_d$, where the different factors are pairwise coprime, then the Chinese remainder theorem reindexing makes $\mathbb{Z}^3/\mathbf{N}\mathbb{Z}^3$ isomorphic to a direct sum.

$$\mathbb{Z}^3/\mathbf{N}\mathbb{Z}^3 \cong (\mathbb{Z}^3/\mathbf{N}_1\mathbb{Z}^3) \oplus \ldots \oplus (\mathbb{Z}^3/\mathbf{N}_d\mathbb{Z}^3),$$

where each p-primary piece is endowed with an induced $\mathbb{Z}G$-module structure by letting G operate in the usual way but with the corresponding modular arithmetic. The situation is thus more favourable than with the Cooley–Tukey method, since there is no interference between the factors (no 'carry'). In the terminology of Section 1.3.4.2.2.2, G acts *diagonally* on this direct sum, and results of a partial transform may be transposed by orbit exchange as in Section 1.3.4.3.4.1 but without the extra terms $\boldsymbol{\mu}$ or $\boldsymbol{\eta}$. The analysis of the symmetry properties of partial transforms also carries over, again without the extra terms. Further simplification occurs for all p-primary pieces with p other than 2 or 3, since all nonprimitive translations (including those associated to lattice centring) disappear modulo p.

Thus the cost of the CRT reindexing is compensated by the computational savings due to the absence of twiddle factors and of other phase shifts associated with nonprimitive translations and with geometric 'carries'.

Within each p-primary piece, however, higher powers of p may need to be split up by a Cooley–Tukey factorization, or carried out directly by a suitably adapted Winograd algorithm.

1.3.4.3.4.3. Crystallographic extension of the Rader/Winograd factorization

As was the case in the absence of symmetry, the two previous classes of algorithms can only factor the global transform into partial transforms on prime numbers of points, but cannot break the latter down any further. Rader's idea of using the action of the group of units $U(p)$ to obtain further factorization of a p-primary transform has been used in 'scalar' form by Auslander & Shenefelt (1987), Shenefelt (1988) and Auslander *et al.* (1988). It will be shown here that it can be adapted to the crystallographic case so as to take advantage also of the possible existence of n-fold cyclic symmetry elements ($n = 3, 4, 6$) in a two-dimensional transform (Bricogne & Tolimieri, 1990). This adaptation entails the use of certain rings of *algebraic* integers rather than ordinary integers, whose connection with the handling of cyclic symmetry will now be examined.

Let G be the group associated with a threefold axis of symmetry: $G = \{e, g, g^2\}$ with $g^3 = e$. In a standard trigonal basis, G has matrix representation

$$\mathbf{R}_e = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} = \mathbf{I}, \quad \mathbf{R}_g = \begin{pmatrix} 0 & -1 \\ 1 & -1 \end{pmatrix}, \quad \mathbf{R}_{g^2} = \begin{pmatrix} -1 & 1 \\ -1 & 0 \end{pmatrix}$$

in real space,

$$\mathbf{R}^*_e = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} = \mathbf{I}, \quad \mathbf{R}^*_g = \begin{pmatrix} -1 & -1 \\ 1 & 0 \end{pmatrix}, \quad \mathbf{R}^*_{g^2} = \begin{pmatrix} 0 & 1 \\ -1 & -1 \end{pmatrix}$$

in reciprocal space. Note that

$$\mathbf{R}^*_{g^2} = [\mathbf{R}^{-1}_{g^2}]^T = \mathbf{R}^T_g,$$

and that

$$\mathbf{R}^T_g = \mathbf{J}^{-1}\mathbf{R}_g\mathbf{J}, \qquad \text{where } \mathbf{J} = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}$$

so that $\mathbf{R}_g$ and $\mathbf{R}^T_g$ are conjugate in the group of 2×2 unimodular integer matrices. The group ring $\mathbb{Z}G$ is commutative, and has the structure of the polynomial ring $\mathbb{Z}[X]$ with the single relation $X^2 + X + 1 = 0$ corresponding to the minimal polynomial of $\mathbf{R}_g$. In the terminology of Section 1.3.3.2.4, the ring structure of $\mathbb{Z}G$ is obtained from that of $\mathbb{Z}[X]$ by carrying out polynomial addition and multiplication modulo $X^2 + X + 1$, then replacing X by any generator of G. This type of construction forms the very basis of algebraic number theory [see Artin (1944, Section IIc) for an illustration of this viewpoint], and $\mathbb{Z}G$ as just defined is isomorphic to the ring $\mathbb{Z}[\omega]$ of algebraic integers of the form

$a + b\omega$ [$a, b \in \mathbb{Z}$, $\omega = \exp(2\pi i/3)$] under the identification $X \leftrightarrow \omega$. Addition in this ring is defined component-wise, while multiplication is defined by

$$(a_1 + b_1\omega) \times (a_2 + b_2\omega) = (a_1a_2 - b_1b_2) + [(a_1 - b_1)b_2 + b_1a_2]\omega.$$

In the case of a fourfold axis, $G = \{e, g, g^2, g^3\}$ with $g^4 = e$, and

$$\mathbf{R}_g = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} = \mathbf{R}_g^*, \quad \text{with again } \mathbf{R}_g^T = \mathbf{J}^{-1}\mathbf{R}_g\mathbf{J}.$$

$\mathbb{Z}G$ is obtained from $\mathbb{Z}[X]$ by carrying out polynomial arithmetic modulo $X^2 + 1$. This identifies $\mathbb{Z}G$ with the ring $\mathbb{Z}[i]$ of Gaussian integers of the form $a + bi$, in which addition takes place component-wise while multiplication is defined by

$$(a_1 + b_1i) \times (a_2 + b_2i) = (a_1a_2 - b_1b_2) + (a_1b_2 + b_1a_2)i.$$

In the case of a sixfold axis, $G = \{e, g, g^2, g^3, g^4, g^5\}$ with $g^6 = e$, and

$$\mathbf{R}_g = \begin{pmatrix} 1 & -1 \\ 1 & 0 \end{pmatrix}, \quad \mathbf{R}_g^* = \begin{pmatrix} 0 & -1 \\ 1 & 1 \end{pmatrix}, \quad \mathbf{R}_g^T = \mathbf{J}^{-1}\mathbf{R}_g\mathbf{J}.$$

$\mathbb{Z}G$ is isomorphic to $\mathbb{Z}[\omega]$ under the mapping $g \leftrightarrow 1 + \omega$ since $(1 + \omega)^6 = 1$.

Thus in all cases $\mathbb{Z}G \cong \mathbb{Z}[X]/P(X)$ where $P(X)$ is an irreducible quadratic polynomial with integer coefficients.

The actions of G on lattices in real and reciprocal space (Sections 1.3.4.2.2.4, 1.3.4.2.2.5) extend naturally to actions of $\mathbb{Z}G$ on $\mathbb{Z}^2$ in which an element $z = a + bg$ of $\mathbb{Z}G$ acts *via*

$$\mathbf{m} = \begin{pmatrix} m_1 \\ m_2 \end{pmatrix} \longmapsto z\mathbf{m} = (a\mathbf{I} + b\mathbf{R}_g)\begin{pmatrix} \mathbf{m}_1 \\ \mathbf{m}_2 \end{pmatrix}$$

in real space, and *via*

$$\mathbf{h} = \begin{pmatrix} h_1 \\ h_2 \end{pmatrix} \longmapsto z\mathbf{h} = (a\mathbf{I} + b\mathbf{R}_g^T)\begin{pmatrix} h_1 \\ h_2 \end{pmatrix}$$

in reciprocal space. These two actions are related by conjugation, since

$$(a\mathbf{I} + b\mathbf{R}_g^T) = \mathbf{J}^{-1}(a\mathbf{I} + b\mathbf{R}_g)\mathbf{J}$$

and the following identity (which is fundamental in the sequel) holds:

$$(z\mathbf{h}) \cdot \mathbf{m} = \mathbf{h} \cdot (z\mathbf{m}) \quad \text{for all } \mathbf{m}, \mathbf{h} \in \mathbb{Z}^2.$$

Let us now consider the calculation of a $p \times p$ two-dimensional DFT with n-fold cyclic symmetry ($n = 3, 4, 6$) for an odd prime $p \geq 5$. Denote $\mathbb{Z}/p\mathbb{Z}$ by $\mathbb{Z}_p$. Both the data and the results of the DFT are indexed by $\mathbb{Z}_p \times \mathbb{Z}_p$: hence the action of $\mathbb{Z}G$ on these indices is in fact an action of $\mathbb{Z}_pG$, the latter being obtained from $\mathbb{Z}G$ by carrying out all integer arithmetic in $\mathbb{Z}G$ modulo p. The algebraic structure of $\mathbb{Z}_pG$ combines the symmetry-carrying ring structure of $\mathbb{Z}G$ with the finite field structure of $\mathbb{Z}_p$ used in Section 1.3.3.2.3.1, and holds the key to a symmetry-adapted factorization of the DFT at hand.

The structure of $\mathbb{Z}_pG$ depends on whether $P(X)$ remains irreducible when considered as a polynomial over $\mathbb{Z}_p$. Thus two cases arise:

(1) $P(X)$ remains irreducible mod p, *i.e.* there is no nth root of unity in $\mathbb{Z}_p$;

(2) $P(X)$ factors as $(X - u)(X - v)$, *i.e.* there are nth roots of unity in $\mathbb{Z}_p$.

These two cases require different developments.

Case 1. $\mathbb{Z}_pG$ is a finite field with p^2 elements. There is essentially (*i.e.* up to isomorphism) only one such field, denoted $GF(p^2)$, and its group of units is a cyclic group with $p^2 - 1$ elements. If γ is a generator of this group of units, the input data $\rho_{\mathbf{m}}$ with $\mathbf{m} \neq \mathbf{0}$ may be reordered as

$$\mathbf{m}_0, \gamma\mathbf{m}_0, \gamma^2\mathbf{m}_0, \gamma^3\mathbf{m}_0, \ldots, \gamma^{p^2-2}\mathbf{m}_0$$

by the *real-space action* of γ; while the results $F_{\mathbf{h}}$ with $\mathbf{h} \neq \mathbf{0}$ may be reordered as

$$\mathbf{h}_0, \gamma\mathbf{h}_0, \gamma^2\mathbf{h}_0, \gamma^3\mathbf{h}_0, \ldots, \gamma^{p^2-2}\mathbf{h}_0$$

by the *reciprocal-space action* of γ, where $\mathbf{m}_0$ and $\mathbf{h}_0$ are arbitrary nonzero indices.

The core $\mathbf{C}_{p\times p}$ of the DFT matrix, defined by

$$\mathbf{F}_{p\times p} = \begin{pmatrix} 1 & 1 & \ldots & 1 \\ 1 & & & \\ \vdots & & \mathbf{C}_{p\times p} & \\ 1 & & & \end{pmatrix},$$

will then have a skew-circulant structure (Section 1.3.3.2.3.1) since

$$(\mathbf{C}_{p\times p})_{jk} = e\left[\frac{(\gamma^j\mathbf{h}_0) \cdot (\gamma^k\mathbf{m}_0)}{p}\right] = e\left[\frac{\mathbf{h}_0 \cdot (\gamma^{j+k}\mathbf{m}_0)}{p}\right]$$

depends only on $j + k$. Multiplication by $\mathbf{C}_{p\times p}$ may then be turned into a cyclic convolution of length $p^2 - 1$, which may be factored by two DFTs (Section 1.3.3.2.3.1) or by Winograd's techniques (Section 1.3.3.2.4). The latter factorization is always favourable, as it is easily shown that $p^2 - 1$ is divisible by 24 for any odd prime $p \geq 5$. This procedure is applicable even if no symmetry is present in the data.

Assume now that cyclic symmetry of order $n = 3$, 4 or 6 *is* present. Since n divides 24 hence divides $p^2 - 1$, the generator g of this symmetry is representable as $\gamma^{(p^2-1)/n}$ for a suitable generator γ of the group of units. The reordered data will then be $(p^2 - 1)/n$-periodic rather than simply $(p^2 - 1)$-periodic; hence the reindexed results will be *n-decimated* (Section 1.3.2.7.2), and the $(p^2 - 1)/n$ nonzero results can be calculated by applying the DFT to the $(p^2 - 1)/n$ unique input data. In this way, the n-fold symmetry can be used in full to calculate the core contributions from the unique data to the unique results by a DFT of length $(p^2 - 1)/n$.

It is a simple matter to incorporate nonprimitive translations into this scheme. For example, when going from structure factors to electron densities, reordered data items separated by $(p^2 - 1)/n$ are not equal but differ by a phase shift proportional to their index mod p, whose effect is simply to shift the origin of the n-decimated transformed sequence. The same economy of

computation can therefore be achieved as in the purely cyclic case.

Dihedral symmetry elements, which map g to g^{-1} (Section 1.3.4.2.2.3), induce extra one-dimensional symmetries of order 2 in the reordered data which can also be fully exploited to reduce computation.

Case 2. If $p \geq 5$, it can be shown that the two roots u and v are always distinct. Then, by the Chinese remainder theorem (CRT) for polynomials (Section 1.3.3.2.4) we have a ring isomorphism

$$\mathbb{Z}_p[X]/P(X) \cong \{\mathbb{Z}_p[X]/(X-u)\} \times \{\mathbb{Z}_p[X]/(X-v)\}$$

defined by sending a polynomial $Q(X)$ from the left-hand-side ring to its two residue classes modulo $X-u$ and $X-v$, respectively. Since the latter are simply the constants $Q(u)$ and $Q(v)$, the CRT reindexing has the particularly simple form

$$a + bX \longmapsto (a+bu, a+bv) = (\alpha, \beta)$$

or equivalently

$$\begin{pmatrix} a \\ b \end{pmatrix} \longmapsto \begin{pmatrix} \alpha \\ \beta \end{pmatrix} = \mathbf{M}\begin{pmatrix} a \\ b \end{pmatrix} \bmod p, \quad \text{with } \mathbf{M} = \begin{pmatrix} 1 & u \\ 1 & v \end{pmatrix}.$$

The CRT reconstruction formula similarly simplifies to

$$\begin{pmatrix} \alpha \\ \beta \end{pmatrix} \longmapsto \begin{pmatrix} a \\ b \end{pmatrix} = \mathbf{M}^{-1}\begin{pmatrix} \alpha \\ \beta \end{pmatrix} \bmod p,$$
$$\text{with } \mathbf{M}^{-1} = \frac{1}{v-u}\begin{pmatrix} v & -u \\ -1 & 1 \end{pmatrix}.$$

The use of the CRT therefore amounts to the *simultaneous diagonalization* (by $\mathbf{M}$) of all the matrices representing the elements of $\mathbb{Z}_p G$ in the basis $(1, X)$.

A first consequence of this diagonalization is that the internal structure of $\mathbb{Z}_p G$ becomes clearly visible. Indeed, $\mathbb{Z}_p G$ is mapped isomorphically to a direct product of two copies of $\mathbb{Z}_p$, in which arithmetic is carried out *component-wise* between eigenvalues α and β. Thus if

$$z = a + bX \overset{\text{CRT}}{\longleftrightarrow} (\alpha, \beta),$$
$$z' = a' + b'X \overset{\text{CRT}}{\longleftrightarrow} (\alpha', \beta'),$$

then

$$z + z' \overset{\text{CRT}}{\longleftrightarrow} (\alpha + \alpha', \beta + \beta'),$$
$$zz' \overset{\text{CRT}}{\longleftrightarrow} (\alpha\alpha', \beta\beta').$$

Taking in particular

$$z \overset{\text{CRT}}{\longleftrightarrow} (\alpha, 0) \neq (0, 0),$$
$$z' \overset{\text{CRT}}{\longleftrightarrow} (0, \beta) \neq (0, 0),$$

we have $zz' = 0$, so that $\mathbb{Z}_p G$ contains zero divisors; therefore $\mathbb{Z}_p G$ *is not a field.* On the other hand, if $z \overset{\text{CRT}}{\longleftrightarrow} (\alpha, \beta)$ with $\alpha \neq 0$ and $\beta \neq 0$, then α and β belong to the group of units $U(p)$ (Section 1.3.3.2.3.1) and hence have inverses α^{-1} and β^{-1}; it follows that z is a unit in $\mathbb{Z}_p G$, with inverse $z^{-1} \overset{\text{CRT}}{\longleftrightarrow} (\alpha^{-1}, \beta^{-1})$. Therefore, $\mathbb{Z}_p G$ consists of four distinct pieces:

$$0 \overset{\text{CRT}}{\longleftrightarrow} \{(0,0)\},$$
$$D_1 \overset{\text{CRT}}{\longleftrightarrow} \{(\alpha, 0) | \alpha \in U(p)\} \cong U(p),$$
$$D_2 \overset{\text{CRT}}{\longleftrightarrow} \{(0, \beta) | \beta \in U(p)\} \cong U(p),$$
$$U \overset{\text{CRT}}{\longleftrightarrow} \{(\alpha, \beta) | \alpha \in U(p), \beta \in U(p)\} \cong U(p) \times U(p).$$

A second consequence of this diagonalization is that the actions of $\mathbb{Z}_p G$ on indices $\mathbf{m}$ and $\mathbf{h}$ can themselves be brought to diagonal form by basis changes:

$$\mathbf{m} \longmapsto (a\mathbf{I} + b\mathbf{R}_g)\mathbf{m}$$
$$\text{becomes } \boldsymbol{\mu} \longmapsto \begin{pmatrix} \alpha & 0 \\ 0 & \beta \end{pmatrix}\boldsymbol{\mu} \quad \text{with } \boldsymbol{\mu} = \mathbf{M}\mathbf{m},$$
$$\mathbf{h} \longmapsto (a\mathbf{I} + b\mathbf{R}_g^T)\mathbf{h}$$
$$\text{becomes } \boldsymbol{\eta} \longmapsto \begin{pmatrix} \alpha & 0 \\ 0 & \beta \end{pmatrix}\boldsymbol{\eta} \quad \text{with } \boldsymbol{\eta} = \mathbf{M}\mathbf{J}\mathbf{h}.$$

Thus the sets of indices $\boldsymbol{\mu}$ and $\boldsymbol{\eta}$ can be split into four pieces as $\mathbb{Z}_p G$ itself, according as these indices have none, one or two of their coordinates in $U(p)$. These pieces will be labelled by the same symbols – 0, D_1, D_2 and U – as those of $\mathbb{Z}_p G$.

The scalar product $\mathbf{h} \cdot \mathbf{m}$ may be written in terms of $\boldsymbol{\eta}$ and $\boldsymbol{\mu}$ as

$$\mathbf{h} \cdot \mathbf{m} = [\boldsymbol{\eta} \cdot ((\mathbf{M}^{-1})^T \mathbf{J} \mathbf{M}^{-1})\boldsymbol{\mu}],$$

and an elementary calculation shows that the matrix $\boldsymbol{\Delta} = (\mathbf{M}^{-1})^T \mathbf{J} \mathbf{M}^{-1}$ is *diagonal* by virtue of the relation

$$uv = \text{constant term in } P(X) = 1.$$

Therefore, $\mathbf{h} \cdot \mathbf{m} = 0$ if $\mathbf{h} \in D_1$ and $\boldsymbol{\mu} \in D_2$ or *vice versa.*

We are now in a position to rearrange the DFT matrix $\mathbf{F}_{p \times p}$. Clearly, the structure of $\mathbf{F}_{p \times p}$ is more complex than in case 1, as there are three types of 'core' matrices:

type 1: $D \times D$ (with $D = D_1$ or D_2);
type 2: $D \times U$ or $U \times D$;
type 3: $U \times U$.

(Submatrices of type $D_1 \times D_2$ and $D_2 \times D_1$ have all their elements equal to 1 by the previous remark.)

Let γ be a generator of $U(p)$. We may reorder the elements in D_1, D_2 and U – and hence the data and results indexed by these elements – according to powers of γ. This requires one exponent in each of D_1 and D_2, and two exponents in U. For instance, in the $\mathbf{h}$-index space:

$$D_1 = \left\{ \begin{pmatrix} \gamma & 0 \\ 0 & 0 \end{pmatrix}^j \begin{pmatrix} \eta_1 \\ 0 \end{pmatrix}_0 \Big| j = 1, \ldots, p-1 \right\}$$

$$D_2 = \left\{ \begin{pmatrix} 0 & 0 \\ 0 & \gamma \end{pmatrix}^j \begin{pmatrix} 0 \\ \eta_2 \end{pmatrix}_0 \Big| j = 1, \ldots, p-1 \right\}$$

$$U = \left\{ \begin{pmatrix} \gamma & 0 \\ 0 & 1 \end{pmatrix}^{j_1} \begin{pmatrix} 1 & 0 \\ 0 & \gamma \end{pmatrix}^{j_2} \begin{pmatrix} \eta_1 \\ \eta_2 \end{pmatrix}_0 \Big| j_1 = 1, \ldots, p-1; \; j_2 = 1, \ldots, p-1 \right\}$$

and similarly for the $\boldsymbol{\mu}$ index.

Since the diagonal matrix $\boldsymbol{\Delta}$ commutes with all the matrices representing the action of γ, this rearrangement will induce skew-circulant structures in all the core matrices. The corresponding cyclic convolutions may be carried out by Rader's method, *i.e.* by diagonalizing them by means of two $(p-1)$-point one-dimensional DFTs in the $D \times D$ pieces and of two $(p-1) \times (p-1)$-point two-dimensional DFTs in the $U \times U$ piece (the $U \times D$ and $D \times U$ pieces involve extra section and projection operations).

In the absence of symmetry, no computational saving is achieved, since the same reordering could have been applied to the initial $\mathbb{Z}_p \times \mathbb{Z}_p$ indexing, without the CRT reindexing.

In the presence of n-fold cyclic symmetry, however, the rearranged $\mathbf{F}_{p\times p}$ lends itself to an n-fold reduction in size. The basic fact is that whenever case 2 occurs, $p-1$ is divisible by n (*i.e.* $p-1$ is divisible by 6 when $n = 3$ or 6, and by 4 when $n = 4$), say $p - 1 = nq$. If g is a generator of the cyclic symmetry, the generator γ of $U(p)$ may be chosen in such a way that $g = \gamma^q$. The action of g is then to increment the j index in D_1 and D_2 by q, and the (j_1, j_2) index in U by (q, q). Since the data items whose indices are related in this way have identical values, the DFTs used to diagonalize the Rader cyclic convolutions will operate on *periodized data*, hence yield *decimated results*; and the nonzero results will be obtained from the unique data by DFTs n times smaller than their counterparts in the absence of symmetry.

A more thorough analysis is needed to obtain a Winograd factorization into the normal from **CBA** in the presence of symmetry (see Bricogne & Tolimieri, 1990).

Nonprimitive translations and dihedral symmetry may also be accommodated within this framework, as in case 1.

This reindexing by means of algebraic integers yields larger orbits, hence more efficient algorithms, than that of Auslander *et al.* (1988) which only uses ordinary integers acting by scalar dilation.

1.3.4.3.5. Treatment of conjugate and parity-related symmetry properties

Most crystallographic Fourier syntheses are real-valued and originate from Hermitian-symmetric collections of Fourier coefficients. Hermitian symmetry is closely related to the action of a centre of inversion in reciprocal space, and thus interacts strongly with all other genuinely crystallographic symmetry elements of order 2. All these symmetry properties are best treated by factoring by 2 and reducing the computation of the initial transform to that of a collection of smaller transforms with less symmetry or none at all.

1.3.4.3.5.1. Hermitian-symmetric or real-valued transforms

The computation of a DFT with Hermitian-symmetric or real-valued data can be carried out at a cost of half that of an ordinary transform, essentially by 'multiplexing' pairs of special partial transforms into general complex transforms, and then 'demultiplexing' the results on the basis of their symmetry properties. The treatment given below is for general dimension n; a subset of cases for $n = 1$ was treated by Ten Eyck (1973).

(*a*) *Underlying group action*

Hermitian symmetry is not a geometric symmetry, but it is defined in terms of the action in reciprocal space of point group $G = \bar{1}$, *i.e.* $G = \{e, -e\}$, where e acts as $\mathbf{I}$ (the $n \times n$ identity matrix) and $-e$ acts as $-\mathbf{I}$.

This group action on $\mathbb{Z}^n/\mathbf{N}\mathbb{Z}^n$ with $\mathbf{N} = \mathbf{N}_1\mathbf{N}_2$ will now be characterized by the calculation of the cocycle $\boldsymbol{\eta}_1$ (Section 1.3.4.3.4.1) under the assumption that $\mathbf{N}_1$ and $\mathbf{N}_2$ are both *diagonal*. For this purpose it is convenient to associate to any integer vector

$$\mathbf{v} = \begin{pmatrix} v_1 \\ \vdots \\ v_n \end{pmatrix}$$

in $\mathbb{Z}^n$ the vector $\boldsymbol{\zeta}(\mathbf{v})$ whose jth component is

$$\begin{cases} 0 \text{ if } & v_j = 0 \\ 1 \text{ if } & v_j \neq 0. \end{cases}$$

Let $\mathbf{m} = \mathbf{m}_1 + \mathbf{N}_1\mathbf{m}_2$, and hence $\mathbf{h} = \mathbf{h}_2 + \mathbf{N}_2\mathbf{h}_1$. Then

$$-\mathbf{h}_2 \bmod \mathbf{N}\mathbb{Z}^n = \mathbf{N}\boldsymbol{\zeta}(\mathbf{h}_2) - \mathbf{h}_2,$$
$$-\mathbf{h}_2 \bmod \mathbf{N}_2\mathbb{Z}^n = \mathbf{N}_2\boldsymbol{\zeta}(\mathbf{h}_2) - \mathbf{h}_2,$$

hence

$$\begin{aligned} \boldsymbol{\eta}_1(-e, \mathbf{h}_2) &= \mathbf{N}_2^{-1}\{[\mathbf{N}\boldsymbol{\zeta}(\mathbf{h}_2) - \mathbf{h}_2] - [\mathbf{N}_2\boldsymbol{\zeta}(\mathbf{h}_2) - \mathbf{h}_2]\} \bmod \mathbf{N}_1\mathbb{Z}^n \\ &= -\boldsymbol{\zeta}(\mathbf{h}_2) \bmod \mathbf{N}_1\mathbb{Z}^n. \end{aligned}$$

Therefore $-e$ acts by

$$(\mathbf{h}_2, \mathbf{h}_1) \longmapsto [\mathbf{N}_2\boldsymbol{\zeta}(\mathbf{h}_2) - \mathbf{h}_2, \mathbf{N}_1\boldsymbol{\zeta}(\mathbf{h}_1) - \mathbf{h}_1 - \boldsymbol{\zeta}(\mathbf{h}_2)].$$

Hermitian symmetry is traditionally dealt with by factoring by 2, *i.e.* by assuming $\mathbf{N} = 2\mathbf{M}$. If $\mathbf{N}_2 = 2\mathbf{I}$, then each $\mathbf{h}_2$ is invariant under G, so that each partial vector $\mathbf{Z}^*_{\mathbf{h}_2}$ (Section 1.3.4.3.4.1) inherits the symmetry internally, with a 'modulation' by $\boldsymbol{\eta}_1(g, \mathbf{h}_2)$. The 'multiplexing–demultiplexing' technique provides an efficient treatment of this singular case.

(*b*) *Calculation of structure factors*

The computation may be summarized as follows:

$$\mathcal{P} \overset{\mathbf{dec}(\mathbf{N}_1)}{\longmapsto} \mathbf{Y} \overset{\bar{F}(\mathbf{N}_2)}{\longmapsto} \mathbf{Y}^* \overset{\text{TW}}{\longmapsto} \mathbf{Z} \overset{\bar{F}(\mathbf{N}_1)}{\longmapsto} \mathbf{Z}^* \overset{\mathbf{rev}(\mathbf{N}_2)}{\longmapsto} \mathbf{F}$$

where $\mathbf{dec}(\mathbf{N}_1)$ is the initial decimation given by $Y_{\mathbf{m}_1}(\mathbf{m}_2) = \mathcal{P}(\mathbf{m}_1 + \mathbf{N}_1\mathbf{m}_2)$, TW is the transposition and twiddle-factor stage, and $\mathbf{rev}(\mathbf{N}_2)$ is the final unscrambling by coset reversal given by $F(\mathbf{h}_2 + \mathbf{N}_2\mathbf{h}_1) = \mathbf{Z}^*_{\mathbf{h}_2}(\mathbf{h}_1)$.

(i) *Decimation in time* ($\mathbf{N}_1 = 2\mathbf{I}, \mathbf{N}_2 = \mathbf{M}$)

The decimated vectors $\mathbf{Y}_{\mathbf{m}_1}$ are real and hence have Hermitian transforms $\mathbf{Y}^*_{\mathbf{m}_1}$. The 2^n values of $\mathbf{m}_1$ may be grouped into 2^{n-1} pairs $(\mathbf{m}_1', \mathbf{m}_1'')$ and the vectors corresponding to each pair may be multiplexed into a general complex vector

$$\mathbf{Y} = \mathbf{Y}_{\mathbf{m}_1'} + i\mathbf{Y}_{\mathbf{m}_1''}.$$

The transform $\mathbf{Y}^* = \bar{F}(\mathbf{M})[\mathbf{Y}]$ can then be resolved into the separate transforms $\mathbf{Y}^*_{\mathbf{m}_1'}$ and $\mathbf{Y}^*_{\mathbf{m}_1''}$ by using the Hermitian symmetry of the latter, which yields the demultiplexing formulae

$$\begin{aligned} Y^*_{\mathbf{m}_1'}(\mathbf{h}_2) + iY^*_{\mathbf{m}_1''}(\mathbf{h}_2) &= Y^*(\mathbf{h}_2) \\ \overline{Y^*_{\mathbf{m}_1'}(\mathbf{h}_2)} + i\overline{Y^*_{\mathbf{m}_1''}(\mathbf{h}_2)} &= Y^*[\mathbf{M}\boldsymbol{\zeta}(\mathbf{h}_2) - \mathbf{h}_2]. \end{aligned}$$

The number of partial transforms $\bar{F}(\mathbf{M})$ is thus reduced from 2^n to 2^{n-1}. Once this separation has been achieved, the remaining steps need only be carried out for a unique half of the values of $\mathbf{h}_2$.

(ii) *Decimation in frequency* ($\mathbf{N}_1 = \mathbf{M}, \mathbf{N}_2 = 2\mathbf{I}$)

Since $\mathbf{h}_2 \in \mathbb{Z}^n/2\mathbb{Z}^n$ we have $-\mathbf{h}_2 = \mathbf{h}_2$ and $\boldsymbol{\zeta}(\mathbf{h}_2) = \mathbf{h}_2 \bmod 2\mathbb{Z}^n$. The vectors of decimated and scrambled results $\mathbf{Z}^*_{\mathbf{h}_2}$ then obey the symmetry relations

$$Z^*_{\mathbf{h}_2}(\mathbf{h}_1 - \mathbf{h}_2) = \overline{Z^*_{\mathbf{h}_2}[\mathbf{M}\boldsymbol{\zeta}(\mathbf{h}_1) - \mathbf{h}_1]}$$

which can be used to halve the number of $\bar{F}(\mathbf{M})$ necessary to compute them, as follows.

Having formed the vectors $\mathbf{Z}_{\mathbf{h}_2}$ given by

$$Z_{\mathbf{h}_2}(\mathbf{m}_1) = \left[\sum_{\mathbf{m}_2 \in \mathbb{Z}^n/2\mathbb{Z}^n} \frac{(-1)^{\mathbf{h}_2\cdot\mathbf{m}_2}}{2^n} \rho(\mathbf{m}_1 + \mathbf{M}\mathbf{m}_2)\right] e[\mathbf{h}_2 \cdot (\mathbf{N}^{-1}\mathbf{m}_1)],$$

we may group the 2^n values of $\mathbf{h}_2$ into 2^{n-1} pairs $(\mathbf{h}_2', \mathbf{h}_2'')$ and for each pair form the multiplexed vector:

$$\mathbf{Z} = \mathbf{Z}_{\mathbf{h}_2'} + i\mathbf{Z}_{\mathbf{h}_2''}.$$

After calculating the 2^{n-1} transforms $\mathbf{Z}^* = \bar{F}(\mathbf{M})[\mathbf{Z}]$, the 2^n individual transforms $\mathbf{Z}^*_{\mathbf{h}_2'}$ and $\mathbf{Z}^*_{\mathbf{h}_2''}$ can be separated by using for each pair the demultiplexing formulae

$$\begin{aligned} Z^*_{\mathbf{h}_2'}(\mathbf{h}_1) + iZ^*_{\mathbf{h}_2''}(\mathbf{h}_1) &= Z^*(\mathbf{h}_1) \\ Z^*_{\mathbf{h}_2'}(\mathbf{h}_1 - \mathbf{h}_2') + iZ^*_{\mathbf{h}_2''}(\mathbf{h}_1 - \mathbf{h}_2'') &= \overline{Z^*[\mathbf{M}\boldsymbol{\zeta}(\mathbf{h}_1) - \mathbf{h}_1]} \end{aligned}$$

which can be solved recursively. If all pairs are chosen so that they differ only in the jth coordinate $(\mathbf{h}_2)_j$, the recursion is along $(\mathbf{h}_1)_j$ and can be initiated by introducing the (real) values of $Z^*_{\mathbf{h}_2'}$ and $Z^*_{\mathbf{h}_2''}$ at $(\mathbf{h}_1)_j = 0$ and $(\mathbf{h}_1)_j = M_j$, accumulated *e.g.* while forming $\mathbf{Z}$ for that pair. Only points with $(\mathbf{h}_1)_j$ going from 0 to $\frac{1}{2}M_j$ need be resolved, and they contain the unique half of the Hermitian-symmetric transform $\mathbf{F}$.

(*c*) *Calculation of electron densities*

The computation may be summarized as follows:

$$\mathbf{F} \overset{\mathbf{scr}(\mathbf{N}_2)}{\longmapsto} \mathbf{Z}^* \overset{F(\mathbf{N}_1)}{\longmapsto} \mathbf{Z} \overset{\mathrm{TW}}{\longmapsto} \mathbf{Y}^* \overset{F(\mathbf{N}_2)}{\longmapsto} \mathbf{Y} \overset{\mathbf{nat}(\mathbf{N}_1)}{\longmapsto} \rho$$

where $\mathbf{scr}(\mathbf{N}_2)$ is the decimation with coset reversal given by $\mathbf{Z}^*_{\mathbf{h}_2}(\mathbf{h}_1) = F(\mathbf{h}_2 + \mathbf{N}_2\mathbf{h}_1)$, TW is the transposition and twiddle-factor stage, and $\mathbf{nat}(\mathbf{N}_1)$ is the recovery in natural order given by $\rho(\mathbf{m}_1 + \mathbf{N}_1\mathbf{m}_2) = Y_{\mathbf{m}_1}(\mathbf{m}_2)$.

(i) *Decimation in time* ($\mathbf{N}_1 = \mathbf{M}, \mathbf{N}_2 = 2\mathbf{I}$)

The last transformation $F(2\mathbf{I})$ has a real-valued matrix, and the final result ρ is real-valued. It follows that the vectors $\mathbf{Y}^*_{\mathbf{m}_1}$ of intermediate results after the twiddle-factor stage are real-valued, hence lend themselves to multiplexing along the real and imaginary components of half as many general complex vectors.

Let the 2^n initial vectors $\mathbf{Z}^*_{\mathbf{h}_2}$ be multiplexed into 2^{n-1} vectors

$$\mathbf{Z}^* = \mathbf{Z}^*_{\mathbf{h}_2'} + i\mathbf{Z}^*_{\mathbf{h}_2''}$$

[one for each pair $(\mathbf{h}_2', \mathbf{h}_2'')$], each of which yields by $F(\mathbf{M})$ a vector

$$\mathbf{Z} = \mathbf{Z}_{\mathbf{h}_2'} + i\mathbf{Z}_{\mathbf{h}_2''}.$$

The real-valuedness of the $\mathbf{Y}^*_{\mathbf{m}_1}$ may be used to recover the separate result vectors for $\mathbf{h}_2'$ and $\mathbf{h}_2''$. For this purpose, introduce the abbreviated notation

$$\begin{aligned} e[-\mathbf{h}_2' \cdot (\mathbf{N}^{-1}\mathbf{m}_1)] &= (c' + is')(\mathbf{m}_1) \\ e[-\mathbf{h}_2'' \cdot (\mathbf{N}^{-1}\mathbf{m}_1)] &= (c'' + is'')(\mathbf{m}_1) \\ R_{\mathbf{h}_2}(\mathbf{m}_1) &= Y^*_{\mathbf{m}_1}(\mathbf{h}_2) \\ \mathbf{R}' = \mathbf{R}_{\mathbf{h}_2'}, &\quad \mathbf{R}'' = \mathbf{R}_{\mathbf{h}_2''}. \end{aligned}$$

Then we may write

$$\begin{aligned} \mathbf{Z} &= (c' + is')\mathbf{R}' + i(c'' + is'')\mathbf{R}'' \\ &= (c'\mathbf{R}' + s''\mathbf{R}'') + i(-s'\mathbf{R}' + c''\mathbf{R}'') \end{aligned}$$

or, equivalently, for each $\mathbf{m}_1$,

$$\begin{pmatrix} \mathscr{R}e\, Z \\ \mathscr{I}m\, Z \end{pmatrix} = \begin{pmatrix} c' & s'' \\ -s' & c'' \end{pmatrix} \begin{pmatrix} R' \\ R'' \end{pmatrix}.$$

Therefore $\mathbf{R}'$ and $\mathbf{R}''$ may be retrieved from $\mathbf{Z}$ by the 'demultiplexing' formula:

$$\begin{pmatrix} R' \\ R'' \end{pmatrix} = \frac{1}{c'c'' + s's''} \begin{pmatrix} c'' & -s'' \\ s' & c' \end{pmatrix} \begin{pmatrix} \mathscr{R}e\, Z \\ \mathscr{I}m\, Z \end{pmatrix}$$

which is valid at all points $\mathbf{m}_1$ where $c'c'' + s's'' \neq 0$, *i.e.* where

$$\cos[2\pi(\mathbf{h}_2' - \mathbf{h}_2'') \cdot (\mathbf{N}^{-1}\mathbf{m}_1)] \neq 0.$$

Demultiplexing fails when

$$(\mathbf{h}_2' - \mathbf{h}_2'') \cdot (\mathbf{N}^{-1}\mathbf{m}_1) = \tfrac{1}{2} \bmod 1.$$

If the pairs $(\mathbf{h}_2', \mathbf{h}_2'')$ are chosen so that their members differ only in one coordinate (the jth, say), then the exceptional points are at $(\mathbf{m}_1)_j = \frac{1}{2}M_j$ and the missing transform values are easily obtained *e.g.* by accumulation while forming $\mathbf{Z}^*$.

The final stage of the calculation is then

$$\rho(\mathbf{m}_1 + \mathbf{M}\mathbf{m}_2) = \sum_{\mathbf{h}_2 \in \mathbb{Z}^n/2\mathbb{Z}^n} (-1)^{\mathbf{h}_2\cdot\mathbf{m}_2} R_{\mathbf{h}_2}(\mathbf{m}_1).$$

(ii) *Decimation in frequency* ($\mathbf{N}_1 = 2\mathbf{I}, \mathbf{N}_2 = \mathbf{M}$)

The last transformation $F(\mathbf{M})$ gives the real-valued results ρ, therefore the vectors $\mathbf{Y}^*_{\mathbf{m}_1}$ after the twiddle-factor stage each have Hermitian symmetry.

A first consequence is that the intermediate vectors $\mathbf{Z}_{\mathbf{h}_2}$ need only be computed for the unique half of the values of $\mathbf{h}_2$, the other half being related by the Hermitian symmetry of $\mathbf{Y}^*_{\mathbf{m}_1}$.

A second consequence is that the 2^n vectors $\mathbf{Y}^*_{\mathbf{m}_1}$ may be condensed into 2^{n-1} general complex vectors

$$\mathbf{Y}^* = \mathbf{Y}^*_{\mathbf{m}'_1} + i\mathbf{Y}^*_{\mathbf{m}''_1}$$

[one for each pair $(\mathbf{m}'_1, \mathbf{m}''_1)$] to which a general complex $F(\mathbf{M})$ may be applied to yield

$$\mathbf{Y} = \mathbf{Y}_{\mathbf{m}'_1} + i\mathbf{Y}_{\mathbf{m}''_1}$$

with $\mathbf{Y}_{\mathbf{m}'_1}$ and $\mathbf{Y}_{\mathbf{m}''_1}$ *real-valued*. The final results can therefore be retrieved by the particularly simple demultiplexing formulae:

$$\rho(\mathbf{m}'_1 + 2\mathbf{m}_2) = \mathscr{R}e\, Y(\mathbf{m}_2),$$
$$\rho(\mathbf{m}''_1 + 2\mathbf{m}_2) = \mathscr{I}m\, Y(\mathbf{m}_2).$$

1.3.4.3.5.2. Hermitian-antisymmetric or pure imaginary transforms

A vector $\mathbf{X} = \{X(\mathbf{k}) | \mathbf{k} \in \mathbb{Z}^n/\mathbf{N}\mathbb{Z}^n\}$ is said to be Hermitian-antisymmetric if

$$X(\mathbf{k}) = -\overline{X(-\mathbf{k})} \text{ for all } \mathbf{k}.$$

Its transform $\mathbf{X}^*$ then satisfies

$$X^*(\mathbf{k}^*) = -\overline{X^*(\mathbf{k}^*)} \text{ for all } \mathbf{k}^*,$$

i.e. is purely imaginary.

If $\mathbf{X}$ is Hermitian-antisymmetric, then $\mathbf{F} = \pm i\mathbf{X}$ is Hermitian-symmetric, with $\rho = \pm i\mathbf{X}^*$ real-valued. The treatment of Section 1.3.4.3.5.1 may therefore be adapted, with trivial factors of i or -1, or used as such in conjunction with changes of variable by multiplication by $\pm i$.

1.3.4.3.5.3. Complex symmetric and antisymmetric transforms

The matrix $-\mathbf{I}$ is its own contragredient, and hence (Section 1.3.2.4.2.2) the transform of a symmetric (respectively antisymmetric) function is symmetric (respectively antisymmetric). In this case the group $G = \{e, -e\}$ acts in both real and reciprocal space as $\{\mathbf{I}, -\mathbf{I}\}$. If $\mathbf{N} = \mathbf{N}_1\mathbf{N}_2$ with both factors diagonal, then $-e$ acts by

$$(\mathbf{m}_1, \mathbf{m}_2) \longmapsto [\mathbf{N}_1\boldsymbol{\zeta}(\mathbf{m}_1) - \mathbf{m}_1, \mathbf{N}_2\boldsymbol{\zeta}(\mathbf{m}_2) - \mathbf{m}_2 - \boldsymbol{\zeta}(\mathbf{m}_1)],$$
$$(\mathbf{h}_2, \mathbf{h}_1) \longmapsto [\mathbf{N}_2\boldsymbol{\zeta}(\mathbf{h}_2) - \mathbf{h}_2, \mathbf{N}_1\boldsymbol{\zeta}(\mathbf{h}_1) - \mathbf{h}_1 - \boldsymbol{\zeta}(\mathbf{h}_2)],$$

i.e.

$$\boldsymbol{\mu}_2(-e, \mathbf{m}_1) = -\boldsymbol{\zeta}(\mathbf{m}_1) \bmod \mathbf{N}_2\mathbb{Z}^n,$$
$$\boldsymbol{\eta}_1(-e, \mathbf{h}_2) = -\boldsymbol{\zeta}(\mathbf{h}_2) \bmod \mathbf{N}_1\mathbb{Z}^n.$$

The symmetry or antisymmetry properties of $\mathbf{X}$ may be written

$$X(-\mathbf{m}) = -\varepsilon X(\mathbf{m}) \text{ for all } \mathbf{m},$$

with $\varepsilon = +1$ for symmetry and $\varepsilon = -1$ for antisymmetry.

The computation will be summarized as

$$\mathbf{X} \overset{\mathbf{dec}(\mathbf{N}_1)}{\longmapsto} \mathbf{Y} \overset{\tilde{F}(\mathbf{N}_2)}{\longmapsto} \mathbf{Y}^* \overset{\mathrm{TW}}{\longmapsto} \mathbf{Z} \overset{\tilde{F}(\mathbf{N}_1)}{\longmapsto} \mathbf{Z}^* \overset{\mathbf{rev}(\mathbf{N}_2)}{\longmapsto} \mathbf{X}^*$$

with the same indexing as that used for structure-factor calculation. In both cases it will be shown that a transform $F(\mathbf{N})$ with $\mathbf{N} = \mathbf{2M}$ and $\mathbf{M}$ diagonal can be computed using only 2^{n-1} partial transforms $F(\mathbf{M})$ instead of 2^n.

(i) *Decimation in time* ($\mathbf{N}_1 = 2\mathbf{I}, \mathbf{N}_2 = \mathbf{M}$)

Since $\mathbf{m}_1 \in \mathbb{Z}^n/2\mathbb{Z}^n$ we have $-\mathbf{m}_1 = \mathbf{m}_1$ and $\boldsymbol{\zeta}(\mathbf{m}_1) = \mathbf{m}_1 \bmod 2\mathbb{Z}^n$, so that the symmetry relations for each parity class of data $\mathbf{Y}_{\mathbf{m}_1}$ read

$$Y_{\mathbf{m}_1}[\mathbf{M}\boldsymbol{\zeta}(\mathbf{m}_2) - \mathbf{m}_2 - \mathbf{m}_1] = \varepsilon Y_{\mathbf{m}_1}(\mathbf{m}_2)$$

or equivalently

$$\tau_{\mathbf{m}_1}\mathbf{Y}_{\mathbf{m}_1} = \varepsilon\check{\mathbf{Y}}_{\mathbf{m}_1}.$$

Transforming by $F(\mathbf{M})$, this relation becomes

$$e[-\mathbf{h}_2 \cdot (\mathbf{M}^{-1}\mathbf{m}_1)]\mathbf{Y}^*_{\mathbf{m}_1} = \varepsilon\mathbf{Y}^*_{\mathbf{m}_1}.$$

Each parity class thus obeys a different symmetry relation, so that we may multiplex them in pairs by forming for each pair $(\mathbf{m}'_1, \mathbf{m}''_1)$ the vector

$$\mathbf{Y} = \mathbf{Y}_{\mathbf{m}'_1} + \mathbf{Y}_{\mathbf{m}''_1}.$$

Putting

$$e[-\mathbf{h}_2 \cdot (\mathbf{M}^{-1}\mathbf{m}'_1)] = (c' + is')(\mathbf{h}_2)$$
$$e[-\mathbf{h}_2 \cdot (\mathbf{M}^{-1}\mathbf{m}''_1)] = (c'' + is'')(\mathbf{h}_2)$$

we then have the demultiplexing relations for each $\mathbf{h}_2$:

$$Y^*_{\mathbf{m}'_1}(\mathbf{h}_2) + Y^*_{\mathbf{m}''_1}(\mathbf{h}_2) = Y^*(\mathbf{h}_2)$$
$$(c' + is')(\mathbf{h}_2)Y^*_{\mathbf{m}'_1}(\mathbf{h}_2) + (c'' + is'')(\mathbf{h}_2)Y^*_{\mathbf{m}''_1}(\mathbf{h}_2)$$
$$= \varepsilon Y^*[\mathbf{M}\boldsymbol{\zeta}(\mathbf{h}_2) - \mathbf{h}_2]$$

which can be solved recursively. Transform values at the exceptional points $\mathbf{h}_2$ where demultiplexing fails (*i.e.* where $c' + is' = c'' + is''$) can be accumulated while forming $\mathbf{Y}$.

Only the unique half of the values of $\mathbf{h}_2$ need to be considered at the demultiplexing stage and at the subsequent TW and $F(2\mathbf{I})$ stages.

(ii) *Decimation in frequency* ($\mathbf{N}_1 = \mathbf{M}, \mathbf{N}_2 = 2\mathbf{I}$)

The vectors of final results $\mathbf{Z}^*_{\mathbf{h}_2}$ for each parity class $\mathbf{h}_2$ obey the symmetry relations

$$\tau_{\mathbf{h}_2}\mathbf{Z}^*_{\mathbf{h}_2} = \varepsilon\check{\mathbf{Z}}^*_{\mathbf{h}_2},$$

which are different for each $\mathbf{h}_2$. The vectors $\mathbf{Z}_{\mathbf{h}_2}$ of intermediate results after the twiddle-factor stage may then be multiplexed in pairs as

$$\mathbf{Z} = \mathbf{Z}_{\mathbf{h}_2'} + \mathbf{Z}_{\mathbf{h}_2''}.$$

After transforming by $F(\mathbf{M})$, the results $\mathbf{Z}^*$ may be demultiplexed by using the relations

$$\begin{aligned} Z^*_{\mathbf{h}_2'}(\mathbf{h}_1) \quad + Z^*_{\mathbf{h}_2''}(\mathbf{h}_1) \qquad &= Z^*(\mathbf{h}_1) \\ Z^*_{\mathbf{h}_2'}(\mathbf{h}_1 - \mathbf{h}_2') + Z^*_{\mathbf{h}_2''}(\mathbf{h}_1 - \mathbf{h}_2'') &= \varepsilon Z^*[\mathbf{M}\boldsymbol{\zeta}(\mathbf{h}_1) - \mathbf{h}_1] \end{aligned}$$

which can be solved recursively as in Section 1.3.4.3.5.1(*b*)(ii).

1.3.4.3.5.4. Real symmetric transforms

Conjugate symmetric (Section 1.3.2.4.2.3) implies that if the data $\mathbf{X}$ are real and symmetric [*i.e.* $X(\mathbf{k}) = \overline{X(\mathbf{k})}$ and $X(-\mathbf{k}) = X(\mathbf{k})$], then so are the results $\mathbf{X}^*$. Thus if $\mathcal{P}$ contains a centre of symmetry, $\mathbf{F}$ is real symmetric. There is no distinction (other than notation) between structure-factor and electron-density calculation; the algorithms will be described in terms of the former. It will be shown that if $\mathbf{N} = 2\mathbf{M}$, a real symmetric transform can be computed with only 2^{n-2} partial transforms $F(\mathbf{M})$ instead of 2^n.

(i) *Decimation in time* ($\mathbf{N}_1 = 2\mathbf{I}, \mathbf{N}_2 = \mathbf{M}$)

Since $\mathbf{m}_1 \in \mathbb{Z}^n/2\mathbb{Z}^n$ we have $-\mathbf{m}_1 = \mathbf{m}_1$ and $\boldsymbol{\zeta}(\mathbf{m}_1) = \mathbf{m}_1 \bmod 2\mathbb{Z}^n$. The decimated vectors $\mathbf{Y}_{\mathbf{m}_1}$ are not only real, but have an internal symmetry expressed by

$$\mathbf{Y}_{\mathbf{m}_1}[\mathbf{M}\boldsymbol{\zeta}(\mathbf{m}_2) - \mathbf{m}_2 - \mathbf{m}_1] = \varepsilon \mathbf{Y}_{\mathbf{m}_1}(\mathbf{m}_2).$$

This symmetry, however, is different for each $\mathbf{m}_1$ so that we may multiplex two such vectors $\mathbf{Y}_{\mathbf{m}_1'}$ and $\mathbf{Y}_{\mathbf{m}_1''}$ into a general *real* vector

$$\mathbf{Y} = \mathbf{Y}_{\mathbf{m}_1'} + \mathbf{Y}_{\mathbf{m}_1''},$$

for each of the 2^{n-1} pairs $(\mathbf{m}_1', \mathbf{m}_1'')$. The 2^{n-1} Hermitian-symmetric transform vectors

$$\mathbf{Y}^* = \mathbf{Y}^*_{\mathbf{m}_1'} + \mathbf{Y}^*_{\mathbf{m}_1''}$$

can then be evaluated by the methods of Section 1.3.4.3.5.1(*b*) at the cost of only 2^{n-2} general complex $F(\mathbf{M})$.

The demultiplexing relations by which the separate vectors $\mathbf{Y}^*_{\mathbf{m}_1'}$ and $\mathbf{Y}^*_{\mathbf{m}_1''}$ may be recovered are most simply obtained by observing that the vectors $\mathbf{Z}$ after the twiddle-factor stage are real-valued since $F(2\mathbf{I})$ has a real matrix. Thus, as in Section 1.3.4.3.5.1(*c*)(i),

$$\begin{aligned} \mathbf{Y}^*_{\mathbf{m}_1'} &= (c' - is')\mathbf{R}' \\ \mathbf{Y}^*_{\mathbf{m}_1''} &= (c'' - is'')\mathbf{R}'', \end{aligned}$$

where $\mathbf{R}'$ and $\mathbf{R}''$ are real vectors and where the multipliers $(c' - is')$ and $(c'' - is'')$ are the inverse twiddle factors. Therefore,

$$\begin{aligned} \mathbf{Y}^* &= (c' - is')\mathbf{R}' + (c'' - is'')\mathbf{R}'' \\ &= (c'\mathbf{R}' + c''\mathbf{R}'') - i(s'\mathbf{R}' + s''\mathbf{R}'') \end{aligned}$$

and hence the demultiplexing relation for each $\mathbf{h}_2$:

$$\begin{pmatrix} R' \\ R'' \end{pmatrix} = \frac{1}{c's'' - s'c''} \begin{pmatrix} s'' & -c'' \\ -s' & c' \end{pmatrix} \begin{pmatrix} \mathscr{R}e\, Y^* \\ -\mathscr{I}m\, Y^* \end{pmatrix}.$$

The values of $R'_{\mathbf{h}_2}$ and $R''_{\mathbf{h}_2}$ at those points $\mathbf{h}_2$ where $c's'' - s'c'' = 0$ can be evaluated directly while forming $\mathbf{Y}$. This demultiplexing and the final stage of the calculation, namely

$$F(\mathbf{h}_2 + \mathbf{M}\mathbf{h}_1) = \frac{1}{2^n} \sum_{\mathbf{m}_1 \in \mathbf{Z}^n/2\mathbf{Z}^n} (-1)^{\mathbf{h}_1 \cdot \mathbf{m}_1} R_{\mathbf{m}_1}(\mathbf{h}_2)$$

need only be carried out for the unique half of the range of $\mathbf{h}_2$.

(ii) *Decimation in frequency* ($\mathbf{N}_1 = \mathbf{M}, \mathbf{N}_2 = 2\mathbf{I}$)

Similarly, the vectors $\mathbf{Z}^*_{\mathbf{h}_2}$ of decimated and scrambled results are real and obey internal symmetries

$$\tau_{\mathbf{h}_2} \mathbf{Z}^*_{\mathbf{h}_2} = \varepsilon \check{\mathbf{Z}}^*_{\mathbf{h}_2}$$

which are different for each $\mathbf{h}_2$. For each of the 2^{n-1} pairs $(\mathbf{h}_2', \mathbf{h}_2'')$ the multiplexed vector

$$\mathbf{Z} = \mathbf{Z}_{\mathbf{h}_2'} + \mathbf{Z}_{\mathbf{h}_2''}$$

is a Hermitian-symmetric vector without internal symmetry, and the 2^{n-1} real vectors

$$\mathbf{Z}^* = \mathbf{Z}^*_{\mathbf{h}_2'} + \mathbf{Z}^*_{\mathbf{h}_2''}$$

may be evaluated at the cost of only 2^{n-2} general complex $F(\mathbf{M})$ by the methods of Section 1.3.4.3.5.1(*c*). The individual transforms $\mathbf{Z}_{\mathbf{h}_2'}$ and $\mathbf{Z}_{\mathbf{h}_2''}$ may then be retrieved *via* the demultiplexing relations

$$\begin{aligned} Z^*_{\mathbf{h}_2'}(\mathbf{h}_1) \quad + Z^*_{\mathbf{h}_2''}(\mathbf{h}_1) \qquad &= Z^*(\mathbf{h}_1) \\ Z^*_{\mathbf{h}_2'}(\mathbf{h}_1 - \mathbf{h}_2') + Z^*_{\mathbf{h}_2''}(\mathbf{h}_1 - \mathbf{h}_2'') &= Z^*[\mathbf{M}\boldsymbol{\zeta}(\mathbf{h}_1) - \mathbf{h}_1] \end{aligned}$$

which can be solved recursively as described in Section 1.3.4.3.5.1(*b*)(ii). This yields the unique half of the real symmetric results $\mathbf{F}$.

1.3.4.3.5.5. Real antisymmetric transforms

If $\mathbf{X}$ is real antisymmetric, then its transform $\mathbf{X}^*$ is purely imaginary and antisymmetric. The double-multiplexing techniques used for real symmetric transforms may therefore be adapted with only minor changes involving signs and factors of *i*.

1.3.4.3.5.6. Generalized multiplexing

So far the multiplexing technique has been applied to pairs of vectors with similar types of parity-related and/or conjugate symmetry properties, in particular the same value of ε.

It can be generalized so as to accommodate mixtures of vectors with different symmetry characteristics. For example if $\mathbf{X}_1$ is Hermitian-symmetric and $\mathbf{X}_2$ is Hermitian-antisymmetric, so that $\mathbf{X}_1^*$ is real-valued while $\mathbf{X}_2^*$ has purely imaginary values, the multiplexing process should obviously form $\mathbf{X} = \mathbf{X}_1 + \mathbf{X}_2$ (instead of $\mathbf{X} = \mathbf{X}_1 + i\mathbf{X}_2$ if both had the same type of symmetry), and demultiplexing consists in separating

$$\begin{aligned} \mathbf{X}_1^* &= \mathscr{R}e\, \mathbf{X}^* \\ \mathbf{X}_2^* &= i\mathscr{I}m\, \mathbf{X}^*. \end{aligned}$$

The general multiplexing formula for pairs of vectors may therefore be written

$$\mathbf{X} = \mathbf{X}_1 + \omega \mathbf{X}_2,$$

where ω is a phase factor (*e.g.* 1 or i) chosen in such a way that all nonexceptional components of $\mathbf{X}_1$ and $\mathbf{X}_2$ (or $\mathbf{X}_1^*$ and $\mathbf{X}_2^*$) be embedded in the complex plane $\mathbb{C}$ along linearly independent directions, thus making multiplexing possible.

It is possible to develop a more general form of multiplexing/demultiplexing for more than two vectors, which can be used to deal with symmetry elements of order 3, 4 or 6. It is based on the theory of group characters (Ledermann, 1987).

1.3.4.3.6. Global crystallographic algorithms

All the necessary ingredients are now available for calculating the CDFT for any given space group.

1.3.4.3.6.1. Triclinic groups

Space group $P1$ is dealt with by the methods of Section 1.3.4.3.5.1 and $P\bar{1}$ by those of Section 1.3.4.3.5.4.

1.3.4.3.6.2. Monoclinic groups

A general monoclinic transformation is of the form

$$S_g : \mathbf{x} \longmapsto \mathbf{R}_g \mathbf{x} + \mathbf{t}_g$$

with $\mathbf{R}_g$ a diagonal matrix whose entries are $+1$ or -1, and $\mathbf{t}_g$ a vector whose entries are 0 or $\frac{1}{2}$. We may thus decompose both real and reciprocal space into a direct sum of a subspace $\mathbb{Z}^{n+}$ where $\mathbf{R}_g$ acts as the identity, and a subspace $\mathbb{Z}^{n-}$ where $\mathbf{R}_g$ acts as minus the identity, with $n_+ + n_- = n = 3$. All usual entities may be correspondingly written as direct sums, for instance:

$$\begin{array}{lll}
\mathbf{R}_g = \mathbf{R}_g^+ \oplus \mathbf{R}_g^-, & \mathbf{N} = \mathbf{N}^+ \oplus \mathbf{N}^-, & \mathbf{M} = \mathbf{M}^+ \oplus \mathbf{M}^-, \\
\mathbf{t}_g = \boldsymbol{t}_g^+ \oplus \mathbf{t}_g^-, & \mathbf{t}_g^{(1)} = \mathbf{t}_g^{(1)+} \oplus \mathbf{t}_g^{(1)-}, & \mathbf{t}_g^{(2)} = \mathbf{t}_g^{(2)+} \oplus \mathbf{t}_g^{(2)-}, \\
\mathbf{m} = \mathbf{m}^+ \oplus \mathbf{m}^-, & \mathbf{m}_1 = \mathbf{m}_1^+ \oplus \mathbf{m}_1^-, & \mathbf{m}_2 = \mathbf{m}_2^+ \oplus \mathbf{m}_2^-, \\
\mathbf{h} = \mathbf{h}^+ \oplus \mathbf{h}^-, & \mathbf{h}_1 = \mathbf{h}_1^+ \oplus \mathbf{h}_1^-, & \mathbf{h}_2 = \mathbf{h}_2^+ \oplus \mathbf{h}_2^-.
\end{array}$$

We will use factoring by 2, with decimation in frequency when computing structure factors, and decimation in time when computing electron densities; this corresponds to $\mathbf{N} = \mathbf{N}_1 \mathbf{N}_2$ with $\mathbf{N}_1 = \mathbf{M}$, $\mathbf{N}_2 = 2\mathbf{I}$. The nonprimitive translation vector $\mathbf{N}\mathbf{t}_g$ then belongs to $\mathbf{M}\mathbb{Z}^n$, and thus

$$\mathbf{t}_g^{(1)} = \mathbf{0} \bmod \mathbf{M}\mathbb{Z}^n, \quad \mathbf{t}_g^{(2)} \in \mathbb{Z}^n / 2\mathbb{Z}^n.$$

The symmetry relations obeyed by ρ and F are as follows: for electron densities

$$\rho(\mathbf{m}^+, \mathbf{m}^-) = \rho(\mathbf{m}^+ + \mathbf{N}^+ \mathbf{t}_g^+, -\mathbf{m}^- - \mathbf{N}^- \mathbf{t}_g^-)$$

or, after factoring by 2,

$$\begin{aligned}
&\rho(\mathbf{m}_1^+, \mathbf{m}_2^+, \mathbf{m}_1^-, \mathbf{m}_2^-) \\
&\quad = \rho(\mathbf{m}_1^+, \mathbf{m}_2^+ + \mathbf{t}_g^{(2)+}, \mathbf{M}^- \boldsymbol{\zeta}(\mathbf{m}_1^-) - \mathbf{m}_1^- - \mathbf{m}_2^-, \mathbf{m}_2^- + \mathbf{t}_g^{(2)-});
\end{aligned}$$

while for structure factors

$$F(\mathbf{h}^+, \mathbf{h}^-) = \exp[2\pi i(\mathbf{h}^+ \cdot \mathbf{t}_g^+ + \mathbf{h}^- \cdot \mathbf{t}_g^-)] F(\mathbf{h}^+, -\mathbf{h}^-)$$

with its Friedel counterpart

$$F(\mathbf{h}^+, \mathbf{h}^-) = \exp[2\pi i(\mathbf{h}^+ \cdot \mathbf{t}_g^+ + \mathbf{h}^- \cdot \mathbf{t}_g^-)] \overline{F(-\mathbf{h}^+, \mathbf{h}^-)}$$

or, after factoring by 2,

$$\begin{aligned}
F(\mathbf{h}_1^+, \mathbf{h}_2^+, \mathbf{h}_1^-, \mathbf{h}_2^-) &= (-1)^{\mathbf{h}_2^+ \cdot \mathbf{t}_g^{(2)+} + \mathbf{h}_2^- \cdot \mathbf{t}_g^{(2)-}} \\
&\quad \times F(\mathbf{h}_1^+, \mathbf{h}_2^+, \mathbf{M}^- \boldsymbol{\zeta}(\mathbf{h}_1^-) - \mathbf{h}_1^- - \mathbf{h}_2^-, \mathbf{h}_2^-)
\end{aligned}$$

with Friedel counterpart

$$\begin{aligned}
&F(\mathbf{h}_1^+, \mathbf{h}_2^+, \mathbf{h}_1^-, \mathbf{h}_2^-) \\
&\quad = (-1)^{\mathbf{h}_2^+ \cdot \mathbf{t}_g^{(2)+} + \mathbf{h}_2^- \cdot \mathbf{t}_g^{(2)-}} \overline{F[\mathbf{M}^+ \boldsymbol{\zeta}(\mathbf{h}_1^+) - \mathbf{h}_1^+ - \mathbf{h}_2^+, \mathbf{h}_2^+, \mathbf{h}_1^-, \mathbf{h}_2^-]}.
\end{aligned}$$

When calculating electron densities, two methods may be used.

(i) Transform on $\mathbf{h}^-$ first.

The partial vectors defined by $X_{\mathbf{h}^+, \mathbf{h}_2^-} = F(\mathbf{h}^+, \mathbf{h}_1^-, \mathbf{h}_2^-)$ obey symmetry relations of the form

$$X(\mathbf{h}_1^- - \mathbf{h}_2^-) = \varepsilon X[\mathbf{M}^- \boldsymbol{\zeta}(\mathbf{h}_1^-) - \mathbf{h}_1^-]$$

with $\varepsilon = \pm 1$ independent of $\mathbf{h}_1^-$. This is the same relation as for the same parity class of data for a (complex or real) symmetric ($\varepsilon = +1$) or antisymmetric ($\varepsilon = -1$) transform. The same techniques can be used to decrease the number of $F(\mathbf{M}^-)$ by multiplexing pairs of such vectors and demultiplexing their transforms. Partial vectors with different values of ε may be mixed in this way (Section 1.3.4.3.5.6).

Once $F(\mathbf{N}^-)$ is completed, its results have Hermitian symmetry with respect to $\mathbf{h}^+$, and the methods of Section 1.3.4.3.5.1 may be used to obtain the unique electron densities.

(ii) Transform on $\mathbf{h}^+$ first.

The partial vectors defined by $X_{\mathbf{h}^-, \mathbf{h}_2^+} = F(\mathbf{h}_1^+, \mathbf{h}_2^+, \mathbf{h}^-)$ obey symmetry relations of the form

$$X(\mathbf{h}_1^+ - \mathbf{h}_2^+) = \overline{\varepsilon X[\mathbf{M}^+ \boldsymbol{\zeta}(\mathbf{h}_1^+) - \mathbf{h}_1^+]}$$

with $\varepsilon = \pm 1$ independent of $\mathbf{h}_1^+$. This is the same relation as for the same parity class of data for a Hermitian symmetric ($\varepsilon = +1$) or antisymmetric ($\varepsilon = -1$) transform. The same techniques may be used to decrease the number of $F(\mathbf{M}^+)$. This generalizes the procedure described by Ten Eyck (1973) for treating dyad axes, *i.e.* for the case $n_+ = 1$, $\mathbf{t}_g^{(2)-} = \mathbf{0}$, and $\mathbf{t}_g^{(2)+} = \mathbf{0}$ (simple dyad) or $\mathbf{t}_g^{(2)+} \neq \mathbf{0}$ (screw dyad).

Once $F(\mathbf{N}^+)$ is completed, its results have Hermitian symmetry properties with respect to $\mathbf{h}^-$ which can be used to obtain the unique electron densities.

Structure factors may be computed by applying the reverse procedures in the reverse order.

1.3.4.3.6.3. Orthorhombic groups

Almost all orthorhombic space groups are generated by two monoclinic transformations g_1 and g_2 of the type described in Section 1.3.4.3.6.2, with the addition of a centre of inversion $-e$ for centrosymmetric groups. The only exceptions are *Fdd*2 and *Fddd* which contain diamond glides, in which some nonprimitive translations are 'square roots' not of primitive lattice translations, but of centring translations. The generic case will be examined first.

To calculate electron densities, the unique octant of data may first be transformed on $\mathbf{h}^+$ (respectively $\mathbf{h}^-$) as in Section 1.3.4.3.6.2 using the symmetry pertaining to generator g_1. These intermediate results may then be expanded by generator g_2 by the formula of Section 1.3.4.3.3 prior to the final transform on $\mathbf{h}^-$ (respectively $\mathbf{h}^+$). To calculate structure factors, the reverse operations are applied in the reverse order.

The two exceptional groups *Fdd*2 and *Fddd* only require a small modification. The *F*-centring causes the systematic absence of parity classes with mixed parities, leaving only (000) and (111). For the former, the phase factors $\exp[2\pi i(\mathbf{h}^+ \cdot \mathbf{t}_g^+ + \mathbf{h}^- \cdot \mathbf{t}_g^-)]$ in the symmetry relations of Section 1.3.4.3.6.2 become powers of (-1) so that one is back to the generic case. For the latter, these phase factors are odd powers of i which it is a simple matter to incorporate into a modified multiplexing/demultiplexing procedure.

1.3.4.3.6.4. Trigonal, tetragonal and hexagonal groups

All the symmetries in this class of groups can be handled by the generalized Rader/Winograd algorithms of Section 1.3.4.3.4.3, but no implementation of these is yet available.

In groups containing axes of the form n_m with g.c.d. $(m, n) = 1$ (*i.e.* $3_1, 3_2, 4_1, 4_3, 6_1, 6_5$) along the c direction, the following procedure may be used (Ten Eyck, 1973):

(i) to calculate electron densities, the unique structure factors indexed by

$$[\text{unique } (h, k)] \times (\text{all } l)$$

are transformed on l; the results are rearranged by the transposition formula of Section 1.3.4.3.3 so as to be indexed by

$$[\text{all } (h, k)] \times \left[\text{unique } \left(\frac{1}{n}\right)\text{th of } z\right]$$

and are finally transformed on (h, k) to produce an asymmetric unit. For a dihedral group, the extra twofold axis may be used in the transposition to produce a unique $(1/2n)$th of z.

(ii) to calculate structure factors, the unique densities in $(1/n)$th of z [or $(1/2n)$th for a dihedral group] are first transformed on x and y, then transposed by the formula of Section 1.3.4.3.3 to reindex the intermediate results by

$$[\text{unique } (h, k)] \times (\text{all } z);$$

the last transform on z is then carried out.

1.3.4.3.6.5. Cubic groups

These are usually treated as their orthorhombic or tetragonal subgroups, as the body-diagonal threefold axis cannot be handled by ordinary methods of decomposition.

The three-dimensional factorization technique of Section 1.3.4.3.4.1 allows a complete treatment of cubic symmetry. Factoring by 2 along all three dimensions gives four types (*i.e.* orbits) of parity classes:

(000)	with residual threefold symmetry,
(100), (010), (001)	related by threefold axis,
(110), (101), (011)	related by threefold axis,
(111)	with residual threefold symmetry.

Orbit exchange using the threefold axis thus allows one to reduce the number of partial transforms from 8 to 4 (one per orbit). Factoring by 3 leads to a reduction from 27 to 11 (in this case, further reduction to 9 can be gained by multiplexing the three diagonal classes with residual threefold symmetry into a single class; see Section 1.3.4.3.5.6). More generally, factoring by q leads to a reduction from q^3 to $\frac{1}{3}(q^3 - q) - q$. Each of the remaining transforms then has a symmetry induced from the orthorhombic or tetragonal subgroup, which can be treated as above.

No implementation of this procedure is yet available.

1.3.4.3.6.6. Treatment of centred lattices

Lattice centring is an instance of the duality between periodization and decimation: the extra translational periodicity of ρ induces a decimation of $\mathbf{F} = \{F_\mathbf{h}\}$ described by the 'reflection conditions' on $\mathbf{h}$. As was pointed out in Section 1.3.4.2.2.3, nonprimitive lattices are introduced in order to retain the same matrix representation for a given geometric symmetry operation in all the arithmetic classes in which it occurs. From the computational point of view, therefore, the main advantage in using centred lattices is that it *maximizes decomposability* (Section 1.3.4.2.2.4); reindexing to a primitive lattice would for instance often destroy the diagonal character of the matrix representing a dyad.

In the usual procedure involving three successive one-dimensional transforms, the loss of efficiency caused by the duplication of densities or the systematic vanishing of certain classes of structure factors may be avoided by using a multiplexing/demultiplexing technique (Ten Eyck, 1973):

(i) for base-centred or body-centred lattices, two successive planes of structure factors may be overlaid into a single plane; after transformation, the results belonging to each plane may be separated by parity considerations;

(ii) for face-centred lattices the same method applies, using four successive planes (the third and fourth with an origin translation);

(iii) for rhombohedral lattices in hexagonal coordinates, three successive planes may be overlaid, and the results may be separated by linear combinations involving cube roots of unity.

The three-dimensional factorization technique of Section 1.3.4.3.4.1 is particularly well suited to the treatment of centred lattices: if the decimation matrix of $\mathbf{N}$ contains as a factor $\mathbf{N}_1$ a matrix which 'integerizes' all the nonprimitive lattice vectors, then centring is reflected by the systematic vanishing of certain classes of vectors of decimated data or results, which can simply be omitted from the calculation. An alternative possibly is to reindex on a primitive lattice and use different representative matrices for the symmetry operations: the loss of decomposability is of little consequence in this three-dimensional scheme, although it substantially complicates the definition of the cocycles $\boldsymbol{\mu}_2$ and $\boldsymbol{\eta}_1$.

1.3.4.3.6.7. Programming considerations

The preceding sections have been devoted to showing how the raw computational efficiency of a crystallographic Fourier transform *algorithm* can be maximized. This section will briefly discuss another characteristic (besides speed) which a crystallographic Fourier transform *program* may be required to possess if it is to be useful in various applications: a convenient and versatile mode of presentation of input data or output results.

The standard crystallographic FFT programs (Ten Eyck, 1973, 1985) are rather rigid in this respect, and use rather rudimentary data structures (lists of structure-factor values, and two-dimensional arrays containing successive sections of electron-density maps). It is frequently the case that considerable reformatting of these data or results must be carried out before they can be used in other computations; for instance, maps have to be converted from 2D sections to 3D 'bricks' before they can be inspected on a computer graphics display.

The explicitly three-dimensional approach to the factorization of the DFT and the use of symmetry offers the possibility of richer and more versatile data structures. For instance, the use of 'decimation in frequency' in real space and of 'decimation in time' in reciprocal space leads to data structures in which real-space coordinates are handled by blocks (thus preserving, at least locally, the three-dimensional topological connectivity of the maps) while reciprocal-space indices are handled by parity classes or their generalizations for factors other than 2 (thus making the treatment of centred lattices extremely easy). This global three-dimensional indexing also makes it possible to carry symmetry and multiplicity characteristics for each subvector of intermediate results for the purpose of automating the use of the orbit exchange mechanism.

Brünger (1989) has described the use of a similar three-dimensional factoring technique in the context of structure-factor calculations for the refinement of macromolecular structures.

1.3.4.4. Basic crystallographic computations

1.3.4.4.1. Introduction

Fourier transform (FT) calculations play an indispensable role in crystallography, because the Fourier transformation is inherent in the diffraction phenomenon itself.

Besides this obligatory use, the FT has numerous other applications, motivated more often by its mathematical properties than by direct physical reasoning (although the latter can be supplied after the fact). Typically, many crystallographic computations turn out to be convolutions in disguise, which can be speeded up by orders of magnitude through a judicious use of the FT. Several recent advances in crystallographic computation have been based on this kind of observation.

1.3.4.4.2. Fourier synthesis of electron-density maps

Bragg (1929) was the first to use this type of calculation to assist structure determination. Progress in computing techniques since that time was reviewed in Section 1.3.4.3.1.

The usefulness of the maps thus obtained can be adversely affected by three main factors:

(i) limited resolution;

(ii) errors in the data;

(iii) computational errors.

Limited resolution causes 'series-termination errors' first investigated by Bragg & West (1930), who used an optical analogy with the numerical aperture of a microscope. James (1948*b*) gave a quantitative description of this phenomenon as a convolution with the 'spherical Dirichlet kernel' (Section 1.3.4.2.1.3), which reflects the truncation of the Fourier spectrum by multiplication with the indicator function of the limiting resolution sphere. Bragg & West (1930) suggested that the resulting ripples might be diminished by applying an artificial temperature factor to the data, which performs a further convolution with a Gaussian point-spread function. When the electron-density map is to be used for model refinement, van Reijen (1942) suggested using Fourier coefficients calculated from the model when no observation is available, as a means of combating series-termination effects.

Errors in the data introduce errors in the electron-density maps, with the same mean-square value by virtue of Parseval's theorem. Special positions accrue larger errors (Cruickshank & Rollett, 1953; Cruickshank, 1965*a*). To minimize the mean-square electron-density error due to large phase uncertainties, Blow & Crick (1959) introduced the 'best Fourier' which uses centroid Fourier coefficients; the associated error level in the electron-density map was evaluated by Blow & Crick (1959) and Dickerson *et al.* (1961*a*,*b*).

Computational errors used to be a serious concern when Beevers–Lipson strips were used, and Cochran (1948*a*) carried out a critical evaluation of the accuracy limitations imposed by strip methods. Nowadays, the FFT algorithm implemented on digital computers with a word size of at least 32 bits gives results accurate to six decimal places or better in most applications (see Gentleman & Sande, 1966).

1.3.4.4.3. Fourier analysis of modified electron-density maps

Various approaches to the phase problem are based on certain modifications of the electron-density map, followed by Fourier analysis of the modified map and extraction of phase information from the resulting Fourier coefficients.

1.3.4.4.3.1. Squaring

Sayre (1952*a*) derived his 'squaring method equation' for structures consisting of equal, resolved and spherically symmetric atoms by observing that squaring such an electron density is equivalent merely to sharpening each atom into its square. Thus

$$F_{\mathbf{h}} = \theta_{\mathbf{h}} \sum_{\mathbf{k}} F_{\mathbf{k}} F_{\mathbf{h}-\mathbf{k}},$$

where $\theta_{\mathbf{h}} = f(\mathbf{h})/f^{\mathrm{sq}}(\mathbf{h})$ is the ratio between the form factor $f(\mathbf{h})$ common to all the atoms and the form factor $f^{\mathrm{sq}}(\mathbf{h})$ for the squared version of that atom.

Most of the central results of direct methods, such as the tangent formula, are an immediate consequence of Sayre's equation. Phase refinement for a macromolecule by enforcement of the squaring method equation was demonstrated by Sayre (1972, 1974).

1.3.4.4.3.2. Other nonlinear operations

A category of phase improvement procedures known as 'density modification' is based on the pointwise application of various quadratic or cubic 'filters' to electron-density maps after removal of negative regions (Hoppe & Gassmann, 1968; Hoppe *et al.*, 1970; Barrett & Zwick, 1971; Gassmann & Zechmeister, 1972; Collins, 1975; Collins *et al.*, 1976; Gassmann, 1976). These operations are claimed to be equivalent to reciprocal-space phase-refinement techniques such as those based on the tangent formula. Indeed the replacement of

$$\rho(\mathbf{x}) = \sum_{\mathbf{h}} F_{\mathbf{h}} \exp(-2\pi i \mathbf{h} \cdot \mathbf{x})$$

by $P[\rho(\mathbf{x})]$, where P is a polynomial

$$P(\rho) = a_0 + a_1\rho + a_2\rho^2 + a_3\rho^3 + \ldots$$

yields

$$P[\rho(\mathbf{x})] = a_0 + \sum_{\mathbf{h}} \Bigg[a_1 F_{\mathbf{h}} + a_2 \sum_{\mathbf{k}} F_{\mathbf{k}} F_{\mathbf{h}-\mathbf{k}} + a_3 \sum_{\mathbf{k}} \sum_{\mathbf{l}} F_{\mathbf{k}} F_{\mathbf{l}} F_{\mathbf{h}-\mathbf{k}-\mathbf{l}} + \ldots \Bigg] \exp(-2\pi i \mathbf{h} \cdot \mathbf{x})$$

and hence gives rise to the convolution-like families of terms encountered in direct methods. This equivalence, however, has been shown to be rather superficial (Bricogne, 1982) because the 'uncertainty principle' embodied in Heisenberg's inequality (Section 1.3.2.4.4.3) imposes severe limitations on the effectiveness of any procedure which operates *pointwise* in *both* real and reciprocal space.

In applying such methods, sampling considerations must be given close attention. If the spectrum of ρ extends to resolution Δ and if the pointwise nonlinear filter involves a polynomial P of

degree n, then $P(\rho)$ should be sampled at intervals of at most $\Delta/2n$ to accommodate the full bandwidth of its spectrum.

1.3.4.4.3.3. Solvent flattening

Crystals of proteins and nucleic acids contain large amounts of mother liquor, often in excess of 50% of the unit-cell volume, occupying connected channels. The well ordered electron density $\rho_{\rm M}(\mathbf{x})$ corresponding to the macromolecule thus occupies only a periodic subregion $\mathscr{U}$ of the crystal. Thus

$$\rho_{\rm M} = \chi_{\mathscr{U}} \times \rho_{\rm M},$$

implying the convolution identity between structure factors (Main & Woolfson, 1963):

$$F_{\rm M}(\mathbf{h}) = \sum_{\mathbf{k}} \bar{\mathscr{F}}\left[\frac{1}{\mathscr{U}}\chi_{\mathscr{U}}\right](\mathbf{h}-\mathbf{k})F_{\rm M}(\mathbf{k})$$

which is a form of the Shannon interpolation formula (Sections 1.3.2.7.1, 1.3.4.2.1.7; Bricogne, 1974; Colman, 1974).

It is often possible to obtain an approximate 'molecular envelope' $\mathscr{U}$ from a poor electron-density map ρ, either interactively by computer graphics (Bricogne, 1976) or automatically by calculating a moving average of the electron density within a small sphere S. The latter procedure can be implemented in real space (Wang, 1985). However, as it is a convolution of ρ with $\chi_{\rm S}$, it can be speeded up considerably (Leslie, 1987) by computing the moving average $\rho_{\rm mav}$ as

$$\rho_{\rm mav}(\mathbf{x}) = \mathscr{T}[\bar{\mathscr{F}}[\rho] \times \bar{\mathscr{F}}[\chi_{\rm S}]](\mathbf{x}).$$

This remark is identical in substance to Booth's method of computation of 'bounded projections' (Booth, 1945*a*) described in Section 1.3.4.2.1.8, except that the summation is kept three-dimensional.

The iterative use of the estimated envelope $\mathscr{U}$ for the purpose of phase improvement (Wang, 1985) is a submethod of the previously developed method of molecular averaging, which is described below. Sampling rules for the Fourier analysis of envelope-truncated maps will be given there.

1.3.4.4.3.4. Molecular averaging by noncrystallographic symmetries

Macromolecules and macromolecular assemblies frequently crystallize with several identical subunits in the asymmetric metric unit, or in several crystal forms containing the same molecule in different arrangements. Rossmann & Blow (1963) recognized that intensity data collected from such structures are redundant (Sayre, 1952*b*) and that their redundancy could be a source of phase information.

The phase constraints implied by the consistency of geometrically redundant intensities were first derived by Rossmann & Blow (1963), and were generalized by Main & Rossmann (1966). Crowther (1967, 1969) reformulated them as linear eigenvalue equations between structure factors, for which he proposed an iterative matrix solution method. Although useful in practice (Jack, 1973), this reciprocal-space approach required computations of size $\propto N^2$ for N reflections, so that N could not exceed a few thousands.

The theory was then reformulated in real space (Bricogne, 1974), showing that the most costly step in Crowther's procedure could be carried out much more economically by averaging the electron densities of all crystallographically independent subunits, then rebuilding the crystal(s) from this averaged subunit, flattening the density in the solvent region(s) by resetting it to its average value. This operation is a *projection* [by virtue of Section 1.3.4.2.2.2(*d*)]. The overall complexity was thus reduced from N^2 to $N \log N$. The design and implementation of a general-purpose program package for averaging, reconstructing and solvent-flattening electron-density maps (Bricogne, 1976) led rapidly to the first high-resolution determinations of virus structures (Bloomer *et al.*, 1978; Harrison *et al.*, 1978), with $N \sim 200\,000$.

The considerable gain in speed is a consequence of the fact that the masking operations used to retrieve the various copies of the common subunit are carried out by simple *pointwise multiplication* by an indicator function χ_U in real space, whereas they involve a *convolution* with $\bar{\mathscr{F}}[\chi_U]$ in reciprocal space.

The averaging by noncrystallographic symmetries of an electron-density map calculated by FFT – hence sampled on a grid which is an integral subdivision of the period lattice – necessarily entails the interpolation of densities at nonintegral points of that grid. The effect of interpolation on the structure factors recalculated from an averaged map was examined by Bricogne (1976). This study showed that, if linear interpolation is used, the initial map should be calculated on a fine grid, of size $\Delta/5$ or $\Delta/6$ at resolution Δ (instead of the previously used value of $\Delta/3$). The analysis about to be given applies to all interpolation schemes which consist in a *convolution* of the sampled density with a fixed *interpolation kernel* function K.

Let ρ be a $\mathbb{Z}^3$-periodic function. Let K be the interpolation kernel in 'normalized' form, *i.e.* such that $\int_{\mathbb{R}^3} K(\mathbf{x})\,{\rm d}^3\mathbf{x} = 1$ and scaled so as to interpolate between sample values given on a unit grid $\mathbb{Z}^3$; in the case of linear interpolation, K is the 'trilinear wedge'

$$K(\mathbf{x}) = W(x)W(y)W(z),$$

where

$$\begin{aligned} W(t) &= 1 - |t| \quad &\text{if } |t| \le 1,\\ &= 0 &\text{if } |t| \ge 1.\end{aligned}$$

Let ρ be sampled on a grid $\mathscr{G}_1 = \mathbf{N}_1^{-1}\mathbb{Z}^3$, and let $I_{\mathbf{N}_1}\rho$ denote the function interpolated from this sampled version of ρ. Then:

$$I_{\mathbf{N}_1}\rho = \left[\rho \times \sum_{\mathbf{m}\in\mathbb{Z}^3} \delta_{(\mathbf{N}_1^{-1}\mathbf{m})}\right] * [(\mathbf{N}_1^{-1})^{\#}K],$$

where $[(N_1^{-1})^{\#}K](\mathbf{x}) = K(\mathbf{N}_1\mathbf{x})$, so that

$$\begin{aligned}\bar{\mathscr{F}}[I_{\mathbf{N}_1}\rho] &= \left[\bar{\mathscr{F}}[\rho] * |\det \mathbf{N}_1| \sum_{\mathbf{k}_1\in\mathbb{Z}^3} \delta_{(\mathbf{N}_1^T\mathbf{k}_1)}\right]\\ &\quad\times \left[\frac{1}{|\det \mathbf{N}_1|}(N_1^T)^{\#}\bar{\mathscr{F}}[K]\right]\\ &= \left[\sum_{\mathbf{k}_1\in\mathbb{Z}^3} \boldsymbol{\tau}_{\mathbf{N}_1^T\mathbf{k}_1}\bar{\mathscr{F}}[\rho]\right] \times (N_1^T)^{\#}\bar{\mathscr{F}}[K].\end{aligned}$$

The transform of $I_{\mathbf{N}_1}\rho$ thus consists of

(i) a 'main band' corresponding to $\mathbf{k}_1 = \mathbf{0}$, which consists of the true transform $\bar{\mathscr{F}}[\rho](\boldsymbol{\xi})$ attenuated by multiplication by the central region of $\bar{\mathscr{F}}[K][(\mathbf{N}^{-1})^T\boldsymbol{\xi}]$; in the case of linear interpolation, for example,

$$\bar{\mathscr{F}}[K](\xi,\eta,\zeta) = \left(\frac{\sin\pi\xi}{\pi\xi}\right)^2\left(\frac{\sin\pi\eta}{\pi\eta}\right)^2\left(\frac{\sin\pi\zeta}{\pi\zeta}\right)^2;$$

(ii) a series of 'ghost bands' corresponding to $\mathbf{k}_1 \neq \mathbf{0}$, which consist of translates of $\bar{\mathscr{F}}[\rho]$ multiplied by the tail regions of $(N_1^T)^{\#}\bar{\mathscr{F}}[K]$.

Thus $I_{\mathbf{N}_1}\rho$ is not band-limited even if ρ is. Supposing, however, that ρ is band-limited and that grid $\mathscr{G}_1$ satisfies the Shannon sampling criterion, we see that there will be no overlap between the different bands: $\bar{\mathscr{F}}[\rho]$ may therefore be recovered from the main band by compensating its attenuation, which is approximately a temperature-factor correction.

For numerical work, however, $I_{\mathbf{N}_1}\rho$ must be resampled onto another grid $\mathscr{G}_2$, which causes its transform to become periodized into

$$|\det \mathbf{N}_2| \sum_{\mathbf{k}_2 \in \mathbb{Z}^3} \boldsymbol{\tau}_{\mathbf{N}_2^T\mathbf{k}_2} \left\{ \left[\sum_{\mathbf{k}_1 \in \mathbb{Z}^3} \boldsymbol{\tau}_{\mathbf{N}_1^T\mathbf{k}_1} \bar{\mathscr{F}}[\rho] \right] (N_1^T)^{\#} \bar{\mathscr{F}}[K] \right\}.$$

This now causes the main band $\mathbf{k}_1 = \mathbf{k}_2 = \mathbf{0}$ to become contaminated by the ghost bands ($\mathbf{k}_1 \neq \mathbf{0}$) of the translates ($\mathbf{k}_2 \neq \mathbf{0}$) of $I_{\mathbf{N}_1}\rho$.

Aliasing errors may be minimized by increasing the sampling rate in grid $\mathscr{G}_1$ well beyond the Shannon minimum, which rapidly reduces the r.m.s. content of the ghost bands.

The sampling rate in grid $\mathscr{G}_2$ needs only exceed the Shannon minimum to the extent required to accommodate the increase in bandwidth due to convolution with $\bar{\mathscr{F}}[\chi_U]$, which is the reciprocal-space counterpart of envelope truncation (or solvent flattening) in real space.

1.3.4.4.3.5. Molecular-envelope transforms via Green's theorem

Green's theorem stated in terms of distributions (Section 1.3.2.3.9.1) is particularly well suited to the calculation of the Fourier transforms $\bar{\mathscr{F}}[\chi_U]$ of indicator functions. Let f be the indicator function χ_U and let S be the boundary of U (assumed to be a smooth surface). The jump σ_0 in the value of f across S along the outer normal vector is $\sigma_0 = -1$, the jump σ_ν in the normal derivative of f across S is $\sigma_\nu = 0$, and the Laplacian of f as a function is (almost everywhere) 0 so that $T_{\Delta f} = 0$. Green's theorem then reads:

$$\begin{aligned}\Delta(T_f) &= T_{\Delta f} + \sigma_\nu \delta_{(S)} + \partial_\nu[\sigma_0 \delta_{(S)}] \\ &= -\partial_\nu[\delta_{(S)}].\end{aligned}$$

The function $e_{\mathbf{H}}(\mathbf{X}) = \exp(2\pi i \mathbf{H}\cdot\mathbf{X})$ satisfies the identity $\Delta e_{\mathbf{H}} = -4\pi^2\|\mathbf{H}\|^2 e_{\mathbf{H}}$. Therefore, in Cartesian coordinates:

$$\begin{aligned}\bar{F}[\chi_U](\mathbf{H}) &= \langle T_{\chi_U}, e_{\mathbf{H}} \rangle \\ &= -\frac{1}{4\pi^2\|\mathbf{H}\|^2} \langle T_{\chi_U}, \Delta e_{\mathbf{H}} \rangle \\ &= -\frac{1}{4\pi^2\|\mathbf{H}\|^2} \langle \Delta(T_{\chi_U}), e_{\mathbf{H}} \rangle \qquad \text{[Section 1.3.2.3.9.1}(a)\text{]} \\ &= -\frac{1}{4\pi^2\|\mathbf{H}\|^2} \langle -\partial_\nu[\delta_{(S)}], e_{\mathbf{H}} \rangle \\ &= -\frac{1}{4\pi^2\|\mathbf{H}\|^2} \int_S \partial_\nu e_{\mathbf{H}} \, \mathrm{d}^2 S \qquad \text{[Section 1.3.2.3.9.1}(c)\text{]} \\ &= -\frac{1}{4\pi^2\|\mathbf{H}\|^2} \int_S 2\pi i \mathbf{H}\cdot\mathbf{n} \exp(2\pi i \mathbf{H}\cdot\mathbf{X}) \, \mathrm{d}^2 S,\end{aligned}$$

i.e.

$$\bar{\mathscr{F}}[\chi_U](\mathbf{H}) = \frac{1}{2\pi i\|\mathbf{H}\|^2} \int_S \mathbf{H}\cdot\mathbf{n} \exp(2\pi i \mathbf{H}\cdot\mathbf{X}) \, \mathrm{d}^2 S,$$

where $\mathbf{n}$ is the outer normal to S. This formula was used by von Laue (1936) for a different purpose, namely to calculate the transforms of crystal shapes (see also Ewald, 1940). If the surface S is given by a triangulation, the surface integral becomes a sum over all faces, since $\mathbf{n}$ is constant on each face. If U is a solid sphere with radius R, an integration by parts gives immediately:

$$\frac{1}{\mathrm{vol}(U)} \bar{\mathscr{F}}[\chi_U](\mathbf{H}) = \frac{3}{X^3}[\sin X - X\cos X] \quad \text{with } X = 2\pi\|\mathbf{H}\|R.$$

1.3.4.4.4. Structure factors from model atomic parameters

An atomic model of a crystal structure consists of a list of symmetry-unique atoms described by their positions, their thermal agitation and their chemical identity (which can be used as a pointer to form-factor tables). Form factors are usually parameterized as sums of Gaussians, and thermal agitation by a Gaussian temperature factor or tensor. The formulae given in Section 1.3.4.2.2.6 for Gaussian atoms are therefore adequate for most purposes. High-resolution electron-density studies use more involved parameterizations.

Early calculations were carried out by means of Bragg–Lipson charts (Bragg & Lipson, 1936) which gave a graphical representation of the symmetrized trigonometric sums Ξ of Section 1.3.4.2.2.9. The approximation of form factors by Gaussians goes back to the work of Vand *et al.* (1957) and Forsyth & Wells (1959). Agarwal (1978) gave simplified expansions suitable for medium-resolution modelling of macromolecular structures.

This method of calculating structure factors is expensive because *each* atom sends contributions of essentially equal magnitude to *all* structure factors in a resolution shell. The calculation is therefore of size $\propto N\mathscr{N}$ for N atoms and $\mathscr{N}$ reflections. Since N and $\mathscr{N}$ are roughly proportional at a given resolution, this method is very costly for large structures.

Two distinct programming strategies are available (Rollett, 1965) according to whether the fast loop is on all atoms for each reflection, or on all reflections for each atom. The former method was favoured in the early times when computers were unreliable. The latter was shown by Burnett & Nordman (1974) to be more amenable to efficient programming, as no multiplication is required in calculating the arguments of the sine/cosine terms: these can be accumulated by integer addition, and used as subscripts in referencing a trigonometric function table.

1.3.4.4.5. Structure factors via model electron-density maps

Robertson (1936*b*) recognized the similarity between the calculation of structure factors by Fourier summation and the calculation of Fourier syntheses, the main difference being of course that atomic coordinates do not usually lie exactly on a grid obtained by integer subdivision of the crystal lattice. He proposed to address this difficulty by the use of his sorting board, which could extend the scale of subdivision and thus avoid phase errors. In this way the calculation of structure factors became amenable to Beevers–Lipson strip methods, with considerable gain of speed.

Later, Beevers & Lipson (1952) proposed that trigonometric functions attached to atomic positions falling between the grid points on which Beevers–Lipson strips were based should be obtained by linear interpolation from the values found on the strips for the closest grid points. This amounts (Section 1.3.4.4.3.4) to using atoms in the shape of a trilinear wedge, whose

form factor was indicated in Section 1.3.4.4.3.4 and gives rise to aliasing effects (see below) not considered by Beevers & Lipson.

The correct formulation of this idea came with the work of Sayre (1951), who showed that structure factors could be calculated by Fourier analysis of a sampled electron-density map previously generated on a subdivision $\mathbf{N}^{-1}\Lambda$ of the crystal lattice Λ. When generating such a map, care must be taken to distribute onto the sample grid not only the electron densities of all the atoms in the asymmetric motif, but also those of their images under space-group symmetries and lattice translations. Considerable savings in computation occur, especially for large structures, because atoms are *localized*: each atom sends contributions to only a few grid points in real space, rather than to all reciprocal-lattice points. The generation of the sampled electron-density map is still of complexity $\propto N\mathcal{N}$ for N atoms and $\mathcal{N}$ reflections, but the proportionality constant is smaller than that in Section 1.3.4.4.4 by orders of magnitude; the extra cost of Fourier analysis, proportional to $\mathcal{N}\log\mathcal{N}$, is negligible.

The idea of approximating a Fourier transform by a discrete transform on sampled values had already been used by Whittaker (1948), who tested it on the first three odd Hermite functions and did not consider the problem of aliasing errors. By contrast, Sayre gave a lucid analysis of the sampling problems associated to this technique. If the periodic sampled map is written in the form of a weighted lattice distribution (as in Section 1.3.2.7.3) as

$$\rho^{\mathrm{s}} = \sum_{\mathbf{m}\in\mathbb{Z}^3} \rho(\mathbf{N}^{-1}\mathbf{m})\delta_{(\mathbf{N}^{-1}\mathbf{m})},$$

then its discrete Fourier transform yields

$$F^{\mathrm{s}}(\mathbf{h}) = \sum_{\boldsymbol{\eta}\in\mathbb{Z}^3} F(\mathbf{h}+\mathbf{N}^T\boldsymbol{\eta})$$

so that each correct value $F(\mathbf{h})$ is corrupted by its aliases $F(\mathbf{h}+\mathbf{N}^T\boldsymbol{\eta})$ for $\boldsymbol{\eta}\neq\mathbf{0}$.

To cure this aliasing problem, Sayre used 'hypothetical atoms' with form factors equal to those of standard atoms within the resolution range of interest, but set to zero outside that range. This amounts to using atomic densities with built-in series-termination errors, which has the detrimental effect of introducing slowly decaying ripples around the atom which require incrementing sample densities at many more grid points per atom.

Sayre considered another cure in the form of an artificial temperature factor B (Bragg & West, 1930) applied to all atoms. This spreads each atom on more grid points in real space but speeds up the decay of its transform in reciprocal space, thus allowing the use of a coarser sampling grid in real space. He discounted it as spoiling the agreement with observed data, but Ten Eyck (1977) pointed out that this agreement could be restored by applying the negative of the artificial temperature factor to the results. This idea cannot be carried to extremes: if B is chosen too large, the atoms will be so spread out in real space as each to occupy a sizeable fraction of the unit cell and the advantage of atom localization will be lost; furthermore, the form factors will fall off so rapidly that round-off error amplification will occur when the results are sharpened back. Clearly, there exists an optimal combination of B and sampling rate yielding the most economical computation for a given accuracy at a given resolution, and a formula will now be given to calculate it.

Let us make the simplifying assumption that all atoms are roughly equal and that their common form factor can be represented by an equivalent temperature factor B_{eq}. Let $\Delta = 1/d^*_{\max}$ be the resolution to which structure factors are wanted. The Shannon sampling interval is $\Delta/2 = 1/2d^*_{\max}$. Let σ be the oversampling rate, so that the actual sampling interval in the map is $\Delta/2\sigma = 1/2\sigma d^*_{\max}$: then consecutive copies of the transform are separated by a distance $2\sigma d^*_{\max}$ in reciprocal space. Let the artificial temperature factor B_{extra} be added, and let

$$B = B_{\mathrm{eq}} + B_{\mathrm{extra}}.$$

The worst aliasing occurs at the outer resolution limit $d^*_{\max}$, where the 'signal' due to an atom is proportional to

$$\exp[(-B/4)(d^*_{\max})^2],$$

while the 'noise' due to the closest alias is proportional to

$$\exp\{(-B/4)[(2\sigma-1)d^*_{\max}]^2\}.$$

Thus the signal-to-noise ratio, or quality factor, Q is

$$\exp[B\sigma(\sigma-1)(d^*_{\max})^2].$$

If a certain value of Q is desired (*e.g.* $Q = 100$ for 1% accuracy), then the equation

$$B = \frac{\log Q}{\sigma(\sigma-1)(d^*_{\max})^2}$$

defines B in terms of σ, $d^*_{\max}$ and Q.

The overall cost of the structure-factor calculation from N atoms is then

(i) $C_1 \times B^{2/3} \times N$ for density generation,

(ii) $C_2 \times (2\sigma d^*_{\max})^3 \times \log[(2\sigma d^*_{\max})^3]$ for Fourier analysis,

where C_1 and C_2 are constant depending on the speed of the computer used. This overall cost may be minimized with respect to σ for given $d^*_{\max}$ and Q, determining the optimal B (and hence B_{extra}) in passing by the above relation.

Sayre (1951) did observe that applying an artificial temperature factor in real space would not create series-termination ripples: the resulting atoms would have a smaller effective radius than his hypothetical atoms, so that step (i) would be faster. This optimality of Gaussian smearing is ultimately a consequence of Hardy's theorem (Section 1.3.2.4.4.3).

1.3.4.4.6. Derivatives for variational phasing techniques

Some methods of phase determination rely on maximizing a certain global criterion $S[\rho]$ involving the electron density, of the form $\int_{\mathbb{R}^3/\mathbb{Z}^3} K[\rho(\mathbf{x})]\,\mathrm{d}^3\mathbf{x}$, under constraint of agreement with the observed structure-factor amplitudes, typically measured by a χ^2 residual C. Several recently proposed methods use for $S[\rho]$ various measures of entropy defined by taking $K(\rho) = -\rho\log(\rho/\mu)$ or $K(\rho) = \log\rho$ (Bricogne, 1982; Britten & Collins, 1982; Narayan & Nityananda, 1982; Bryan *et al.*, 1983; Wilkins *et al.*, 1983; Bricogne, 1984; Navaza, 1985; Livesey & Skilling, 1985). Sayre's use of the squaring method to improve protein phases (Sayre, 1974) also belongs to this category, and is amenable to the same computational strategies (Sayre, 1980).

These methods differ from the density-modification procedures of Section 1.3.4.4.3.2 in that they seek an optimal solution by moving electron densities (or structure factors) *jointly* rather than pointwise, *i.e.* by moving along suitably chosen *search directions* $v_i(\mathbf{x})$ [or $V_i(\mathbf{h})$].

For computational purposes, these search directions may be handled either as column vectors of sample values $\{v_i(\mathbf{N}^{-1}\mathbf{m})\}_{\mathbf{m}\in\mathbb{Z}^3/\mathbf{N}\mathbb{Z}^3}$ on a grid in real space, or as column vectors of Fourier coefficients $\{V_i(\mathbf{h})\}_{\mathbf{h}\in\mathbb{Z}^3/\mathbf{N}^T\mathbb{Z}^3}$ in reciprocal space. These column vectors are the coordinates of the same vector $\mathbf{V}_i$ in an

abstract vector space $\mathscr{V} \cong L(\mathbb{Z}^3/\mathbf{N}\mathbb{Z}^3)$ of dimension $\mathscr{N} = |\det \mathbf{N}|$ over $\mathbb{R}$, but referred to two different bases which are related by the DFT and its inverse (Section 1.3.2.7.3).

The problem of finding the optimum of S for a given value of C amounts to achieving collinearity between the gradients ∇S and ∇C of S and of C in $\mathscr{V}$, the scalar ratio between them being a Lagrange multiplier. In order to move towards such a solution from a trial position, the dependence of ∇S and ∇C on position in $\mathscr{V}$ must be represented. This involves the $\mathscr{N} \times \mathscr{N}$ Hessian matrices $\mathbf{H}(S)$ and $\mathbf{H}(C)$, whose size precludes their use in the whole of $\mathscr{V}$. Restricting the search to a smaller *search subspace* of dimension n spanned by $\{\mathbf{V}_i\}_{i=1,\ldots,n}$ we may build local quadratic models of S and C (Bryan & Skilling, 1980; Burch *et al.*, 1983) with respect to n coordinates $\mathbf{X}$ in that subspace:

$$\begin{aligned} S(\mathbf{X}) &= S(\mathbf{X}_0) + \mathbf{S}_0^T(\mathbf{X} - \mathbf{X}_0) \\ &\quad + \tfrac{1}{2}(\mathbf{X} - \mathbf{X}_0)^T \mathbf{H}_0(S)(\mathbf{X} - \mathbf{X}_0) \\ C(\mathbf{X}) &= C(\mathbf{X}_0) + \mathbf{C}_0^T(\mathbf{X} - \mathbf{X}_0) \\ &\quad + \tfrac{1}{2}(\mathbf{X} - \mathbf{X}_0)^T \mathbf{H}_0(C)(\mathbf{X} - \mathbf{X}_0). \end{aligned}$$

The coefficients of these linear models are given by scalar products:

$$\begin{aligned} [\mathbf{S}_0]_i &= (\mathbf{V}_i, \nabla S) \\ [\mathbf{C}_0]_i &= (\mathbf{V}_i, \nabla C) \\ [\mathbf{H}_0(S)]_{ij} &= [\mathbf{V}_i, \mathbf{H}(S)\mathbf{V}_j] \\ [\mathbf{H}_0(C)]_{ij} &= [\mathbf{V}_i, \mathbf{H}(C)\mathbf{V}_j] \end{aligned}$$

which, by virtue of Parseval's theorem, may be evaluated either in real space or in reciprocal space (Bricogne, 1984). In doing so, special positions and reflections must be taken into account, as in Section 1.3.4.2.2.8. Scalar products involving S are best evaluated by real-space grid summation, because $\mathbf{H}(S)$ is *diagonal* in this representation; those involving C are best calculated by reciprocal-space summation, because $\mathbf{H}(C)$ is at worst 2×2 *block-diagonal* in this representation. Using these Hessian matrices in the wrong space would lead to prohibitively expensive convolutions instead of scalar (or at worst 2×2 matrix) multiplications.

1.3.4.4.7. Derivatives for model refinement

Since the origins of X-ray crystal structure analysis, the calculation of crystallographic Fourier series has been closely associated with the process of refinement. Fourier coefficients *with phases* were obtained for all or part of the measured reflections in the basis of some trial model for all or part of the structure, and Fourier syntheses were then used to complete and improve this initial model. This approach is clearly described in the classic paper by Bragg & West (1929), and was put into practice in the determination of the structures of topaz (Alston & West, 1929) and diopside (Warren & Bragg, 1929). Later, more systematic methods of arriving at a trial model were provided by the Patterson synthesis (Patterson, 1934, 1935*a*,*b*; Harker, 1936) and by isomorphous replacement (Robertson, 1935, 1936*c*). The role of Fourier syntheses, however, remained essentially unchanged [see Robertson (1937) for a review] until more systematic methods of structure refinement were introduced in the 1940s. A particularly good account of the processes of structure completion and refinement may be found in Chapters 15 and 16 of Stout & Jensen (1968).

It is beyond the scope of this section to review the vast topic of refinement methods: rather, it will give an account of those aspects of their development which have sought improved power by exploiting properties of the Fourier transformation. It is of more than historical interest that some recent advances in the crystallographic refinement of macromolecular structures had been anticipated by Cochran and Cruickshank in the early 1950s.

1.3.4.4.7.1. The method of least squares

Hughes (1941) was the first to use the already well established multivariate least-squares method (Whittaker & Robinson, 1944) to refine initial estimates of the parameters describing a model structure. The method gained general acceptance through the programming efforts of Friedlander *et al.* (1955), Sparks *et al.* (1956), Busing & Levy (1961) and others.

The Fourier relations between ρ and F (Section 1.3.4.2.2.6) are used to derive the 'observational equations' connecting the structure parameters $\{u_p\}_{p=1,\ldots,n}$ to the observations $\{|F_\mathbf{h}|^{\rm obs}, (\sigma_\mathbf{h}^2)^{\rm obs}\}_{\mathbf{h}\in\mathscr{H}}$ comprising the amplitudes and their experimental variances for a set $\mathscr{H}$ of unique reflections.

The normal equations giving the corrections $\delta\mathbf{u}$ to the parameters are then

$$(\mathbf{A}^T\mathbf{W}\mathbf{A})\delta\mathbf{u} = -\mathbf{A}^T\mathbf{W}\Delta,$$

where

$$\begin{aligned} A_{\mathbf{h}p} &= \frac{\partial |F_\mathbf{h}^{\rm calc}|}{\partial u_p} \\ \Delta_\mathbf{h} &= |F_\mathbf{h}^{\rm calc}| - |F_\mathbf{h}|^{\rm obs} \\ \mathbf{W} &= \text{diag } (W_\mathbf{h}) \quad \text{with} \quad W_\mathbf{h} = \frac{1}{(\sigma_\mathbf{h}^2)^{\rm obs}}. \end{aligned}$$

To calculate the elements of $\mathbf{A}$, write:

$$F = |F| \exp(i\varphi) = \alpha + i\beta;$$

hence

$$\begin{aligned} \frac{\partial |F|}{\partial u} &= \frac{\partial \alpha}{\partial u}\cos\varphi + \frac{\partial \beta}{\partial u}\sin\varphi \\ &= \mathscr{R}e\left[\frac{\partial F}{\partial u}\overline{\exp(i\varphi)}\right] = \mathscr{R}e\left[\frac{\overline{\partial F}}{\partial u}\exp(i\varphi)\right]. \end{aligned}$$

In the simple case of atoms with real-valued form factors and isotropic thermal agitation in space group $P1$,

$$F_\mathbf{h}^{\rm calc} = \sum_{j\in J} g_j(\mathbf{h}) \exp(2\pi i \mathbf{h}\cdot\mathbf{x}_j),$$

where

$$g_j(\mathbf{h}) = Z_j f_j(\mathbf{h}) \exp[-\tfrac{1}{4}B_j(d_\mathbf{h}^*)^2],$$

Z_j being a fractional occupancy.

Positional derivatives with respect to $\mathbf{x}_j$ are given by

$$\begin{aligned} \frac{\partial F_\mathbf{h}^{\rm calc}}{\partial \mathbf{x}_j} &= (2\pi i\mathbf{h}) g_j(\mathbf{h}) \exp(2\pi i \mathbf{h}\cdot\mathbf{x}_j) \\ \frac{\partial |F_\mathbf{h}^{\rm calc}|}{\partial \mathbf{x}_j} &= \mathscr{R}e[(-2\pi i\mathbf{h}) g_j(\mathbf{h}) \exp(-2\pi i \mathbf{h}\cdot\mathbf{x}_j) \exp(i\varphi_\mathbf{h}^{\rm calc})] \end{aligned}$$

so that the corresponding 3×1 subvector of the right-hand side of the normal equations reads:

$$-\sum_{\mathbf{h}\in\mathscr{H}} W_{\mathbf{h}} \frac{\partial|F_{\mathbf{h}}^{\rm calc}|}{\partial \mathbf{x}_j}(|F_{\mathbf{h}}^{\rm calc}| - |F_{\mathbf{h}}|^{\rm obs}) = -\mathscr{R}e\Bigg[\sum_{\mathbf{h}\in\mathscr{H}} g_j(\mathbf{h})(-2\pi i\mathbf{h})W_{\mathbf{h}}(|F_{\mathbf{h}}^{\rm calc}| - |F_{\mathbf{h}}|^{\rm obs}) \times \exp(i\varphi_{\mathbf{h}}^{\rm calc})\exp(-2\pi i\mathbf{h}\cdot\mathbf{x}_j)\Bigg].$$

The setting up and solution of the normal equations lends itself well to computer programming and has the advantage of providing a thorough analysis of the accuracy of its results (Cruickshank, 1965*b*, 1970; Rollett, 1970). It is, however, an expensive task, of complexity $\propto n \times |\mathscr{H}|^2$, which is unaffordable for macromolecules.

1.3.4.4.7.2. Booth's differential Fourier syntheses

It was the use of Fourier syntheses in the completion of trial structures which provided the incentive to find methods for computing 2D and 3D syntheses efficiently, and led to the Beevers–Lipson strips. The limited accuracy of the latter caused the estimated positions of atoms (identified as peaks in the maps) to be somewhat in error. Methods were therefore sought to improve the accuracy with which the coordinates of the electron-density maxima could be determined. The naive method of peak-shape analysis from densities recalculated on a $3 \times 3 \times 3$ grid using high-accuracy trigonometric tables entailed 27 summations per atom.

Booth (1946*a*) suggested examining the rapidly varying derivatives of the electron density rather than its slowly varying values. If

$$\rho(\mathbf{x}) = \sum_{\mathbf{h}} F_{\mathbf{h}} \exp(-2\pi i\mathbf{h}\cdot\mathbf{x})$$

then the gradient vector $\nabla_{\mathbf{x}}\rho$ of ρ at $\mathbf{x}^0$

$$(\nabla_{\mathbf{x}}\rho)(\mathbf{x}^0) = \sum_{\mathbf{h}} F_{\mathbf{h}}(-2\pi i\mathbf{h})\exp(-2\pi i\mathbf{h}\cdot\mathbf{x}^0)$$

can be calculated by means of three Fourier summations from the 3×1 vector of Fourier coefficients

$$(-2\pi i\mathbf{h})F_{\mathbf{h}}.$$

Similarly, the Hessian matrix of ρ at $\mathbf{x}^0$

$$[(\nabla_{\mathbf{x}}\nabla_{\mathbf{x}}^T)\rho](\mathbf{x}^0) = \sum_{\mathbf{h}} F_{\mathbf{h}}(-4\pi^2\mathbf{h}\mathbf{h}^T)\exp(-2\pi i\mathbf{h}\cdot\mathbf{x}^0)$$

can be calculated by six Fourier summations from the unique elements of the symmetric matrix of Fourier coefficients:

$$-4\pi^2\begin{pmatrix} h^2 & hk & hl \\ hk & k^2 & kl \\ hl & kl & l^2 \end{pmatrix}F_{\mathbf{h}}.$$

The scalar maps giving the components of the gradient and Hessian matrix of ρ will be called differential syntheses of 1st order and 2nd order respectively. If $\mathbf{x}^0$ is approximately but not exactly a maximum of ρ, then the Newton–Raphson estimate of the true maximum $\mathbf{x}^*$ is given by:

$$\mathbf{x}^* = \mathbf{x}^0 - [[(\nabla_{\mathbf{x}}\nabla_{\mathbf{x}}^T)\rho](\mathbf{x}^0)]^{-1}[\nabla_{\mathbf{x}}\rho(\mathbf{x}^0)].$$

This calculation requires only nine accurate Fourier summations (instead of 27), and this number is further reduced to four if the peak is assumed to be spherically symmetrical.

The resulting positions are affected by series-termination errors in the differential syntheses. Booth (1945*c*, 1946*c*) proposed a 'back-shift correction' to eliminate them, and extended this treatment to the acentric case (Booth, 1946*b*). He cautioned against the use of an artificial temperature factor to fight series-termination errors (Brill *et al.*, 1939), as this could be shown to introduce coordinate errors by causing overlap between atoms (Booth, 1946*c*, 1947*a*,*b*).

Cruickshank was able to derive estimates for the standard uncertainties of the atomic coordinates obtained in this way (Cox & Cruickshank, 1948; Cruickshank, 1949*a*,*b*) and to show that they agreed with those provided by the least-squares method.

The calculation of differential Fourier syntheses was incorporated into the crystallographic programs of Ahmed & Cruickshank (1953*b*) and of Sparks *et al.* (1956).

1.3.4.4.7.3. Booth's method of steepest descents

Having defined the now universally adopted R factors (Booth, 1945*b*) as criteria of agreement between observed and calculated amplitudes or intensities, Booth proposed that R should be minimized with respect to the set of atomic coordinates $\{\mathbf{x}_j\}_{j\in J}$ by descending along the gradient of R in parameter space (Booth, 1947*c*,*d*). This 'steepest descents' procedure was compared with Patterson methods by Cochran (1948*d*).

When calculating the necessary derivatives, Booth (1948*a*, 1949) used the formulae given above in connection with least squares. This method was implemented by Qurashi (1949) and by Vand (1948, 1951) with parameter-rescaling modifications which made it very close to the least-squares method (Cruickshank, 1950; Qurashi & Vand, 1953; Qurashi, 1953).

1.3.4.4.7.4. Cochran's Fourier method

Cochran (1948*b*,*c*, 1951*a*) undertook to exploit an algebraic similarity between the right-hand side of the normal equations in the least-squares method on the one hand, and the expression for the coefficients used in Booth's differential syntheses on the other hand (see also Booth, 1948*a*). In doing so he initiated a remarkable sequence of formal and computational developments which are still actively pursued today.

Let $\rho_{\rm C}(\mathbf{x})$ be the electron-density map corresponding to the current atomic model, with structure factors $|F_{\mathbf{h}}^{\rm calc}|\exp(i\varphi_{\mathbf{h}}^{\rm calc})$; and let $\rho_{\rm O}(\mathbf{x})$ be the map calculated from observed moduli and calculated phases, *i.e.* with coefficients $\{|F_{\mathbf{h}}|^{\rm obs}\exp(i\varphi_{\mathbf{h}}^{\rm calc})\}_{\mathbf{h}\in\mathscr{H}}$. If there are enough data for $\rho_{\rm C}$ to have a resolved peak at each model atomic position $\mathbf{x}_j$, then

$$(\nabla_{\mathbf{x}}\rho_{\rm C})(\mathbf{x}_j) = \mathbf{0} \quad \text{for each } j \in J;$$

while if the calculated phases $\varphi_{\mathbf{h}}^{\rm calc}$ are good enough, $\rho_{\rm O}$ will also have peaks at each $\mathbf{x}_j$:

$$(\nabla_{\mathbf{x}}\rho_{\rm O})(\mathbf{x}_j) = \mathbf{0} \quad \text{for each } j \in J.$$

It follows that

$$[\nabla_{\mathbf{x}}(\rho_{\rm C}-\rho_{\rm O})](\mathbf{x}_j)=\sum_{\mathbf{h}}(-2\pi i\mathbf{h})[(|F_{\mathbf{h}}^{\rm calc}|-|F_{\mathbf{h}}|^{\rm obs})\exp(i\varphi_{\mathbf{h}}^{\rm calc})]\times\exp(-2\pi i\mathbf{h}\cdot\mathbf{x}_j)=\mathbf{0}\text{ for each }j\in J,$$

where the summation is over all reflections in $\mathscr{H}$ or related to $\mathscr{H}$ by space-group and Friedel symmetry (overlooking multiplicity factors!). This relation is less sensitive to series-termination errors than either of the previous two, since the spectrum of $\rho_{\rm O}$ could have been extrapolated beyond the data in $\mathscr{H}$ by using that of $\rho_{\rm C}$ [as in van Reijen (1942)] without changing its right-hand side.

Cochran then used the identity

$$\frac{\partial F_{\mathbf{h}}^{\rm calc}}{\partial\mathbf{x}_j}=(2\pi i\mathbf{h})g_j(\mathbf{h})\exp(2\pi i\mathbf{h}\cdot\mathbf{x}_j)$$

in the form

$$(-2\pi i\mathbf{h})\exp(-2\pi i\mathbf{h}\cdot\mathbf{x}_j)=\frac{1}{g_j(\mathbf{h})}\overline{\frac{\partial F_{\mathbf{h}}^{\rm calc}}{\partial\mathbf{x}_j}}$$

to rewrite the previous relation as

$$\begin{aligned}&[\nabla_{\mathbf{x}}(\rho_{\rm C}-\rho_{\rm O})](\mathbf{x}_j)\\&=\sum_{\mathbf{h}}\frac{1}{g_j(\mathbf{h})}(|F_{\mathbf{h}}^{\rm calc}|-|F_{\mathbf{h}}|^{\rm obs})\mathscr{R}e\left[\overline{\frac{\partial F_{\mathbf{h}}^{\rm calc}}{\partial\mathbf{x}_j}}\exp(i\varphi_{\mathbf{h}}^{\rm calc})\right]\\&=\sum_{\mathbf{h}}\frac{1}{g_j(\mathbf{h})}(|F_{\mathbf{h}}^{\rm calc}|-|F_{\mathbf{h}}|^{\rm obs})\frac{\partial|F_{\mathbf{h}}^{\rm calc}|}{\partial\mathbf{x}_j}\\&=\mathbf{0}\quad\text{for each }j\in J\end{aligned}$$

(the operation $\mathscr{R}e[]$ on the first line being neutral because of Friedel symmetry). This is equivalent to the vanishing of the 3×1 subvector of the right-hand side of the normal equations associated to a least-squares refinement in which the weights would be

$$W_{\mathbf{h}}=\frac{1}{g_j(\mathbf{h})}.$$

Cochran concluded that, for equal-atom structures with $g_j(\mathbf{h})=g(\mathbf{h})$ for all j, the positions $\mathbf{x}_j$ obtained by Booth's method applied to the difference map $\rho_{\rm O}-\rho_{\rm C}$ are such that they minimize the residual

$$\tfrac{1}{2}\sum_{\mathbf{h}}\frac{1}{g(\mathbf{h})}(|F_{\mathbf{h}}^{\rm calc}|-|F_{\mathbf{h}}|^{\rm obs})^2$$

with respect to the atomic positions. If it is desired to minimize the residual of the ordinary least-squares method, then the differential synthesis method should be applied to the *weighted* difference map

$$\sum_{\mathbf{h}}\frac{W_{\mathbf{h}}}{g(\mathbf{h})}(|F_{\mathbf{h}}^{\rm calc}|-|F_{\mathbf{h}}|^{\rm obs})\exp(i\varphi_{\mathbf{h}}^{\rm calc}).$$

He went on to show (Cochran, 1951*b*) that the refinement of temperature factors could also be carried out by inspecting appropriate derivatives of the weighted difference map.

This Fourier method was used by Freer *et al.* (1976) in conjunction with a stereochemical regularization procedure to refine protein structures.

1.3.4.4.7.5. Cruickshank's modified Fourier method

Cruickshank consolidated and extended Cochran's derivations in a series of classic papers (Cruickshank, 1949*b*, 1950, 1952, 1956). He was able to show that all the coefficients involved in the right-hand side and normal matrix of the least-squares method could be calculated by means of suitable differential Fourier syntheses *even when the atoms overlap*. This remarkable achievement lay essentially dormant until its independent rediscovery by Agarwal in 1978 (Section 1.3.4.4.7.6).

To ensure rigorous equivalence between the summations over $\mathbf{h}\in\mathscr{H}$ (in the expressions of least-squares right-hand side and normal matrix elements) and genuine Fourier summations, multiplicity-corrected weights were introduced by:

$$w_{\mathbf{h}}=\frac{1}{|G_{\mathbf{h}}|}W_{\mathbf{h}}\quad\text{if }\mathbf{h}\in G\mathbf{h}\quad\text{with }\mathbf{h}\in\mathscr{H},$$

$$w_{\mathbf{h}}=0\qquad\text{otherwise},$$

where $G\mathbf{h}$ denotes the orbit of $\mathbf{h}$ and $G_{\mathbf{h}}$ its isotropy subgroup (Section 1.3.4.2.2.5). Similarly, derivatives with respect to parameters of symmetry-unique atoms were expressed, *via* the chain rule, as sums over the orbits of these atoms.

Let $p=1,\ldots,n$ be the label of a parameter u_p belonging to atoms with label j. Then Cruickshank showed that the pth element of the right-hand side of the normal equations can be obtained as $D_{p,j}(\mathbf{x}_j)$, where $D_{p,j}$ is a differential synthesis of the form

$$D_{p,j}(\mathbf{x})=\sum_{\mathbf{h}}P_p(\mathbf{h})g_j(\mathbf{h})w_{\mathbf{h}}(|F_{\mathbf{h}}^{\rm calc}|-|F_{\mathbf{h}}|^{\rm obs})\times\exp(i\varphi_{\mathbf{h}}^{\rm calc})\exp(-2\pi i\mathbf{h}\cdot\mathbf{x})$$

with $P_p(\mathbf{h})$ a polynomial in (h, k, l) depending on the type of parameter p. The correspondence between parameter type and the associated polynomial extends Booth's original range of differential syntheses, and is recapitulated in the following table.

Parameter type	$P(h,k,l)$
x coordinate	$-2\pi ih$
y coordinate	$-2\pi ik$
z coordinate	$-2\pi il$
B isotropic	$-\frac{1}{4}(d_{\mathbf{h}}^*)^2$
B^{11} anisotropic	$-h^2$
B^{12} anisotropic	$-hk$
B^{13} anisotropic	$-hl$
B^{22} anisotropic	$-k^2$
B^{23} anisotropic	$-kl$
B^{33} anisotropic	$-l^2$.

Unlike Cochran's original heuristic argument, this result does not depend on the atoms being resolved.

Cruickshank (1952) also considered the elements of the normal matrix, of the form

$$\sum_{\mathbf{h}} w_{\mathbf{h}} \frac{\partial |F_{\mathbf{h}}^{\rm calc}|}{\partial u_p} \frac{\partial |F_{\mathbf{h}}^{\rm calc}|}{\partial u_q}$$

associated with positional parameters. The 3×3 block for parameters $\mathbf{x}_j$ and $\mathbf{x}_k$ may be written

$$\sum_{\mathbf{h}} w_{\mathbf{h}} (\mathbf{h}\mathbf{h}^T) \mathscr{R}e[(-2\pi i) g_j(\mathbf{h}) \exp(-2\pi i \mathbf{h} \cdot \mathbf{x}_j) \exp(i\varphi_{\mathbf{h}}^{\rm calc})] \times \mathscr{R}e[(-2\pi i) g_k(\mathbf{h}) \exp(-2\pi i \mathbf{h} \cdot \mathbf{x}_k) \exp(i\varphi_{\mathbf{h}}^{\rm calc})]$$

which, using the identity

$$\mathscr{R}e(z_1)\mathscr{R}e(z_2) = \tfrac{1}{2}[\mathscr{R}e(z_1 z_2) + \mathscr{R}e(z_1 \overline{z_2})],$$

becomes

$$2\pi^2 \sum_{\mathbf{h}} w_{\mathbf{h}} (\mathbf{h}\mathbf{h}^T) g_j(\mathbf{h}) g_k(\mathbf{h}) \times \{\exp[-2\pi i \mathbf{h} \cdot (\mathbf{x}_j - \mathbf{x}_k)] - \exp(2i\varphi_{\mathbf{h}}^{\rm calc}) \exp[-2\pi i \mathbf{h} \cdot (\mathbf{x}_j + \mathbf{x}_k)]\}$$

(Friedel's symmetry makes $\mathscr{R}e$ redundant on the last line). Cruickshank argued that the first term would give a good approximation to the diagonal blocks of the normal matrix and to those off-diagonal blocks for which $\mathbf{x}_j$ and $\mathbf{x}_k$ are close. On this basis he was able to justify the '*n*-shift rule' of Shoemaker *et al.* (1950). Cruickshank gave this derivation in a general space group, but using a very terse notation which somewhat obscures it. Using the symmetrized trigonometric structure-factor kernel Ξ^- of Section 1.3.4.2.2.9 and its multiplication formula, the above expression is seen to involve the values of a Fourier synthesis at points of the form $\mathbf{x}_j \pm S_g(\mathbf{x}_k)$.

Cruickshank (1956) showed that this analysis could also be applied to the refinement of temperature factors.

These two results made it possible to obtain all coefficients involved in the normal equations by looking up the values of certain differential Fourier syntheses at $\mathbf{x}_j$ or at $\mathbf{x}_j \pm S_g(\mathbf{x}_k)$. At the time this did not confer any superiority over the standard form of the least-squares procedure, because the accurate computation of Fourier syntheses was an expensive operation. The modified Fourier method was used by Truter (1954) and by Ahmed & Cruickshank (1953*a*), and was incorporated into the program system described by Cruickshank *et al.* (1961). A more recent comparison with the least-squares method was made by Dietrich (1972).

There persisted, however, some confusion about the nature of the relationship between Fourier and least-squares methods, caused by the extra factors $g_j(\mathbf{h})$ which make it necessary to compute a differential synthesis for each type of atom. This led Cruickshank to conclude that 'in spite of their remarkable similarities the least-squares and modified-Fourier methods are fundamentally distinct'.

1.3.4.4.7.6. Agarwal's FFT implementation of the Fourier method

Agarwal (1978) rederived and completed Cruickshank's results at a time when the availability of the FFT algorithm made the Fourier method of calculating the coefficients of the normal equations much more economical than the standard method, especially for macromolecules.

As obtained by Cruickshank, the modified Fourier method required a full 3D Fourier synthesis

– for each type of parameter, since this determines [*via* the polynomial $P_p(\mathbf{h})$] the type of differential synthesis to be computed;

– for each type of atom $j \in J$, since the coefficients of the differential synthesis must be multiplied by $g_j(\mathbf{h})$.

Agarwal disposed of the latter dependence by pointing out that the multiplication involved is equivalent to a real-space *convolution* between the differential synthesis and $\sigma_j(\mathbf{x})$, the standard electron density ρ_j for atom type j (Section 1.3.4.2.1.2) smeared by the isotropic thermal agitation of that atom. Since σ_j is *localized*, this convolution involves only a small number of grid points. The requirement of a distinct differential synthesis for each parameter type, however, continued to hold, and created some difficulties at the FFT level because the symmetries of differential syntheses are more complex than ordinary space-group symmetries. Jack & Levitt (1978) sought to avoid the calculation of difference syntheses by using instead finite differences calculated from ordinary Fourier or difference Fourier maps.

In spite of its complication, this return to the Fourier implementation of the least-squares method led to spectacular increases in speed (Isaacs & Agarwal, 1978; Agarwal, 1980; Baker & Dodson, 1980) and quickly gained general acceptance (Dodson, 1981; Isaacs, 1982*a*,*b*, 1984).

1.3.4.4.7.7. Lifchitz's reformulation

Lifchitz [see Agarwal *et al.* (1981), Agarwal (1981)] proposed that the idea of treating certain multipliers in Cruickshank's modified differential Fourier syntheses by means of a convolution in real space should be applied not only to $g_j(\mathbf{h})$, but also to the polynomials $P_p(\mathbf{h})$ which determine the type of differential synthesis being calculated. This leads to convoluting $\partial\sigma_j/\partial u_p$ with the *same* ordinary weighted difference Fourier synthesis, rather than σ_j with the differential synthesis of type p. In this way, a *single* Fourier synthesis, with *ordinary* (scalar) symmetry properties, needs be computed; the parameter type and atom type both intervene through the function $\partial\sigma_j/\partial u_p$ with which it is convoluted. This approach has been used as the basis of an efficient general-purpose least-squares refinement program for macromolecular structures (Tronrud *et al.*, 1987).

This rearrangement amounts to using the fact (Section 1.3.2.3.9.7) that convolution commutes with differentiation. Let

$$D(\mathbf{x}) = \sum_{\mathbf{h}} w_{\mathbf{h}} (|F_{\mathbf{h}}^{\rm calc}| - |F_{\mathbf{h}}|^{\rm obs}) \exp(i\varphi_{\mathbf{h}}^{\rm calc}) \exp(-2\pi i \mathbf{h} \cdot \mathbf{x})$$

be the inverse-variance weighted difference map, and let us assume that parameter u_p belongs to atom j. Then the Agarwal form for the pth component of the right-hand side of the normal equations is

$$\left(\frac{\partial D}{\partial u_p} * \sigma_j\right)(x_j),$$

while the Lifchitz form is

$$\left(D * \frac{\partial \sigma_j}{\partial u_p}\right)(\mathbf{x}_j).$$

1.3.4.4.7.8. A simplified derivation

A very simple derivation of the previous results will now be given, which suggests the possibility of many generalizations.

The weighted difference map $D(\mathbf{x})$ has coefficients $D_{\mathbf{h}}$ which are the gradients of the global residual with respect to each $F_{\mathbf{h}}^{\rm calc}$:

$$D_{\mathbf{h}} = \frac{\partial R}{\partial A_{\mathbf{h}}^{\rm calc}} + i\frac{\partial R}{\partial B_{\mathbf{h}}^{\rm calc}}.$$

By the chain rule, a variation of each $F_{\mathbf{h}}^{\rm calc}$ by $\delta F_{\mathbf{h}}^{\rm calc}$ will result in a variation of R by δR with

$$\delta R = \sum_{\mathbf{h}}\left[\frac{\partial R}{\partial A_{\mathbf{h}}^{\rm calc}}\delta A_{\mathbf{h}}^{\rm calc} + \frac{\partial R}{\partial B_{\mathbf{h}}^{\rm calc}}\delta B_{\mathbf{h}}^{\rm calc}\right] = \mathscr{R}e\sum_{\mathbf{h}}[\overline{D_{\mathbf{h}}}\delta F_{\mathbf{h}}^{\rm calc}].$$

The $\mathscr{R}e$ operation is superfluous because of Friedel symmetry, so that δR may be simply written in terms of the Hermitian scalar product in $\ell^2(\mathbb{Z}^3)$:

$$\delta R = (\mathbf{D}, \delta\mathbf{F}^{\rm calc}).$$

If $\rho^{\rm calc}$ is the transform of $\delta\mathbf{F}^{\rm calc}$, we have also by Parseval's theorem

$$\delta R = (D, \delta\rho^{\rm calc}).$$

We may therefore write

$$D(\mathbf{x}) = \frac{\partial R}{\partial\rho^{\rm calc}(\mathbf{x})},$$

which states that $D(\mathbf{x})$ is the functional derivative of R with respect to $\rho^{\rm calc}$.

The right-hand side of the normal equations has $\partial R/\partial u_p$ for its pth element, and this may be written

$$\frac{\partial R}{\partial u_p} = \int_{\mathbb{R}^3/\mathbb{Z}^3}\frac{\partial R}{\partial\rho^{\rm calc}(\mathbf{x})}\frac{\partial\rho^{\rm calc}(\mathbf{x})}{\partial u_p}{\rm d}^2\mathbf{x} = \left(D, \frac{\partial\rho^{\rm calc}}{\partial u_p}\right).$$

If u_p belongs to atom j, then

$$\frac{\partial\rho^{\rm calc}}{\partial u_p} = \frac{\partial(\tau_{\mathbf{x}_j}\sigma_j)}{\partial u_p} = \tau_{\mathbf{x}_j}\left(\frac{\partial\sigma_j}{\partial u_p}\right);$$

hence

$$\frac{\partial R}{\partial u_p} = \left(D, \tau_{\mathbf{x}_j}\left(\frac{\partial\sigma_j}{\partial u_p}\right)\right).$$

By the identity of Section 1.3.2.4.3.5, this is identical to Lifchitz's expression $(D * \partial\sigma_j/\partial u_p)(\mathbf{x}_j)$. The present derivation in terms of scalar products [see Brünger (1989) for another presentation of it] is conceptually simpler, since it invokes only the chain rule [other uses of which have been reviewed by Lunin (1985)] and Parseval's theorem; economy of computation is obviously related to the good localization of $\partial\rho^{\rm calc}/\partial u_p$ compared to $\partial F^{\rm calc}/\partial u_p$. Convolutions, whose meaning is less clear, are no longer involved; they were a legacy of having first gone over to reciprocal space *via* differential syntheses in the 1940s.

Cast in this form, the calculation of derivatives by FFT methods appears as a particular instance of the procedure described in connection with variational techniques (Section 1.3.4.4.6) to calculate the coefficients of local quadratic models in a search subspace; this is far from surprising since varying the electron density through a variation of the parameters of an atomic model is a particular case of the 'free' variations considered by the variational approach. The latter procedure would accommodate in a very natural fashion the joint consideration of an energetic (Jack & Levitt, 1978; Brünger *et al.*, 1987; Brünger, 1988; Brünger *et al.*, 1989; Kuriyan *et al.*, 1989) or stereochemical (Konnert, 1976; Sussman *et al.*, 1977; Konnert & Hendrickson, 1980; Hendrickson & Konnert, 1980; Tronrud *et al.*, 1987) restraint function (which would play the role of S) and of the crystallographic residual (which would be C). It would even have over the latter the superiority of affording a genuine *second-order* approximation, albeit only in a subspace, hence the ability of detecting negative curvature and the resulting bifurcation behaviour (Bricogne, 1984). Current methods are unable to do this because they use only *first-order* models, and this is known to degrade severely the overall efficiency of the refinement process.

1.3.4.4.7.9. Discussion of macromolecular refinement techniques

The impossibility of carrying out a full-matrix least-squares refinement of a macromolecular crystal structure, caused by excessive computational cost and by the paucity of observations, led Diamond (1971) to propose a real-space refinement method in which stereochemical knowledge was used to keep the number of free parameters to a minimum. Refinement took place by a least-squares fit between the 'observed' electron-density map and a model density consisting of Gaussian atoms. This procedure, coupled to iterative recalculation of the phases, led to the first highly refined protein structures obtained without using full-matrix least squares (Huber *et al.*, 1974; Bode & Schwager, 1975; Deisenhofer & Steigemann, 1975; Takano, 1977*a*,*b*).

Real-space refinement takes advantage of the localization of atoms (each parameter interacts only with the density near the atom to which it belongs) and gives the most immediate description of stereochemical constraints. A disadvantage is that fitting the 'observed' electron density amounts to treating the phases of the structure factors as observed quantities, and to ignoring the experimental error estimates on their moduli. The method is also much more vulnerable to series-termination errors and accidentally missing data than the least-squares method. These objections led to the progressive disuse of Diamond's method, and to a switch towards reciprocal-space least squares following Agarwal's work.

The connection established above between the Cruickshank–Agarwal modified Fourier method and the simple use of the chain rule affords a partial refutation to both the premises of Diamond's method and to the objections made against it:

(i) it shows that refinement *can* be performed through localized computations in real space *without* having to treat the phases as observed quantities;

(ii) at the same time, it shows that measurement errors on the moduli *can* be fully utilized in real space, *via* the Fourier synthesis of the functional derivative $\partial R/\partial\rho^{\rm calc}(\mathbf{x})$ or by means of the coefficients of a quadratic model of R in a search subspace.

1.3.4.4.7.10. Sampling considerations

The calculation of the inner products $(D, \partial\rho^{\rm calc}/\partial u_p)$ from a *sampled* gradient map D requires even more caution than that of structure factors *via* electron-density maps described in Section 1.3.4.4.5, because the functions $\partial\sigma_j/\partial u_p$ have transforms which extend even further in reciprocal space than the σ_j themselves. Analytically, if the σ_j are Gaussians, the $\partial\sigma_j/\partial u_p$ are finite sums of multivariate Hermite functions (Section 1.3.2.4.4.2) and hence the same is true of their transforms. The difference map D must therefore be finely sampled and the relation between error and sampling rate may be investigated as in Section 1.3.4.4.5. An examination of the sampling rates commonly used (*e.g.* one third of the resolution) shows that they are insufficient. Tronrud *et al.*

(1987) propose to relax this requirement by applying an artificial temperature factor to σ_j (*cf.* Section 1.3.4.4.5) and the negative of that temperature factor to D, a procedure of questionable validity because the latter 'sharpening' operation is ill defined [the function $\exp(\|\mathbf{x}\|^2)$ does not define a tempered distribution, so the associativity properties of convolution may be lost]. A more robust procedure would be to compute the scalar product by means of a more sophisticated numerical quadrature formula than a mere grid sum.

1.3.4.4.8. Miscellaneous correlation functions

Certain correlation functions can be useful to detect the presence of multiple copies of the same molecule (known or unknown) in the asymmetric unit of a crystal of unknown structure.

Suppose that a crystal contains one or several copies of a molecule $\mathscr{M}$ in its asymmetric unit. If $\mu(\mathbf{x})$ is the electron density of that molecule in some reference position and orientation, then

$$\mathscr{P}^0 = \sum_{j\in J}\left[\sum_{g\in G} S_g^{\#}(T_j^{\#}\mu)\right],$$

where $T_j : \mathbf{x} \longmapsto \mathbf{C}_j\mathbf{x} + \mathbf{d}_j$ describes the placement of the jth copy of the molecule with respect to the reference copy. It is assumed that each such copy is in a general position, so that there is no isotropy subgroup.

The methods of Section 1.3.4.2.2.9 (with $\mathscr{P}_j$ replaced by $C_j^{\#}\mu$, and $\mathbf{x}_j$ by $\mathbf{d}_j$) lead to the following expression for the autocorrelation of $\mathscr{P}^0$:

$$\check{\mathscr{P}}^0 * \mathscr{P}^0 = \sum_{j_1}\sum_{j_2}\sum_{g_1}\sum_{g_2} \boldsymbol{\tau}_{S_{g_2}(\mathbf{d}_{j_2})-S_{g_1}(\mathbf{d}_{j_1})} \times [(R_{g_1}^{\#}C_{j_1}^{\#}\check{\mu}) * (R_{g_2}^{\#}C_{j_2}^{\#}\mu)].$$

If μ is unknown, consider the subfamily σ of terms with $j_1 = j_2 = j$ and $g_1 = g_2 = g$:

$$\sigma = \sum_j\sum_g R_g^{\#}C_j^{\#}(\check{\mu} * \mu).$$

The scalar product $(\sigma, R^{\#}\sigma)$ in which R is a variable rotation will have a peak whenever

$$R = (R_{g_1}C_{j_1})^{-1}(R_{g_2}C_{j_2})$$

since two copies of the 'self-Patterson' $\check{\mu} * \mu$ of the molecule will be brought into coincidence. If the interference from terms in the Patterson $\pi = r * \check{\mathscr{P}}^0 * \mathscr{P}^0$ other than those present in σ is not too serious, the 'self-rotation function' $(\pi, R^{\#}\pi)$ (Rossmann & Blow, 1962; Crowther, 1972) will show the same peaks, from which the rotations $\{C_j\}_{j\in J}$ may be determined, either individually or jointly if for instance they form a group.

If μ is known, then its self-Patterson $\check{\mu} * \mu$ may be calculated, and the C_j may be found by examining the 'cross-rotation function' $[\pi, R^{\#}(\check{\mu} * \mu)]$ which will have peaks at $R = R_gC_j$, $g \in G, j \in J$. Once the C_j are known, then the various copies $C_j^{\#}\mu$ of $\mathscr{M}$ may be Fourier-analysed into structure factors:

$$M_j(\mathbf{h}) = \bar{\mathscr{F}}[C_j^{\#}\mu](\mathbf{h}).$$

The cross terms with $j_1 \neq j_2, g_1 \neq g_2$ in $\check{\mathscr{P}}^0 * \mathscr{P}^0$ then contain 'motifs'

$$(R_{g_1}^{\#}C_{j_1}^{\#}\check{\mu}) * (R_{g_2}^{\#}C_{j_2}^{\#}\mu),$$

with Fourier coefficients

$$\overline{M_{j_1}(\mathbf{R}_{g_1}^T\mathbf{h})} \times M_{j_2}(\mathbf{R}_{g_2}^T\mathbf{h}),$$

translated by $S_{g_2}(\mathbf{d}_{j_2}) - S_{g_1}(\mathbf{d}_{j_1})$. Therefore the 'translation functions' (Crowther & Blow, 1967)

$$\mathscr{T}_{j_1g_1,j_2g_2}(\mathbf{s}) = \sum_{\mathbf{h}} |F_{\mathbf{h}}|^2 \overline{M_{j_1}(\mathbf{R}_{g_1}^T\mathbf{h})} \times M_{j_2}(\mathbf{R}_{g_2}^T\mathbf{h}) \exp(-2\pi i\mathbf{h}\cdot\mathbf{s})$$

will have peaks at $\mathbf{s} = S_{g_2}(\mathbf{d}_{j_2}) - S_{g_1}(\mathbf{d}_{j_1})$ corresponding to the detection of these motifs.

1.3.4.5. Related applications

1.3.4.5.1. Helical diffraction

The theory of diffraction by helical structures (Cochran *et al.*, 1952; Klug *et al.*, 1958) has played an important part in the study of polypeptides, of nucleic acids and of tobacco mosaic virus.

1.3.4.5.1.1. Circular harmonic expansions in polar coordinates

Let $f = f(x, y)$ be a reasonably regular function in two-dimensional real space. Going over to polar coordinates

$$x = r\cos\varphi \quad y = r\sin\varphi$$

and writing, by slight misuse of notation, $f(r, \varphi)$ for $f(r\cos\varphi, r\sin\varphi)$ we may use the periodicity of f with respect to φ to expand it as a Fourier series (Byerly, 1893):

$$f(r, \varphi) = \sum_{n\in\mathbb{Z}} f_n(r)\exp(in\varphi)$$

with

$$f_n(r) = \frac{1}{2\pi}\int_0^{2\pi} f(r, \varphi)\exp(-in\varphi)\ \mathrm{d}\varphi.$$

Similarly, in reciprocal space, if $F = F(\xi, \eta)$ and if

$$\xi = R\cos\psi \quad \eta = R\sin\psi$$

then

$$F(R, \psi) = \sum_{n\in\mathbb{Z}} i^n F_n(R)\exp(in\psi)$$

with

$$F_n(R) = \frac{1}{2\pi i^n}\int_0^{2\pi} F(R, \psi)\exp(-in\psi)\ \mathrm{d}\psi,$$

where the phase factor i^n has been introduced for convenience in the forthcoming step.

1.3.4.5.1.2. The Fourier transform in polar coordinates

The Fourier transform relation between f and F may then be written in terms of f_n's and F_n's. Observing that $\xi x + \eta y = Rr\cos(\varphi - \psi)$, and that (Watson, 1944)

$$\int_0^{2\pi} \exp(iX\cos\theta + in\theta)\ \mathrm{d}\theta = 2\pi i^n J_n(X),$$

we obtain:

$$\begin{aligned} F(R,\psi) &= \int_0^{\infty}\int_0^{2\pi}\left[\sum_{n\in\mathbb{Z}} f_n(r)\exp(in\varphi)\right] \\ &\quad\times \exp[2\pi iRr\cos(\varphi-\psi)]r\ \mathrm{d}r\ \mathrm{d}\varphi \\ &= \sum_{n\in\mathbb{Z}} i^n\left[\int_0^{\infty} f_n(r)J_n(2\pi Rr)2\pi r\ \mathrm{d}r\right]\exp(in\psi); \end{aligned}$$

hence, by the uniqueness of the Fourier expansion of F:

$$F_n(R) = \int_0^{\infty} f_n(r)J_n(2\pi Rr)2\pi r\ \mathrm{d}r.$$

The inverse Fourier relationship leads to

$$f_n(r) = \int_0^{\infty} F_n(R)J_n(2\pi rR)2\pi R\ \mathrm{d}R.$$

The integral transform involved in the previous two equations is called the *Hankel transform* (see *e.g.* Titchmarsh, 1922; Sneddon, 1972) of order n.

1.3.4.5.1.3. The transform of an axially periodic fibre

Let ρ be the electron-density distribution in a fibre, which is assumed to have translational periodicity with period 1 along z, and to have compact support with respect to the (x, y) coordinates. Thus ρ may be written

$$\rho = \left[\delta_x \otimes \delta_y \otimes \left(\sum_{k\in\mathbb{Z}}\delta_{(k)}\right)_z\right] * \rho^0,$$

where $\rho^0 = \rho^0(x, y, z)$ is the motif.

By the tensor product property, the inverse Fourier transform $F = \bar{\mathscr{F}}_{xyz}[\rho]$ may be written

$$F = \left[1_\xi \otimes 1_\eta \otimes \left(\sum_{l\in\mathbb{Z}}\delta_{(l)}\right)_\zeta\right] \times \bar{\mathscr{F}}[\rho^0]$$

and hence consists of 'layers' labelled by l:

$$F = \sum_{l\in\mathbb{Z}} F(\xi,\eta,l)(\delta_{(l)})_\zeta$$

with

$$F(\xi,\eta,l) = \int_0^1 \bar{\mathscr{F}}_{xy}[\rho^0](\xi,\eta,z)\exp(2\pi ilz)\ \mathrm{d}z.$$

Changing to polar coordinates in the (x, y) and (ξ, η) planes decomposes the calculation of F from ρ into the following steps:

$$\begin{aligned} g_{nl}(r) &= \frac{1}{2\pi}\int_0^{2\pi}\int_0^1 \rho(r,\varphi,z)\exp[i(-n\varphi + 2\pi lz)]\ \mathrm{d}\varphi\ \mathrm{d}z \\ G_{nl}(R) &= \int_0^{\infty} g_{nl}(r)J_n(2\pi Rr)2\pi r\ \mathrm{d}r \\ F(R,\psi,l) &= \sum_{n\in\mathbb{Z}} i^n G_{nl}(R)\exp(in\psi) \end{aligned}$$

and the calculation of ρ from F into:

$$\begin{aligned} G_{nl}(R) &= \frac{1}{2\pi i^n}\int_0^{2\pi} F(R,\psi,l)\exp(-in\psi)\ \mathrm{d}\psi \\ g_{nl}(r) &= \int_0^{\infty} G_{nl}(R)J_n(2\pi rR)2\pi R\ \mathrm{d}R \\ \rho(r,\varphi,z) &= \sum_{n\in\mathbb{Z}}\sum_{l\in\mathbb{Z}} g_{nl}(r)\exp[i(n\varphi - 2\pi lz)]. \end{aligned}$$

These formulae are seen to involve a 2D Fourier series with respect to the two periodic coordinates φ and z, and Hankel transforms along the radial coordinates. The two periodicities in φ and z are independent, so that all combinations of indices (n, l) occur in the Fourier summations.

1.3.4.5.1.4. Helical symmetry and associated selection rules

Helical symmetry involves a 'clutching' between the two (hitherto independent) periodicities in φ (period 2π) and z (period 1) which causes a subdivision of the period lattice and hence a decimation (governed by 'selection rules') of the Fourier coefficients.

Let **i** and **j** be the basis vectors along $\varphi/2\pi$ and z. The integer lattice with basis **(i, j)** is a period lattice for the (φ, z) dependence of the electron density ρ of an axially periodic fibre considered in Section 1.3.4.5.1.3:

$$\rho(r, \varphi + 2\pi k_1, z + k_2) = \rho(r,\varphi,z).$$

Suppose the fibre now has *helical* symmetry, with u copies of the same molecule in t turns, where g.c.d. $(u, t) = 1$. Using the Euclidean algorithm, write $u = \lambda t + \mu$ with λ and μ positive integers and $\mu < t$. The period lattice for the (φ, z) dependence of ρ may be defined in terms of the new basis vectors:

I, joining subunit 0 to subunit l in the same turn;

J, joining subunit 0 to subunit λ after wrapping around.

In terms of the original basis

$$\mathbf{I} = \frac{t}{u}\mathbf{i} + \frac{1}{u}\mathbf{j}, \quad \mathbf{J} = \frac{-\mu}{u}\mathbf{i} + \frac{\lambda}{u}\mathbf{j}.$$

If α and β are coordinates along **I** and **J**, respectively,

$$\begin{pmatrix}\varphi/2\pi\\ z\end{pmatrix} = \frac{1}{u}\begin{pmatrix}t & -\mu\\ 1 & \lambda\end{pmatrix}\begin{pmatrix}\alpha\\ \beta\end{pmatrix}$$

or equivalently

$$\begin{pmatrix}\alpha\\ \beta\end{pmatrix} = \begin{pmatrix}\lambda & \mu\\ -1 & t\end{pmatrix}\begin{pmatrix}\varphi/2\pi\\ z\end{pmatrix}.$$

By Fourier transformation,

$$\left(\frac{\varphi}{2\pi}, z\right) \Leftrightarrow (-n, l)$$
$$(\alpha, \beta) \Leftrightarrow (m, p)$$

with the transformations between indices given by the contragredients of those between coordinates, *i.e.*

$$\begin{pmatrix} n \\ l \end{pmatrix} = \begin{pmatrix} -\lambda & 1 \\ -\mu & t \end{pmatrix} \begin{pmatrix} m \\ p \end{pmatrix}$$

and

$$\begin{pmatrix} m \\ p \end{pmatrix} = \frac{1}{u} \begin{pmatrix} -t & 1 \\ \mu & \lambda \end{pmatrix} \begin{pmatrix} n \\ l \end{pmatrix}.$$

It follows that

$$l = tn + um,$$

or alternatively that

$$\mu n = up - \lambda l,$$

which are two equivalent expressions of the *selection rules* describing the decimation of the transform. These rules imply that only certain orders n contribute to a given layer l.

The 2D Fourier analysis may now be performed by analysing a *single* subunit referred to coordinates α and β to obtain

$$h_{m,p}(r) = \int_0^1 \int_0^1 \rho(r, \alpha, \beta) \exp[2\pi i(m\alpha + p\beta)] \, \mathrm{d}\alpha \, \mathrm{d}\beta$$

and then reindexing to get only the allowed g_{nl}'s by

$$g_{nl}(r) = u h_{-\lambda m + p, \mu m + tp}(r).$$

This is u times faster than analysing u subunits with respect to the (φ, z) coordinates.

1.3.4.5.2. Application to probability theory and direct methods

The Fourier transformation plays a central role in the branch of probability theory concerned with the limiting behaviour of sums of large numbers of independent and identically distributed random variables or random vectors. This privileged role is a consequence of the convolution theorem and of the 'moment-generating' properties which follow from the exchange between differentiation and multiplication by monomials. When the limit theorems are applied to the calculation of joint probability distributions of structure factors, which are themselves closely related to the Fourier transformation, a remarkable phenomenon occurs, which leads to the saddlepoint approximation and to the maximum-entropy method.

1.3.4.5.2.1. Analytical methods of probability theory

The material in this section is not intended as an introduction to probability theory [for which the reader is referred to Cramér (1946), Petrov (1975) or Bhattacharya & Rao (1976)], but only as an illustration of the role played by the Fourier transformation in certain specific areas which are used in formulating and implementing direct methods of phase determination.

(*a*) *Convolution of probability densities*

The addition of independent random variables or vectors leads to the convolution of their probability distributions: if $\mathbf{X}_1$ and $\mathbf{X}_2$ are two n-dimensional random vectors independently distributed with probability densities P_1 and P_2, respectively, then their sum $\mathbf{X} = \mathbf{X}_1 + \mathbf{X}_2$ has probability density $\mathscr{P}$ given by

$$\begin{aligned} \mathscr{P}(\mathbf{X}) &= \int_{\mathbf{R}^n} P_1(\mathbf{X}_1) P_2(\mathbf{X} - \mathbf{X}_1) \, \mathrm{d}^n\mathbf{X}_1 \\ &= \int_{\mathbf{R}^n} P_1(\mathbf{X} - \mathbf{X}_2) P_2(\mathbf{X}_2) \, \mathrm{d}^n\mathbf{X}_2 \end{aligned}$$

i.e.

$$\mathscr{P} = P_1 * P_2.$$

This result can be extended to the case where P_1 and P_2 are singular measures (distributions of order zero, Section 1.3.2.3.4) and do not have a density with respect to the Lebesgue measure in $\mathbb{R}^n$.

(*b*) *Characteristic functions*

This convolution can be turned into a simple multiplication by considering the Fourier transforms (called the *characteristic functions*) of P_1, P_2 and $\mathscr{P}$, defined with a slightly different normalization in that there is no factor of 2π in the exponent (see Section 1.3.2.4.5), *e.g.*

$$C(\mathbf{t}) = \int_{\mathbf{R}^n} P(\mathbf{X}) \exp(i\mathbf{t} \cdot \mathbf{X}) \, \mathrm{d}^n\mathbf{X}.$$

Then by the convolution theorem

$$\mathscr{C}(\mathbf{t}) = C_1(\mathbf{t}) \times C_2(\mathbf{t}),$$

so that $\mathscr{P}(\mathbf{X})$ may be evaluated by Fourier inversion of its characteristic function as

$$\mathscr{P}(\mathbf{X}) = \frac{1}{(2\pi)^n} \int_{\mathbb{R}^n} C_1(\mathbf{t}) C_2(\mathbf{t}) \exp(-i\mathbf{t} \cdot \mathbf{X}) \, \mathrm{d}^n\mathbf{t}$$

(see Section 1.3.2.4.5 for the normalization factors).

It follows from the differentiation theorem that the partial derivatives of the characteristic function $C(\mathbf{t})$ at $\mathbf{t} = \mathbf{0}$ are related to the moments of a distribution $\boldsymbol{P}$ by the identities

$$\begin{aligned} \mu_{r_1 r_2 \ldots r_n} &\equiv \int_D P(\mathbf{X}) X_1^{r_1} X_2^{r_2} \ldots X_n^{r_n} \, \mathrm{d}^n\mathbf{X} \\ &= i^{-(r_1 + \ldots + r_n)} \frac{\partial^{r_1 + \ldots + r_n} C}{\partial t_1^{r_1} \ldots \partial t_n^{r_n}} \bigg|_{\mathbf{t}=\mathbf{0}} \end{aligned}$$

for any n-tuple of non-negative integers $(r_1, r_2, \ldots, r_n)$.

(*c*) *Moment-generating functions*

The above relation can be freed from powers of i by defining (at least formally) the *moment-generating function*:

$$M(\mathbf{t}) = \int_{\mathbb{R}^n} P(\mathbf{X}) \exp(\mathbf{t} \cdot \mathbf{X}) \, \mathrm{d}^n\mathbf{X}$$

which is related to $C(\mathbf{t})$ by $C(\mathbf{t}) = \boldsymbol{M}(i\mathbf{t})$ so that the inversion formula reads

$$\mathscr{P}(\mathbf{X}) = \frac{1}{(2\pi)^n} \int_{\mathbb{R}^n} M_1(i\mathbf{t}) M_2(i\mathbf{t}) \exp(-i\mathbf{t}\cdot\mathbf{X})\ \mathrm{d}^n\mathbf{t}.$$

The moment-generating function is well defined, in particular, for any probability distribution with compact support, in which case it may be continued analytically from a function over $\mathbb{R}^n$ into an entire function of *n complex* variables by virtue of the Paley–Wiener theorem (Section 1.3.2.4.2.10). Its moment-generating properties are summed up in the following relations:

$$\mu_{r_1 r_2 \ldots r_n} = \left. \frac{\partial^{r_1+\ldots+r_n} M}{\partial t_1^{r_1} \ldots \partial t_n^{r_n}} \right|_{\mathbf{t}=\mathbf{0}}.$$

(*d*) *Cumulant-generating functions*

The multiplication of moment-generating functions may be further simplified into the addition of their logarithms:

$$\log \mathscr{M} = \log M_1 + \log M_2,$$

or equivalently of the coefficients of their Taylor series at $\mathbf{t} = \mathbf{0}$, *viz*:

$$\kappa_{r_1 r_2 \ldots r_n} = \left. \frac{\partial^{r_1+\ldots+r_n} (\log M)}{\partial t_1^{r_1} \ldots \partial t_n^{r_n}} \right|_{\mathbf{t}=\mathbf{0}}.$$

These coefficients are called *cumulants*, since they add when the independent random vectors to which they belong are added, and $\log M$ is called the *cumulant-generating function.* The inversion formula for $\mathscr{P}$ then reads

$$\mathscr{P}(\mathbf{X}) = \frac{1}{(2\pi)^n} \int_{\mathbb{R}^n} \exp[\log M_1(i\mathbf{t}) + \log M_2(i\mathbf{t}) - i\mathbf{t}\cdot\mathbf{X}]\ \mathrm{d}^n\mathbf{t}.$$

(*e*) *Asymptotic expansions and limit theorems*

Consider an n-dimensional random vector $\mathbf{X}$ of the form

$$\mathbf{X} = \mathbf{X}_1 + \mathbf{X}_2 + \ldots + \mathbf{X}_N,$$

where the N summands are independent n-dimensional random vectors identically distributed with probability density P. Then the distribution $\mathscr{P}$ of $\mathbf{X}$ may be written in closed form as a Fourier transform:

$$\begin{aligned}\mathscr{P}(\mathbf{X}) &= \frac{1}{(2\pi)^n} \int_{\mathbb{R}^n} M^N(i\mathbf{t}) \exp(-i\mathbf{t}\cdot\mathbf{X})\ \mathrm{d}^n\mathbf{t} \\ &= \frac{1}{(2\pi)^n} \int_{\mathbb{R}^n} \exp[N \log M(i\mathbf{t}) - i\mathbf{t}\cdot\mathbf{X}]\ \mathrm{d}^n\mathbf{t},\end{aligned}$$

where

$$M(\mathbf{t}) = \int_{\mathbb{R}^n} P(\mathbf{Y}) \exp(\mathbf{t}\cdot\mathbf{Y})\ \mathrm{d}^n\mathbf{Y}$$

is the moment-generating function common to all the summands.

This an exact expression for $\mathscr{P}$, which may be exploited analytically or numerically in certain favourable cases. Supposing for instance that P has compact support, then its characteristic function $M(i\mathbf{t})$ can be sampled finely enough to accommodate the bandwidth of the support of $\mathscr{P} = P^{*N}$ (this sampling rate clearly depends on n) so that the above expression for $\mathscr{P}$ can be used for its numerical evaluation as the *discrete* Fourier transform of $M^N(i\mathbf{t})$. This exact method is practical only for small values of the dimension n.

In all other cases some form of approximation must be used in the Fourier inversion of $M^N(i\mathbf{t})$. For this purpose it is customary (Cramér, 1946) to expand the cumulant-generating function around $\mathbf{t} = \mathbf{0}$ with respect to the carrying variables $\mathbf{t}$:

$$\log[M^N(i\mathbf{t})] = \sum_{\mathbf{r}\in\mathbb{N}^n} \frac{N\kappa_{\mathbf{r}}}{\mathbf{r}!} (i\mathbf{t})^{\mathbf{r}},$$

where $\mathbf{r} = (r_1, r_2, \ldots, r_n)$ is a multi-index (Section 1.3.2.2.3). The first-order terms may be eliminated by recentring $\mathscr{P}$ around its vector of first-order cumulants

$$\langle \mathbf{X} \rangle = \sum_{j=1}^{N} \langle \mathbf{X}_j \rangle,$$

where $\langle\cdot\rangle$ denotes the mathematical expectation of a random vector. The second-order terms may be grouped separately from the terms of third or higher order to give

$$\begin{aligned}M^N(i\mathbf{t}) = \exp(-\tfrac{1}{2} N \mathbf{t}^U \mathbf{Q} \mathbf{t}) \\ \times \exp\left\{ \sum_{|\mathbf{r}|\geq 3} \frac{N\kappa_{\mathbf{r}}}{\mathbf{r}!} (i\mathbf{t})^{\mathbf{r}} \right\},\end{aligned}$$

where $\mathbf{Q} = \nabla\nabla^T (\log M)$ is the covariance matrix of the multivariate distribution P. Expanding the exponential gives rise to a series of terms of the form

$$\exp(-\tfrac{1}{2} N \mathbf{t}^T \mathbf{Q} \mathbf{t}) \times \text{monomial in } t_1, t_2, \ldots, t_n,$$

each of which may now be subjected to a Fourier transformation to yield a Hermite function of $\mathbf{t}$ (Section 1.3.2.4.4.2) with coefficients involving the cumulants κ of P. Taking the transformed terms in natural order gives an asymptotic expansion of P for large N called the *Gram–Charlier series* of $\mathscr{P}$, while grouping the terms according to increasing powers of $1/\sqrt{N}$ gives another asymptotic expansion called the *Edgeworth series* of $\mathscr{P}$. Both expansions comprise a leading Gaussian term which embodies the *central-limit theorem*:

$$\mathscr{P}(\mathbf{E}) = \frac{1}{\sqrt{\det(2\pi\mathbf{Q})}} \exp(-\tfrac{1}{2}\mathbf{E}^T \mathbf{Q}^{-1} \mathbf{E}), \quad \text{where } \mathbf{E} = \frac{\mathbf{X} - \langle \mathbf{X} \rangle}{\sqrt{N}}.$$

(*f*) *The saddlepoint approximation*

A limitation of the Edgeworth series is that it gives an accurate estimate of $\mathscr{P}(\mathbf{X})$ only in the vicinity of $\mathbf{X} = \langle \mathbf{X} \rangle$, *i.e.* for small values of $\mathbf{E}$. These convergence difficulties are easily understood: one is substituting a *local* approximation to $\log M$ (*viz* a Taylor-series expansion valid near $\mathbf{t} = \mathbf{0}$) into an integral, whereas integration is a *global* process which consults values of $\log M$ far from $\mathbf{t} = \mathbf{0}$.

It is possible, however, to let the point $\mathbf{t}$ where $\log M$ is expanded as a Taylor series depend on the particular value $\mathbf{X}^*$ of $\mathbf{X}$ for which an accurate evaluation of $\mathscr{P}(\mathbf{X})$ is desired. This is the essence of the *saddlepoint method* (Fowler, 1936; Khinchin 1949;

Daniels, 1954; de Bruijn, 1970; Bleistein & Handelsman, 1986), which uses an analytical continuation of $M(\mathbf{t})$ from a function over $\mathbb{R}^n$ to a function over $\mathbb{C}^n$ (see Section 1.3.2.4.2.10). Putting then $\mathbf{t} = \mathbf{s} - i\tau$, the $\mathbb{C}^n$ version of Cauchy's theorem (Hörmander, 1973) gives rise to the identity

$$\mathscr{P}(\mathbf{X}^*) = \frac{\exp(-\boldsymbol{\tau}\cdot\mathbf{X}^*)}{(2\pi)^n} \times \int_{\mathbb{R}^n} \exp\left\{N\left[\log M(\boldsymbol{\tau}+i\mathbf{s}) - i\mathbf{s}\cdot\frac{\mathbf{X}^*}{N}\right]\right\} \mathrm{d}^n\mathbf{s}$$

for *any* $\boldsymbol{\tau}\in\mathbb{R}^n$. By a convexity argument involving the positive-definiteness of covariance matrix $\mathbf{Q}$, there is a unique value of $\boldsymbol{\tau}$ such that

$$\nabla(\log M)|_{\mathbf{t}=\mathbf{0}-i\boldsymbol{\tau}} = \frac{\mathbf{X}^*}{N}.$$

At the *saddlepoint* $\mathbf{t}^* = \mathbf{0} - i\boldsymbol{\tau}$, the modulus of the integrand above is a maximum and its phase is stationary with respect to the integration variable $\mathbf{s}$: as N tends to infinity, all contributions to the integral cancel because of rapid oscillation, except those coming from the immediate vicinity of $\mathbf{t}^*$ where there is no oscillation. A Taylor expansion of $\log M^N$ to second order with respect to $\mathbf{s}$ at $\mathbf{t}^*$ then gives

$$\log M^N(\boldsymbol{\tau}+i\mathbf{s}) \approx \log M^N(\boldsymbol{\tau}) + i\mathbf{s}\cdot\mathbf{X}^* - \frac{N}{2}[\mathbf{s}^T\mathbf{Q}\mathbf{s}]$$

and hence

$$\mathscr{P}(\mathbf{X}^*) \approx \exp[\log M^N(\boldsymbol{\tau}) - \boldsymbol{\tau}\cdot\mathbf{X}^*]\frac{1}{(2\pi)^n}\int_{\mathbb{R}^n}\exp(-\tfrac{1}{2}\mathbf{s}^T\mathscr{Q}\mathbf{s})\ \mathrm{d}^n\mathbf{s}.$$

The last integral is elementary and gives the 'saddlepoint approximation':

$$\mathscr{P}^{\mathrm{SP}}(\mathbf{X}^*) = \frac{\exp(\mathsf{S})}{\sqrt{\det(2\pi\mathscr{Q})}},$$

where

$$\mathsf{S} = \log M^N(\boldsymbol{\tau}) - \boldsymbol{\tau}\cdot\mathbf{X}^*$$

and where

$$\mathscr{Q} = \nabla\nabla^T(\log M^N) = N\mathbf{Q}.$$

This approximation scheme amounts to using the 'conjugate distribution' (Khinchin, 1949)

$$P_{\boldsymbol{\tau}}(\mathbf{X}_j) = P(\mathbf{X}_j)\frac{\exp(\boldsymbol{\tau}\cdot\mathbf{X}_j)}{M(\boldsymbol{\tau})}$$

instead of the original distribution $\boldsymbol{P}(\mathbf{X}_j) = \boldsymbol{P}_{\mathbf{0}}(\mathbf{X}_j)$ for the common distribution of all $\boldsymbol{N}$ random vectors $\mathbf{X}_j$. The exponential modulation results from the analytic continuation of the characteristic (or moment-generating) function into $\mathbb{C}^n$, as in Section 1.3.2.4.2.10. The saddlepoint approximation $\mathscr{P}^{\mathrm{SP}}$ is only the leading term of an asymptotic expansion (called the *saddlepoint expansion*) for $\mathscr{P}$, which is actually the Edgeworth expansion associated with $P_{\boldsymbol{\tau}}^{*N}$.

1.3.4.5.2.2. The statistical theory of phase determination

The methods of probability theory just surveyed were applied to various problems formally similar to the crystallographic phase problem [*e.g.* the 'problem of the random walk' of Pearson (1905)] by Rayleigh (1880, 1899, 1905, 1918, 1919) and Kluyver (1906). They became the basis of the statistical theory of communication with the classic papers of Rice (1944, 1945).

The Gram–Charlier and Edgeworth series were introduced into crystallography by Bertaut (1955*a*,*b*,*c*, 1956*a*) and by Klug (1958), respectively, who showed them to constitute the mathematical basis of numerous formulae derived by Hauptman & Karle (1953). The saddlepoint approximation was introduced by Bricogne (1984) and was shown to be related to variational methods involving the maximization of certain entropy criteria. This connection exhibits most of the properties of the Fourier transform at play simultaneously, and will now be described as a final illustration.

(*a*) *Definitions and conventions*

Let H be a set of unique non-origin reflections $\mathbf{h}$ for a crystal with lattice Λ and space group G. Let H contain n_{a} acentric and n_{c} centric reflections. Structure-factor values attached to all reflections in H will comprise $n = 2n_{\mathrm{a}} + n_{\mathrm{c}}$ real numbers. For $\mathbf{h}$ acentric, $\alpha_{\mathbf{h}}$ and $\beta_{\mathbf{h}}$ will be the real and imaginary parts of the complex structure factor; for $\mathbf{h}$ centric, $\gamma_{\mathbf{h}}$ will be the real coordinate of the (possibly complex) structure factor measured along a real axis rotated by one of the two angles $\theta_{\mathbf{h}}$, π apart, to which the phase is restricted modulo 2π (Section 1.3.4.2.2.5). These n real coordinates will be arranged as a column vector containing the acentric then the centric data, *i.e.* in the order

$$\alpha_1, \beta_1, \alpha_2, \beta_2, \ldots, \alpha_{n_{\mathrm{a}}}, \beta_{n_{\mathrm{a}}}, \gamma_1, \gamma_2, \ldots, \gamma_{n_{\mathrm{c}}}.$$

(*b*) *Vectors of trigonometric structure-factor expressions*

Let $\boldsymbol{\xi}(\mathbf{x})$ denote the vector of trigonometric structure-factor expressions associated with $\mathbf{x}\in D$, where D denotes the asymmetric unit. These are defined as follows:

$$\begin{aligned}\alpha_{\mathbf{h}}(\mathbf{x}) + i\beta_{\mathbf{h}}(\mathbf{x}) &= \Xi(\mathbf{h},\mathbf{x}) \quad \text{for } \mathbf{h} \text{ acentric}\\ \gamma_{\mathbf{h}}(\mathbf{x}) &= \exp(-i\theta_{\mathbf{h}})\Xi(\mathbf{h},\mathbf{x}) \quad \text{for } \mathbf{h} \text{ centric,}\end{aligned}$$

where

$$\Xi(\mathbf{h},\mathbf{x}) = \frac{1}{|G_{\mathbf{x}}|}\sum_{g\in G}\exp\{2\pi i\mathbf{h}\cdot[S_g(\mathbf{x})]\}.$$

According to the convention above, the coordinates of $\boldsymbol{\xi}(\mathbf{x})$ in $\mathbb{R}^n$ will be arranged in a column vector as follows:

$$\begin{aligned}\xi_{2r-1}(\mathbf{x}) &= \alpha_{\mathbf{h}_r}(\mathbf{x}) \quad \text{for } r = 1,\ldots,n_{\mathrm{a}},\\ \xi_{2r}(\mathbf{x}) &= \beta_{\mathbf{h}_r}(\mathbf{x}) \quad \text{for } r = 1,\ldots,n_{\mathrm{a}},\\ \xi_{n_{\mathrm{a}}+r}(\mathbf{x}) &= \gamma_{\mathbf{h}_r}(\mathbf{x}) \quad \text{for } r = n_{\mathrm{a}}+1,\ldots,n_{\mathrm{a}}+n_{\mathrm{c}}.\end{aligned}$$

(*c*) *Distributions of random atoms and moment-generating functions*

Let position $\mathbf{x}$ in D now become a random vector with probability density $m(\mathbf{x})$. Then $\boldsymbol{\xi}(\mathbf{x})$ becomes itself a random vector in $\mathbb{R}^n$, whose distribution $p(\boldsymbol{\xi})$ is the image of distribution $m(\mathbf{x})$

through the mapping $\mathbf{x} \rightarrow \boldsymbol{\xi}(\mathbf{x})$ just defined. The locus of $\boldsymbol{\xi}(\mathbf{x})$ in $\mathbb{R}^n$ is a compact algebraic manifold $\mathscr{V}$ (the multidimensional analogue of a Lissajous curve), so that p is a singular measure (a distribution of order 0, Section 1.3.2.3.4, concentrated on that manifold) with compact support. The average with respect to p of any function Ω over $\mathbb{R}^n$ which is infinitely differentiable in a neighbourhood of $\mathscr{V}$ may be calculated as an average with respect to m over D by the 'induction formula':

$$\langle p, \Omega \rangle = \int_D m(\mathbf{x}) \Omega[\boldsymbol{\xi}(\mathbf{x})] \, \mathrm{d}^3\mathbf{x}.$$

In particular, one can calculate the moment-generating function M for distribution p as

$$M(\mathbf{t}) \equiv \langle p_\xi, \exp(\mathbf{t} \cdot \boldsymbol{\xi}) \rangle = \int_D m(\mathbf{x}) \exp[\mathbf{t} \cdot \boldsymbol{\xi}(\mathbf{x})] \, \mathrm{d}^3\mathbf{x}$$

and hence calculate the moments μ (respectively cumulants κ) of p by differentiation of M (respectively $\log M$) at $\mathbf{t} = \mathbf{0}$:

$$\begin{aligned} \mu_{r_1 r_2 \ldots r_n} &\equiv \int_D m(\mathbf{x}) \xi_1^{r_1}(\mathbf{x}) \xi_2^{r_2}(\mathbf{x}) \ldots \xi_n^{r_n}(\mathbf{x}) \, \mathrm{d}^3\mathbf{x} \\ &= \frac{\partial^{r_1+\ldots+r_n}(M)}{\partial t_1^{r_1} \ldots \partial t_n^{r_n}} \\ \kappa_{r_1 r_2 \ldots r_n} &= \frac{\partial^{r_1+\ldots+r_n}(\log M)}{\partial t_1^{r_1} \ldots \partial t_n^{r_n}}. \end{aligned}$$

The structure-factor algebra for group G (Section 1.3.4.2.2.9) then allows one to express products of $\boldsymbol{\xi}$'s as linear combinations of other $\boldsymbol{\xi}$'s, and hence to express all moments and cumulants of distribution $p(\boldsymbol{\xi})$ as linear combinations of real and imaginary parts of Fourier coefficients of the prior distribution of atoms $m(\mathbf{x})$. This plays a key role in the use of nonuniform distributions of atoms.

(*d*) *The joint probability distribution of structure factors*

In the random-atom model of an equal-atom structure, N atoms are placed randomly, independently of each other, in the asymmetric unit D of the crystal with probability density $m(\mathbf{x})$. For point atoms of unit weight, the vector $\mathbf{F}$ of structure-factor values for reflections $\mathbf{h} \in H$ may be written

$$\mathbf{F} = \sum_{I=1}^{N} \boldsymbol{\xi}^{[I]},$$

where the N copies $\boldsymbol{\xi}^{[I]}$ of random vector $\boldsymbol{\xi}$ are independent and have the same distribution $p(\boldsymbol{\xi})$.

The joint probability distribution $\mathscr{P}(\mathbf{F})$ is then [Section 1.3.4.5.2.1(*e*)]

$$\mathscr{P}(\mathbf{X}) = \frac{1}{(2\pi)^n} \int_{\mathbb{R}^n} \exp[N \log M(i\mathbf{t}) - i\mathbf{t} \cdot \mathbf{X}] \, \mathrm{d}^n\mathbf{t}.$$

For low dimensionality n it is possible to carry out the Fourier transformation numerically after discretization, provided $M(i\mathbf{t})$ is sampled sufficiently finely that no aliasing results from taking its Nth power (Barakat, 1974). This exact approach can also accommodate heterogeneity, and has been used first in the field of intensity statistics (Shmueli *et al.*, 1984, 1985; Shmueli & Weiss, 1987, 1988), then in the study of the Σ_1 and Σ_2 relations in triclinic space groups (Shmueli & Weiss, 1985, 1986). Some of these applications are described in Chapter 2.1 of this volume. This method could be extended to the construction of any joint probability distribution (j.p.d.) in any space group by using the generic expression for the moment-generating function (m.g.f.) derived by Bricogne (1984). It is, however, limited to small values of n by the necessity to carry out n-dimensional FFTs on large arrays of sample values.

The asymptotic expansions of Gram–Charlier and Edgeworth have good convergence properties only if $F_{\mathbf{h}}$ lies in the vicinity of $\langle F_{\mathbf{h}} \rangle = N\bar{\mathscr{F}}[m](\mathbf{h})$ for all $\mathbf{h} \in H$. Previous work on the j.p.d. of structure factors has used for $m(\mathbf{x})$ a uniform distribution, so that $\langle \mathbf{F} \rangle = \mathbf{0}$; as a result, the corresponding expansions are accurate only if all moduli $|F_{\mathbf{h}}|$ are small, in which case the j.p.d. contains little phase information.

The saddlepoint method [Section 1.3.4.5.2.1(*f*)] constitutes the method of choice for evaluating the joint probability $\mathscr{P}(\mathbf{F}^*)$ of structure factors when some of the moduli in $\mathbf{F}^*$ are large. As shown previously, this approximation amounts to using the 'conjugate distribution'

$$p_\tau(\xi) = p(\xi) \frac{\exp(\boldsymbol{\tau} \cdot \boldsymbol{\xi})}{M(\boldsymbol{\tau})}$$

instead of the original distribution $p(\boldsymbol{\xi}) = p_{\mathbf{0}}(\boldsymbol{\xi})$ for the distribution of random vector $\boldsymbol{\xi}$. This conjugate distribution $p_{\boldsymbol{\tau}}$ is induced from the modified distribution of atoms

$$q_{\boldsymbol{\tau}}(\mathbf{x}) = m(\mathbf{x}) \frac{\exp[\boldsymbol{\tau} \cdot \boldsymbol{\xi}(\mathbf{x})]}{M(\boldsymbol{\tau})}, \tag{SP1}$$

where, by the induction formula, $M(\boldsymbol{\tau})$ may be written as

$$M(\boldsymbol{\tau}) = \int_D m(\mathbf{x}) \exp[\boldsymbol{\tau} \cdot \boldsymbol{\xi}(\mathbf{x})] \, \mathrm{d}^3\mathbf{x} \tag{SP2}$$

and where $\boldsymbol{\tau}$ is the unique solution of the saddlepoint equation:

$$\nabla_{\boldsymbol{\tau}}(\log M^N) = \mathbf{F}^*. \tag{SP3}$$

The desired approximation is then

$$\mathscr{P}^{\mathrm{SP}}(\mathbf{F}^*) = \frac{\exp(\mathsf{S})}{\sqrt{\det(2\pi \mathscr{Q})}},$$

where

$$\mathsf{S} = \log M^N(\boldsymbol{\tau}) - \boldsymbol{\tau} \cdot \mathbf{F}^*$$

and where

$$\mathscr{Q} = \nabla\nabla^T(\log M^N) = \mathbf{NQ}.$$

Finally, the elements of the Hessian matrix $\mathbf{Q} = \nabla\nabla^T(\log M)$ are just the trigonometric second-order cumulants of distribution p, and hence can be calculated *via* structure-factor algebra from the Fourier coefficients of $q_{\boldsymbol{\tau}}(\mathbf{x})$. All the quantities involved in the expression for $\mathscr{P}^{\mathrm{SP}}(\mathbf{F}^*)$ are therefore effectively computable from the initial data $m(\mathbf{x})$ and $\mathbf{F}^*$.

(*e*) *Maximum-entropy distributions of atoms*

One of the main results in Bricogne (1984) is that the modified distribution $q_{\boldsymbol{\tau}}(\mathbf{x})$ in (SP1) is the unique distribution which has maximum entropy $\mathscr{S}_m(q)$ relative to $m(\mathbf{x})$, where

$$\mathscr{S}_m(q) = -\int_D q(\mathbf{x}) \log\left[\frac{q(\mathbf{x})}{m(\mathbf{x})}\right] \mathrm{d}^3\mathbf{x},$$

under the constraint that $\mathbf{F}^*$ be the centroid vector of the corresponding conjugate distribution $\mathscr{P}_{\boldsymbol{\tau}}(\mathbf{F})$. The traditional notation of maximum-entropy (ME) theory (Jaynes, 1957, 1968, 1983) is in this case (Bricogne, 1984)

$$q^{\mathrm{ME}}(\mathbf{x}) = m(\mathbf{x}) \frac{\exp[\boldsymbol{\lambda} \cdot \boldsymbol{\xi}(\mathbf{x})]}{Z(\boldsymbol{\lambda})} \qquad \text{(ME1)}$$

$$Z(\boldsymbol{\lambda}) = \int_D m(\mathbf{x}) \exp[\boldsymbol{\lambda} \cdot \boldsymbol{\xi}(\mathbf{x})] \, \mathrm{d}^3\mathbf{x} \qquad \text{(ME2)}$$

$$\nabla_\lambda (\log Z^N) = \mathbf{F}^* \qquad \text{(ME3)}$$

so that Z is identical to the m.g.f. M, and the coordinates $\boldsymbol{\tau}$ of the saddlepoint are the Lagrange multipliers $\boldsymbol{\lambda}$ for the constraints $\mathbf{F}^*$.

Jaynes's ME theory also gives an estimate for $\mathscr{P}(\mathbf{F}^*)$:

$$\mathscr{P}^{\mathrm{ME}}(\mathbf{F}^*) \approx \exp(\mathscr{S}),$$

where

$$\mathscr{S} = \log Z^N - \boldsymbol{\lambda} \cdot \mathbf{F}^* = N \mathscr{S}_m(\mathbf{q}^{\mathrm{ME}})$$

is the total entropy and is the counterpart to S under the equivalence just established.

$\mathscr{P}^{\mathrm{ME}}$ is identical to $\mathscr{P}^{\mathrm{SP}}$, but lacks the denominator. The latter, which is the normalization factor of a multivariate Gaussian with covariance matrix $\mathscr{Q}$, may easily be seen to arise through Szegö's theorem (Sections 1.3.2.6.9.4, 1.3.4.2.1.10) from the extra logarithmic term in Stirling's formula

$$\log(q!) \approx q \log q - q + \tfrac{1}{2} \log(2\pi q)$$

(see, for instance, Reif, 1965) beyond the first two terms which serve to define entropy, since

$$\frac{1}{n} \log \det(2\pi \mathbf{Q}) \approx \int_{\mathbb{R}^3/\mathbb{Z}^3} \log 2\pi q^{\mathrm{ME}}(\mathbf{x}) \, \mathrm{d}^3\mathbf{x}.$$

The relative effect of this extra normalization factor depends on the ratio

$$\frac{n}{N} = \frac{\text{dimension of } \mathbf{F} \text{ over } \mathbb{R}}{\text{number of atoms}}.$$

The above relation between entropy maximization and the saddlepoint approximation is the basis of a Bayesian statistical approach to the phase problem (Bricogne, 1988) where the assumptions under which joint distributions of structure factors are sought incorporate many new ingredients (such as molecular boundaries, isomorphous substitutions, known fragments, noncrystallographic symmetries, multiple crystal forms) besides trial phase choices for basis reflections. The ME criterion intervenes in the construction of $q^{\mathrm{ME}}(\mathbf{x})$ under these assumptions, and the distribution $q^{\mathrm{ME}}(\mathbf{x})$ is a very useful computational intermediate in obtaining the approximate joint probability $\mathscr{P}^{\mathrm{SP}}(\mathbf{F}^*)$ and the associated conditional distributions and likelihood functions.

(*f*) *Role of the Fourier transformation*

The formal developments presented above make use of the following properties of the Fourier transformation:

(i) the convolution theorem, which turns the convolution of probability distributions into the multiplication of their characteristic functions;

(ii) the differentiation property, which confers moment-generating properties to characteristic functions;

(iii) the reciprocity theorem, which allows the retrieval of a probability distribution from its characteristic or moment-generating function;

(iv) the Paley–Wiener theorem, which allows the analytic continuation of characteristic functions associated to probability distributions with compact support, and thus gives rise to conjugate families of distributions;

(v) Bertaut's structure-factor algebra (a discrete symmetrized version of the convolution theorem), which allows the calculation of all necessary moments and cumulants when the dimension n is small;

(vi) Szegö's theorem, which provides an asymptotic approximation of the normalization factor when n is large.

This multi-faceted application seems an appropriate point at which to end this description of the Fourier transformation and of its use in crystallography.

Many aspects of the theory of discrete Fourier transform algorithms and of its extension to incorporate crystallographic symmetry have been the focus of a long-standing collaborative effort between Professor Louis Auslander, Professor Richard Tolimieri, their co-workers and the writer. I am most grateful to them for many years of mathematical stimulation and enjoyment, for introducing me to the 'big picture' of the discrete Fourier transform which they have elaborated over the past decade, and for letting me describe here some of their unpublished work. In particular, the crystallographic extensions of the Rader/Winograd algorithms presented in Section 1.3.4.3.4.3 were obtained by Richard Tolimieri, in a collaboration partially supported by NIH grant GM 32362 (to the writer). I am indebted to the Editor for many useful and constructive suggestions of possible improvements to the text, only a few of which I have been able to implement. I hope to incorporate many more of them in the future. I also wish to thank Dr D. Sayre for many useful comments on an early draft of the manuscript. This contribution was written during the tenure of a Visiting Fellowship at Trinity College, Cambridge, with partial financial support from Trinity College and the MRC Laboratory of Molecular Biology. I am most grateful to both institutions for providing ideal working conditions.

1.4. Symmetry in reciprocal space

By U. Shmueli

With Appendix A1.4.2 by U. Shmueli, S. R. Hall and R. W. Grosse-Kunstleve

1.4.1. Introduction

Crystallographic symmetry, as reflected in functions on reciprocal space, can be considered from two complementary points of view.

(1) One can assume the existence of a certain permissible symmetry of the density function of crystalline (scattering) matter, a function which due to its three-dimensional periodicity can be expanded in a triple Fourier series (*e.g.* Bragg, 1966), and inquire about the effects of this symmetry on the Fourier coefficients – the structure factors. Since there exists a one-to-one correspondence between the triplets of summation indices in the Fourier expansion and vectors in the reciprocal lattice (Ewald, 1921), the above approach leads to consequences of the symmetry of the density function which are relevant to the representation of its Fourier image in reciprocal space. The symmetry properties of these Fourier coefficients, which are closely related to the crystallographic experiment, can then be readily established.

This traditional approach, the essentials of which are the basis of Sections 4.5–4.7 of Volume I (*IT* I, 1952), and which was further developed in the works of Buerger (1949, 1960), Waser (1955), Bertaut (1964) and Wells (1965), is one of the cornerstones of crystallographic practice and will be followed in the present chapter, as far as the basic principles are concerned.

(2) The alternative approach, proposed by Bienenstock & Ewald (1962), also presumes a periodic density function in crystal space and its Fourier expansion associated with the reciprocal. However, the argument starts from the Fourier coefficients, taken as a discrete set of complex functions, and linear transformations are sought which leave the magnitudes of these functions unchanged; the variables on which these transformations operate are h, k, l and φ – the Fourier summation indices (*i.e.*, components of a reciprocal-lattice vector) and the phase of the Fourier coefficient, respectively. These transformations, or the groups they constitute, are then interpreted in terms of the symmetry of the density function in direct space. This direct analysis of symmetry in reciprocal space will also be discussed.

We start the next section with a brief discussion of the point-group symmetries of associated direct and reciprocal lattices. The weighted reciprocal lattice is then briefly introduced and the relation between the values of the weight function at symmetry-related points of the weighted reciprocal lattice is discussed in terms of the Fourier expansion of a periodic function in crystal space. The remaining part of Section 1.4.2 is devoted to the formulation of the Fourier series and its coefficients (values of the weight function) in terms of space-group-specific symmetry factors. Section 1.4.3 then explains the basis for an automated generation of simplified geometrical structure-factor formulae, which are presented for all the two- and three-dimensional space groups in Appendix 1.4.3. This is a revised version of the structure-factor tables given in Sections 4.5–4.7 of Volume I (*IT* I, 1952). Appendix 1.4.4 contains a reciprocal-space representation of the 230 crystallographic space groups and some explanatory material related to these space-group tables is given in Section 1.4.4; the latter are interpreted in terms of the two viewpoints discussed above. The tabular material given in this chapter is compatible with the direct-space symmetry tables given in Volume A (*IT* A, 1983) with regard to the space-group settings and choices of the origin.

Most of the tabular material, the new symmetry-factor tables in Appendix 1.4.3 and the space-group tables in Appendix 1.4.4 have been generated by computer with the aid of a combination of numeric and symbolic programming techniques. The algorithm underlying this procedure is briefly summarized in Appendix 1.4.1. Appendix 1.4.2 deals with computer-adapted space-group symbols, including the set of symbols that were used in the preparation of the present tables.

Computer generation of symmetry information is not new. However, we can quote the Bilbao Crystallographic Server (*e.g.* Aroyo *et al.*, 2006) as a rich source of symmetry information which is readily accessible from the Internet.

1.4.2. Effects of symmetry on the Fourier image of the crystal

1.4.2.1. Point-group symmetry of the reciprocal lattice

Regarding the reciprocal lattice as a collection of points generated from a given direct lattice, it is fairly easy to see that each of the two associated lattices must have the same point-group symmetry. The set of all the rotations that bring the direct lattice into self-coincidence can be thought of as interchanging equivalent families of lattice planes in all the permissible manners. A family of lattice planes in the direct lattice is characterized by a common normal and a certain interplanar distance, and these two characteristics uniquely define the direction and magnitude, respectively, of a vector in the reciprocal lattice, as well as the lattice line associated with this vector and passing through the origin. It follows that any symmetry operation on the direct lattice must also bring the reciprocal lattice into self-coincidence, *i.e.* it must also be a symmetry operation on the reciprocal lattice. The roles of direct and reciprocal lattices in the above argument can of course be interchanged without affecting the conclusion.

The above elementary considerations recall that for any point group (not necessarily the full point group of a lattice), the operations which leave the lattice unchanged must also leave unchanged its associated reciprocal. This equivalence of point-group symmetries of the associated direct and reciprocal lattices is fundamental to crystallographic symmetry in reciprocal space, in both points of view mentioned in Section 1.4.1.

With regard to the effect of any given point-group operation on each of the two associated lattices, we recall that:

(i) If $\boldsymbol{P}$ is a point-group rotation operator acting on the direct lattice (*e.g.* by rotation through the angle α about a given axis), the effect of this rotation on the associated reciprocal lattice is that of applying the inverse rotation operator, $\boldsymbol{P}^{-1}$ (*i.e.* rotation through $-\alpha$ about a direction parallel to the direct axis); this is readily found from the requirement that the scalar product $\mathbf{h}^T\mathbf{r}_\mathrm{L}$, where $\mathbf{h}$ and $\mathbf{r}_\mathrm{L}$ are vectors in the reciprocal and direct lattices, respectively, remains invariant under the application of a point-group operation to the crystal.

(ii) If our matrix representation of the rotation operator is such that the point-group operation is applied to the direct-lattice (column) vector by *premultiplying* it with the matrix $\boldsymbol{P}$, the corresponding operation on the reciprocal lattice is applied by *postmultiplying* the (row) vector $\mathbf{h}^T$ with the point-group rotation matrix. We can thus write, *e.g.*, $\mathbf{h}^T\mathbf{r}_\mathrm{L} = (\mathbf{h}^T\boldsymbol{P}^{-1})(\boldsymbol{P}\mathbf{r}_\mathrm{L}) = [(\boldsymbol{P}^{-1})^T\mathbf{h}]^T(\boldsymbol{P}\mathbf{r}_\mathrm{L})$. Note, however, that the orthogonality relation-

Copyright © 2010 International Union of Crystallography

ship: $\boldsymbol{P}^{-1} = \boldsymbol{P}^T$ is not satisfied if $\boldsymbol{P}$ is referred to some oblique crystal systems, higher than the orthorhombic.

Detailed descriptions of the 32 crystallographic point groups are presented in the crystallographic and other literature; their complete tabulation is given in Part 10 of Volume A (*IT* A, 2005).

1.4.2.2. Relationship between structure factors at symmetry-related points of the reciprocal lattice

Of main interest in the context of the present chapter are symmetry relationships that concern the values of a function defined at the points of the reciprocal lattice. Such functions, of crystallographic interest, are Fourier-transform representations of direct-space functions that have the periodicity of the crystal, the structure factor as a Fourier transform of the electron-density function being a representative example (see *e.g.* Lipson & Taylor, 1958). The value of such a function, attached to a reciprocal-lattice point, is called the weight of this point and the set of all such weighted points is often termed the weighted reciprocal lattice. This section deals with a fundamental relationship between functions (weights) associated with reciprocal-lattice points, which are related by point-group symmetry, the weights here considered being the structure factors of Bragg reflections (*cf.* Chapter 1.2).

The electron density, an example of a three-dimensional periodic function with the periodicity of the crystal, can be represented by the Fourier series

$$\rho(\mathbf{r}) = \frac{1}{V}\sum_{\mathbf{h}} F(\mathbf{h}) \exp(-2\pi i \mathbf{h}^T \mathbf{r}), \tag{1.4.2.1}$$

where $\mathbf{h}$ is a reciprocal-lattice vector, V is the volume of the (direct) unit cell, $F(\mathbf{h})$ is the structure factor at the point $\mathbf{h}$ and $\mathbf{r}$ is a position vector of a point in direct space, at which the density is given. The summation in (1.4.2.1) extends over all the reciprocal lattice.

Let $\mathbf{r}' = \boldsymbol{P}\mathbf{r} + \mathbf{t}$ be a space-group operation on the crystal, where $\boldsymbol{P}$ and $\mathbf{t}$ are its rotation and translation parts, respectively, and $\boldsymbol{P}$ must therefore be a point-group operator. We then have, by definition, $\rho(\mathbf{r}) = \rho(\boldsymbol{P}\mathbf{r} + \mathbf{t})$ and the Fourier representation of the electron density, at the equivalent position $\boldsymbol{P}\mathbf{r} + \mathbf{t}$, is given by

$$\begin{aligned}\rho(\boldsymbol{P}\mathbf{r} + \mathbf{t}) &= \frac{1}{V}\sum_{\mathbf{h}} F(\mathbf{h}) \exp[-2\pi i \mathbf{h}^T(\boldsymbol{P}\mathbf{r} + \mathbf{t})] \\ &= \frac{1}{V}\sum_{\mathbf{h}} [F(\mathbf{h}) \exp(-2\pi i \mathbf{h}^T \mathbf{t})] \\ &\quad \times \exp[-2\pi i (\boldsymbol{P}^T\mathbf{h})^T \mathbf{r}],\end{aligned} \tag{1.4.2.2}$$

noting that $\mathbf{h}^T\boldsymbol{P} = (\boldsymbol{P}^T\mathbf{h})^T$. Since $\boldsymbol{P}$ is a point-group operator, the vectors $\boldsymbol{P}^T\mathbf{h}$ in (1.4.2.2) must range over all the reciprocal lattice and a comparison of the functional forms of the equivalent expansions (1.4.2.1) and (1.4.2.2) shows that the coefficients of the exponentials $\exp[-2\pi i(\boldsymbol{P}^T\mathbf{h})^T\mathbf{r}]$ in (1.4.2.2) must be the structure factors at the points $\boldsymbol{P}^T\mathbf{h}$ in the reciprocal lattice. Thus

$$F(\boldsymbol{P}^T\mathbf{h}) = F(\mathbf{h}) \exp(-2\pi i \mathbf{h}^T \mathbf{t}), \tag{1.4.2.3}$$

wherefrom it follows that the magnitudes of the structure factors at $\mathbf{h}$ and $\boldsymbol{P}^T\mathbf{h}$ are the same:

$$|F(\boldsymbol{P}^T\mathbf{h})| = |F(\mathbf{h})|, \tag{1.4.2.4}$$

and their phases are related by

$$\varphi(\boldsymbol{P}^T\mathbf{h}) = \varphi(\mathbf{h}) - 2\pi \mathbf{h}^T\mathbf{t}. \tag{1.4.2.5}$$

The relationship (1.4.2.3) between structure factors of symmetry-related reflections was first derived by Waser (1955), starting from a representation of the structure factor as a Fourier transform of the electron-density function.

It follows that an application of a point-group transformation to the (weighted) reciprocal lattice leaves the moduli of the structure factors unchanged. The distribution of diffracted intensities obeys, in fact, the same point-group symmetry as that of the crystal. If, however, anomalous dispersion is negligibly small, and the point group of the crystal is noncentrosymmetric, the apparent symmetry of the diffraction pattern will also contain a false centre of symmetry and, of course, all the additional elements generated by the inclusion of this centre. Under these circumstances, the diffraction pattern from a single crystal may belong to one of the eleven centrosymmetric point groups, known as Laue groups (*IT* I, 1952).

According to equation (1.4.2.5), the phases of the structure factors of symmetry-related reflections differ, in the general case, by a phase shift that depends on the translation part of the space-group operation involved. Only when the space group is symmorphic, *i.e.* it contains no translations other than those of the Bravais lattice, will the distribution of the phases obey the point-group symmetry of the crystal. These phase shifts are considered in detail in Section 1.4.4 where their tabulation is presented and the alternative interpretation (Bienenstock & Ewald, 1962) of symmetry in reciprocal space, mentioned in Section 1.4.1, is given.

Equation (1.4.2.3) can be usefully applied to a classification of all the general systematic absences or – as defined in the space-group tables in the main editions of *IT* (1935, 1952, 1983, 1987, 1992, 1995, 2002) – general conditions for possible reflections. These systematic absences are associated with special positions in the reciprocal lattice – special with respect to the point-group operations $\boldsymbol{P}$ appearing in the relevant relationships. If, in a given relationship, we have $\boldsymbol{P}^T\mathbf{h} = \mathbf{h}$, equation (1.4.2.3) reduces to

$$F(\mathbf{h}) = F(\mathbf{h}) \exp(-2\pi i \mathbf{h}^T \mathbf{t}). \tag{1.4.2.6}$$

Of course, $F(\mathbf{h})$ may then be nonzero only if $\cos(2\pi \mathbf{h}^T\mathbf{t})$ equals unity, or the scalar product $\mathbf{h}^T\mathbf{t}$ is an integer. This well known result leads to a ready determination of lattice absences, as well as those produced by screw-axis and glide-plane translations, and is routinely employed in crystallographic computing. An exhaustive classification of the general conditions for possible reflections is given in the space-group tables (*IT*, 1952, 1983). It should be noted that since the axes of rotation and planes of reflection in the reciprocal lattice are parallel to the corresponding elements in the direct lattice (Buerger, 1960), the component of $\mathbf{t}$ that depends on the location of the corresponding space-group symmetry element in direct space does not contribute to the scalar product $\mathbf{h}^T\mathbf{t}$ in (1.4.2.6), and it is only the intrinsic part of the translation $\mathbf{t}$ (*IT* A, 1983) that usually matters.

It may, however, be of interest to note that some screw axes in direct space cannot give rise to any systematic absences. For example, the general Wyckoff position No. (10) in the space group $Pa\bar{3}$ (No. 205) (*IT* A, 1983) has the coordinates $\bar{y}, \frac{1}{2}+z, \frac{1}{2}-x$, and corresponds to the space-group operation

$$(\boldsymbol{P}, \mathbf{t}) = (\boldsymbol{P}, \mathbf{t}_i + \mathbf{t}_l) = \left[\begin{pmatrix} 0 & \bar{1} & 0 \\ 0 & 0 & 1 \\ \bar{1} & 0 & 0 \end{pmatrix}, \begin{pmatrix} -\frac{1}{3} \\ \frac{1}{3} \\ \frac{1}{3} \end{pmatrix} + \begin{pmatrix} \frac{1}{3} \\ \frac{1}{6} \\ \frac{1}{6} \end{pmatrix}\right], \tag{1.4.2.7}$$

where $\mathbf{t}_i$ and $\mathbf{t}_l$ are the intrinsic and location-dependent components of the translation part $\mathbf{t}$, and are parallel and perpendicular, respectively, to the threefold axis of rotation represented by the matrix $\boldsymbol{P}$ in (1.4.2.7) (*IT* A, 1983; Shmueli, 1984). This is clearly a threefold screw axis, parallel to $[\bar{1}\bar{1}1]$. The reciprocal-lattice vectors which remain unchanged, when postmultiplied by $\boldsymbol{P}$ (or premultiplied by its transpose), have the form: $\mathbf{h}^T = (h\bar{h}\bar{h})$; this is the special position for the present example. We see that (i) $\mathbf{h}^T\mathbf{t}_l = 0$, as expected, and (ii) $\mathbf{h}^T\mathbf{t}_i = -h$. Since the scalar product $\mathbf{h}^T\mathbf{t}$ is an integer, there are no values of index h for which the structure factor $F(h\bar{h}\bar{h})$ must be absent.

Other approaches to systematically absent reflections include a direct inspection of the structure-factor equation (Lipson & Cochran, 1966), which is of considerable didactical value, and the utilization of transformation properties of direct and reciprocal base vectors and lattice-point coordinates (Buerger, 1942).

Finally, the relationship between the phases of symmetry-related reflections, given by (1.4.2.5), is of fundamental as well as practical importance in the theories and techniques of crystal structure determination which operate in reciprocal space (Part 2 of this volume).

1.4.2.3. Symmetry factors for space-group-specific Fourier summations

The weighted reciprocal lattice, with weights taken as the structure factors, is synonymous with the discrete space of the coefficients of a Fourier expansion of the electron density, or the Fourier space (*F* space) of the latter. Accordingly, the asymmetric unit of the Fourier space can be defined as the subset of structure factors within which the relationship (1.4.2.3) does not hold – except at special positions in the reciprocal lattice. If the point group of the crystal is of order g, this is also the order of the corresponding factor-group representation of the space group (*IT* A, 1983) and there exist g relationships of the form of (1.4.2.3):

$$F(\boldsymbol{P}_s^T\mathbf{h}) = F(\mathbf{h})\exp(-2\pi i\mathbf{h}^T\mathbf{t}_s). \tag{1.4.2.8}$$

We can thus decompose the summation in (1.4.2.1) into g sums, each extending over an asymmetric unit of the *F* space. It must be kept in mind, however, that some classes of reciprocal-lattice vectors may be common to more than one asymmetric unit, and thus each reciprocal-lattice point will be assigned an occupancy factor, denoted by $q(\mathbf{h})$, such that $q(\mathbf{h}) = 1$ for a general position and $q(\mathbf{h}) = 1/m(\mathbf{h})$ for a special one, where $m(\mathbf{h})$ is the multiplicity – or the order of the point group that leaves $\mathbf{h}$ unchanged. Equation (1.4.2.1) can now be rewritten as

$$\rho(\mathbf{r}) = \frac{1}{V}\sum_{s=1}^{g}\sum_{\mathbf{h}_a} q(\mathbf{h}_a)F(\boldsymbol{P}_s^T\mathbf{h}_a)\exp[-2\pi i(\boldsymbol{P}_s^T\mathbf{h}_a)^T\mathbf{r}], \tag{1.4.2.9}$$

where the inner summation in (1.4.2.9) extends over the reference asymmetric unit of the Fourier space, which is associated with the identity operation of the space group. Substituting from (1.4.2.8) for $F(\boldsymbol{P}_s^T\mathbf{h}_a)$, and interchanging the order of the summations in (1.4.2.9), we obtain

$$\rho(\mathbf{r}) = \frac{1}{V}\sum_{\mathbf{h}_a} q(\mathbf{h}_a)F(\mathbf{h}_a)\sum_{s=1}^{g}\exp[-2\pi i\mathbf{h}_s^T(\boldsymbol{P}_s\mathbf{r}+\mathbf{t}_s)] \tag{1.4.2.10}$$

$$= \frac{1}{V}\sum_{\mathbf{h}_a} q(\mathbf{h}_a)F(\mathbf{h}_a)[A(\mathbf{h}_a) - iB(\mathbf{h}_a)], \tag{1.4.2.11}$$

where

$$A(\mathbf{h}) = \sum_{s=1}^{g}\cos[2\pi\mathbf{h}^T(\boldsymbol{P}_s\mathbf{r}+\mathbf{t}_s)] \tag{1.4.2.12}$$

and

$$B(\mathbf{h}) = \sum_{s=1}^{g}\sin[2\pi\mathbf{h}^T(\boldsymbol{P}_s\mathbf{r}+\mathbf{t}_s)]. \tag{1.4.2.13}$$

The symmetry factors A and B are well known as geometric or trigonometric structure factors and a considerable part of Volume I of *IT* (1952) is dedicated to their tabulation. Their formal association with the structure factor – following from direct-space arguments – is closely related to that shown in equation (1.4.2.11) (see Section 1.4.2.4). Simplified trigonometric expressions for A and B are given in Tables A1.4.3.1–A1.4.3.7 in Appendix 1.4.3 for all the two- and three-dimensional crystallographic space groups, and for all the parities of hkl for which A and B assume different functional forms. These expressions are there given for general reflections and can also be used for special ones, provided the occupancy factors $q(\mathbf{h})$ have been properly accounted for.

Equation (1.4.2.11) is quite general and can, of course, be applied to noncentrosymmetric Fourier summations, without neglect of dispersion. Further simplifications are obtained in the centrosymmetric case, when the space-group origin is chosen at a centre of symmetry, and in the noncentrosymmetric case, when dispersion is neglected. In each of the latter two cases the summation over $\mathbf{h}_a$ is restricted to reciprocal-lattice vectors that are not related by real or apparent inversion (denoted by $\mathbf{h}_a > 0$), and we obtain

$$\rho(\mathbf{r}) = \frac{2}{V}\sum_{\mathbf{h}_a>0} q(\mathbf{h}_a)F(\mathbf{h}_a)A(\mathbf{h}_a) \tag{1.4.2.14}$$

and

$$\rho(\mathbf{r}) = \frac{2}{V}\sum_{\mathbf{h}_a>0} q(\mathbf{h}_a)|F(\mathbf{h}_a)|[A(\mathbf{h}_a)\cos\varphi(\mathbf{h}_a) + B(\mathbf{h}_a)\sin\varphi(\mathbf{h}_a)] \tag{1.4.2.15}$$

for the dispersionless centrosymmetric and noncentrosymmetric cases, respectively.

1.4.2.4. Symmetry factors for space-group-specific structure-factor formulae

The explicit dependence of structure-factor summations on the space-group symmetry of the crystal can also be expressed in terms of symmetry factors, in an analogous manner to that described for the electron density in the previous section. It must be pointed out that while the above treatment only presumes that the electron density can be represented by a three-dimensional Fourier series, the present one is restricted by the assumption that the atoms are isotropic with regard to their motion and shape (*cf.* Chapter 1.2).

Under the above assumptions, *i.e.* for isotropically vibrating spherical atoms, the structure factor can be written as

$$F(\mathbf{h}) = \sum_{j=1}^{N} f_j\exp(2\pi i\mathbf{h}^T\mathbf{r}_j), \tag{1.4.2.16}$$

where $\mathbf{h}^T = (hkl)$ is the diffraction vector, N is the number of atoms in the unit cell, f_j is the atomic scattering factor including

its temperature factor and depending on the magnitude of **h** only, and $\mathbf{r}_j$ is the position vector of the jth atom referred to the origin of the unit cell.

If the crystal belongs to a point group of order m_p and the multiplicity of its Bravais lattice is m_L, there are $g' = m_p \times m_L$ general equivalent positions in the unit cell of the space group (*IT* A, 1983). We can thus rewrite (1.4.2.16), grouping the contributions of the symmetry-related atoms, as

$$F(\mathbf{h}) = \sum_j f_j \sum_{s=1}^{g'} \exp[2\pi i \mathbf{h}^T (\boldsymbol{P}_s \mathbf{r} + \mathbf{t}_s)], \tag{1.4.2.17}$$

where $\boldsymbol{P}_s$ and $\mathbf{t}_s$ are the rotation and translation parts of the sth space-group operation respectively. The inner summation in (1.4.2.17) contains the dependence of the structure factor of reflection **h** on the space-group symmetry of the crystal and is known as the (complex) geometric or trigonometric structure factor.

Equation (1.4.2.17) can be rewritten as

$$F(\mathbf{h}) = \sum_j f_j [A_j(\mathbf{h}) + iB_j(\mathbf{h})], \tag{1.4.2.18}$$

where

$$A_j(\mathbf{h}) = \sum_{s=1}^{g'} \cos[2\pi \mathbf{h}^T (\boldsymbol{P}_s \mathbf{r}_j + \mathbf{t}_s)] \tag{1.4.2.19}$$

and

$$B_j(\mathbf{h}) = \sum_{s=1}^{g'} \sin[2\pi \mathbf{h}^T (\boldsymbol{P}_s \mathbf{r}_j + \mathbf{t}_s)] \tag{1.4.2.20}$$

are the real and imaginary parts of the trigonometric structure factor. Equations (1.4.2.19) and (1.4.2.20) are *mathematically* identical to equations (1.4.2.11) and (1.4.2.12), respectively, apart from the numerical coefficients which appear in the expressions for A and B, for space groups with centred lattices: while only the order of the point group need be considered in connection with the Fourier expansion of the electron density (see above), the multiplicity of the Bravais lattice must of course appear in (1.4.2.19) and (1.4.2.20).

Analogous functional forms are arrived at by considerations of symmetry in direct and reciprocal spaces. These quantities are therefore convenient representations of crystallographic symmetry in its interaction with the diffraction experiment and have been indispensable in all of the early crystallographic computing related to structure determination. Their applications to modern crystallographic computing have been largely superseded by fast Fourier techniques, in reciprocal space, and by direct use of matrix and vector representations of space-group operators, in direct space, especially in cases of low space-group symmetry. It should be noted, however, that the degree of simplification of the trigonometric structure factors generally increases with increasing symmetry (see, *e.g.*, Section 1.4.3), and the gain of computing efficiency becomes significant when problems involving high symmetries are treated with this 'old-fashioned' tool. Analytic expressions for the trigonometric structure factors are of course indispensable in studies in which the knowledge of the functional form of the structure factor is required [*e.g.* in theories of structure-factor statistics and direct methods of phase determination (see Chapters 2.1 and 2.2)].

Equations (1.4.2.19) and (1.4.2.20) are simple but their expansion and simplification for all the space groups and relevant *hkl* subsets can be an extremely tedious undertaking when carried out in the conventional manner. As shown below, this process has been automated by a suitable combination of symbolic and numeric high-level programming procedures.

1.4.3. Structure-factor tables

1.4.3.1. Some general remarks

This section is a revised version of the structure-factor tables contained in Sections 4.5 through 4.7 of Volume I (*IT* I, 1952). As in the previous edition, it is intended to present a comprehensive list of explicit expressions for the real and the imaginary parts of the trigonometric structure factor, for all the 17 plane groups and the 230 space groups, and for the *hkl* subsets for which the trigonometric structure factor assumes different functional forms. The tables given here are also confined to the case of general Wyckoff positions (*IT* I, 1952). However, the expressions are presented in a much more concise symbolic form and are amenable to computation just like the explicit trigonometric expressions in Volume I (*IT* I, 1952). The present tabulation is based on equations (1.4.2.19) and (1.4.2.20), *i.e.* the numerical coefficients in A and B which appear in Tables A1.4.3.1–A1.4.3.7 in Appendix 1.4.3 are appropriate to space-group-specific structure-factor formulae. The functional form of A and B is, however, the same when applied to Fourier summations (see Section 1.4.2.3).

1.4.3.2. Preparation of the structure-factor tables

The lists of the coordinates of the general equivalent positions, presented in *IT* A (1983), as well as in earlier editions of the *Tables*, are sufficient for the expansion of the summations in (1.4.2.19) and (1.4.2.20) and the simplification of the resulting expressions can be performed using straightforward algebra and trigonometry (see, *e.g.*, *IT* I, 1952). As mentioned above, the preparation of the present structure-factor tables has been automated and its stages can be summarized as follows:

(i) Generation of the coordinates of the general positions, starting from a computer-adapted space-group symbol (Shmueli, 1984).

(ii) Formation of the scalar products, appearing in (1.4.2.19) and (1.4.2.20), and their separation into components depending on the rotation and translation parts of the space-group operations:

$$\mathbf{h}^T(\boldsymbol{P}_s, \mathbf{t}_s)\mathbf{r} = \mathbf{h}^T \boldsymbol{P}_s \mathbf{r} + \mathbf{h}^T \mathbf{t}_s \tag{1.4.3.1}$$

for the space groups which are not associated with a unique axis; the left-hand side of (1.4.3.1) is separated into contributions of the relevant plane group and unique axis for the remaining space groups.

(iii) Analysis of the translation-dependent parts of the scalar products and automatic determination of all the parities of *hkl* for which A and B must be computed and simplified.

(iv) Expansion of equations (1.4.2.19) and (1.4.2.20) and their reduction to trigonometric expressions comparable to those given in the structure-factor tables in Volume I of *IT* (1952).

(v) Representation of the results in terms of a small number of building blocks, of which the expressions were found to be composed. These representations are described in Section 1.4.3.3.

All the stages outlined above were carried out with suitably designed computer programs, written in numerically and symbolically oriented languages. A brief summary of the underlying algorithms is presented in Appendix 1.4.1. The computer-adapted space-group symbols used in these computations are described in Section A1.4.2.2 and presented in Table A1.4.2.1.

1.4.3.3. Symbolic representation of A and B

We shall first discuss the symbols for the space groups that are not associated with a unique axis. These comprise the triclinic, orthorhombic and cubic space groups. The symbols are also used for the seven rhombohedral space groups which are referred to rhombohedral axes (*IT* I, 1952; *IT* A, 1983).

The abbreviation of triple products of trigonometric functions such as, *e.g.*, denoting $\cos(2\pi hx)\sin(2\pi ky)\cos(2\pi lz)$ by csc, is well known (*IT* I, 1952), and can be conveniently used in representing *A* and *B* for triclinic and orthorhombic space groups. However, the simplified expressions for *A* and *B* in space groups of higher symmetry also possess a high degree of regularity, as is apparent from an examination of the structure-factor tables in Volume I (*IT* I, 1952), and as confirmed by the preparation of the present tables. An example, illustrating this for the cubic system, is given below.

The trigonometric structure factor for the space group $Pm\bar{3}$ (No. 200) is given by

$$\begin{aligned} A = 8[&\cos(2\pi hx)\cos(2\pi ky)\cos(2\pi lz) \\ &+ \cos(2\pi hy)\cos(2\pi kz)\cos(2\pi lx) \\ &+ \cos(2\pi hz)\cos(2\pi kx)\cos(2\pi ly)], \end{aligned} \tag{1.4.3.2}$$

and the sum of the above nine-function block and the following one:

$$\begin{aligned} 8[&\cos(2\pi hx)\cos(2\pi kz)\cos(2\pi ly) \\ &+ \cos(2\pi hz)\cos(2\pi ky)\cos(2\pi lx) \\ &+ \cos(2\pi hy)\cos(2\pi kx)\cos(2\pi lz)] \end{aligned} \tag{1.4.3.3}$$

is the trigonometric structure factor for the space group $Pm\bar{3}m$ (No. 221, *IT* I, 1952, *IT* A, 1983). It is obvious that the only difference between the nine-function blocks in (1.4.3.2) and (1.4.3.3) is that the permutation of the coordinates *xyz* is *cyclic* or *even* in (1.4.3.2), while it is *noncyclic* or *odd* in (1.4.3.3).

It was observed during the generation of the present tables that the expressions for *A* and *B* for all the cubic space groups, and all the relevant *hkl* subsets, can be represented in terms of such 'even' and 'odd' nine-function blocks. Moreover, it was found that the order of the trigonometric functions in each such block remains the same in each of its three terms (triple products). This is not surprising since each of the above space groups contains threefold axes of rotation along [111] and related directions, and such permutations of *xyz* for fixed *hkl* (or *vice versa*) are expected. It was therefore possible to introduce two permutation operators and represent *A* and *B* in terms of the following two basic blocks:

$$\begin{aligned} \mathrm{Epqr} = {}&\mathrm{p}(2\pi hx)\mathrm{q}(2\pi ky)\mathrm{r}(2\pi lz) + \mathrm{p}(2\pi hy)\mathrm{q}(2\pi kz)\mathrm{r}(2\pi lx) \\ &+ \mathrm{p}(2\pi hz)\mathrm{q}(2\pi kx)\mathrm{r}(2\pi ly) \end{aligned} \tag{1.4.3.4}$$

and

$$\begin{aligned} \mathrm{Opqr} = {}&\mathrm{p}(2\pi hx)\mathrm{q}(2\pi kz)\mathrm{r}(2\pi ly) + \mathrm{p}(2\pi hz)\mathrm{q}(2\pi ky)\mathrm{r}(2\pi lx) \\ &+ \mathrm{p}(2\pi hy)\mathrm{q}(2\pi kx)\mathrm{r}(2\pi lz), \end{aligned} \tag{1.4.3.5}$$

where each of p, q and r can be a sine or a cosine, and appears at the same position in each of the three terms of a block. The capital prefixes E and O were chosen to represent even and odd permutations of the coordinates *xyz*, respectively.

For example, the trigonometric structure factor for the space group $Pa\bar{3}$ (No. 205, *IT* I, 1952, *IT* A, 1983) can now be tabulated as follows:

A	*B*	$h+k$	$k+l$	$h+l$
8Eccc	0	even	even	even
−8Ecss	0	even	odd	odd
−8Escs	0	odd	even	odd
−8Essc	0	odd	odd	even

(*cf.* Table A1.4.3.7), where the sines and cosines are abbreviated by s and c, respectively. It is interesting to note that the only maximal non-isomorphic subgroup of $Pa\bar{3}$, not containing a threefold axis, is the orthorhombic *Pbca* (see *IT* A, 1983, p. 621), and this group–subgroup relationship is reflected in the functional forms of the trigonometric structure factors; the representation of *A* and *B* for *Pbca* is in fact analogous to that of $Pa\bar{3}$, including the parities of *hkl* and the corresponding forms of the triple products, except that the prefix E – associated with the threefold rotation – is absent from *Pbca*. The expression for *A* for the space group $Pm\bar{3}m$ [the sum of (1.4.3.2) and (1.4.3.3)] now simply reads: $A = 8(\mathrm{Eccc} + \mathrm{Occc})$.

As pointed out above, the permutation operators also apply to rhombohedral space groups that are referred to rhombohedral axes (Table A1.4.3.6), and the corresponding expressions for *R*3 and $R\bar{3}$ bear the same relationship to those for *P*1 and $P\bar{1}$ (Table A1.4.3.2), respectively, as that shown above for the related $Pa\bar{3}$ and *Pbca*.

When in any given standard space-group setting one of the coordinate axes is parallel to a unique axis, the point-group rotation matrices can be partitioned into 2×2 and 1×1 diagonal blocks, the former corresponding to an operation of the plane group resulting from the projection of the space group down the unique axis. If, for example, the unique axis is parallel to **c**, we can decompose the scalar product in (1.4.2.19) and (1.4.2.20) as follows:

$$\begin{aligned} \mathbf{h}^T(\boldsymbol{P}_s\mathbf{r} + \mathbf{t}_s) = {}&\begin{pmatrix} h & k \end{pmatrix}\left[\begin{pmatrix} P_{11} & P_{12} \\ P_{21} & P_{22} \end{pmatrix}\begin{pmatrix} x \\ y \end{pmatrix} + \begin{pmatrix} t_1 \\ t_2 \end{pmatrix}\right] \\ &+ l(P_{33}z + t_3), \end{aligned} \tag{1.4.3.6}$$

where the first scalar product on the right-hand side of (1.4.3.6) contains the contribution of a plane group and the second product is the contribution of the unique axis itself. The above decomposition often leads to a convenient factorization of *A* and *B*, and is applicable to monoclinic, tetragonal and hexagonal families, the latter including rhombohedral space groups that are referred to hexagonal axes.

The symbols used in Tables A1.4.3.3, A1.4.3.5 and A1.4.3.6 are based on such decompositions. In those few cases where explicit expressions must be given we make use of the convention of replacing $\cos(2\pi u)$ by $\mathrm{c}(u)$ and $\sin(2\pi u)$ by $\mathrm{s}(u)$. For example, $\cos[2\pi(hy + kx)]$ *etc.* is given as $\mathrm{c}(hy + kx)$ *etc.* The symbols are defined below.

Monoclinic space groups (Table A1.4.3.3)

The following symbols are used in this system:

$$\begin{aligned} \mathrm{c}(hl) &= \cos[2\pi(hx + lz)], \quad & \mathrm{c}(hk) &= \cos[2\pi(hx + ky)] \\ \mathrm{s}(hl) &= \sin[2\pi(hx + lz)], \quad & \mathrm{s}(hk) &= \sin[2\pi(hx + ky)] \end{aligned} \tag{1.4.3.7}$$

so that any expression for *A* or *B* in the monoclinic system has the form $K\mathrm{p}(hl)\mathrm{q}(ky)$ or $K\mathrm{p}(hk)\mathrm{q}(lz)$ for the second or first setting, respectively, where p and q can each be a sine or a cosine and *K* is a numerical constant.

Tetragonal space groups (Table A1.4.3.5)

The most frequently occurring expressions in the summations for A and B in this system are of the form

$$\mathrm{P(pq)} = \mathrm{p}(2\pi hx)\mathrm{q}(2\pi ky) + \mathrm{p}(2\pi kx)\mathrm{q}(2\pi hy) \qquad (1.4.3.8)$$

and

$$\mathrm{M(pq)} = \mathrm{p}(2\pi hx)\mathrm{q}(2\pi ky) - \mathrm{p}(2\pi kx)\mathrm{q}(2\pi hy), \qquad (1.4.3.9)$$

where p and q can each be a sine or a cosine. These are typical contributions related to square plane groups.

Trigonal and hexagonal space groups (Table A1.4.3.6)

The contributions of plane hexagonal space groups to the first term in (1.4.3.6) are

$$\begin{aligned} p_1 &= hx + ky, \quad p_2 = kx + iy, \quad p_3 = ix + hy, \\ q_1 &= kx + hy, \quad q_2 = hx + iy, \quad q_3 = ix + ky, \end{aligned} \qquad (1.4.3.10)$$

where $i = -h - k$ (*IT* I, 1952). The symbols which represent the frequently occurring expressions in this family, and given in terms of (1.4.3.10), are

$$\begin{aligned} \mathrm{C}(hki) &= \cos(2\pi p_1) + \cos(2\pi p_2) + \cos(2\pi p_3) \\ \mathrm{C}(khi) &= \cos(2\pi q_1) + \cos(2\pi q_2) + \cos(2\pi q_3) \\ \mathrm{S}(hki) &= \sin(2\pi p_1) + \sin(2\pi p_2) + \sin(2\pi p_3) \\ \mathrm{S}(khi) &= \sin(2\pi q_1) + \sin(2\pi q_2) + \sin(2\pi q_3) \end{aligned} \qquad (1.4.3.11)$$

and these quite often appear as the following sums and differences:

$$\begin{aligned} \mathrm{PH(cc)} &= \mathrm{C}(hki) + \mathrm{C}(khi), \quad \mathrm{PH(ss)} = \mathrm{S}(hki) + \mathrm{S}(khi) \\ \mathrm{MH(cc)} &= \mathrm{C}(hki) - \mathrm{C}(khi), \quad \mathrm{MH(ss)} = \mathrm{S}(hki) - \mathrm{S}(khi). \end{aligned} \qquad (1.4.3.12)$$

The symbols defined in this section are briefly redefined in the appropriate tables, which also contain the conditions for vanishing symbols.

1.4.3.4. Arrangement of the tables

The expressions for A and B are usually presented in terms of the short symbols defined above for all the representations of the plane groups and space groups given in Volume A (*IT* A, 1983), and are fully consistent with the unit-cell choices and space-group origins employed in that volume. The tables are arranged by crystal families and the expressions appear in the order of the appearance of the corresponding plane and space groups in the space-group tables in *IT* A (1983).

The main items in a table entry, not necessarily in the following order, are: (i) the conventional space-group number, (ii) the short Hermann–Mauguin space-group symbol, (iii) brief remarks on the choice of the space-group origin and setting, where appropriate, (iv) the real (A) and imaginary (B) parts of the trigonometric structure factor, and (v) the parity of the hkl subset to which the expressions for A and B pertain. Full space-group symbols are given in the monoclinic system only, since they are indispensable for the recognition of the settings and glide planes appearing in the various representations of monoclinic space groups given in *IT* A (1983).

1.4.4. Symmetry in reciprocal space: space-group tables

1.4.4.1. Introduction

The purpose of this section, and the accompanying table, is to provide a representation of the 230 three-dimensional crystallographic space groups in terms of two fundamental quantities that characterize a weighted reciprocal lattice: (i) coordinates of point-symmetry-related points in the reciprocal lattice, and (ii) phase shifts of the weight functions that are associated with the translation parts of the various space-group operations. Table A1.4.4.1 in Appendix 1.4.4 collects the above information for all the space-group settings which are listed in *IT* A (1983) for the same choice of the space-group origins and following the same numbering scheme used in that volume. Table A1.4.4.1 was generated by computer using the space-group algorithm described by Shmueli (1984) and the space-group symbols given in Table A1.4.2.1 in Appendix 1.4.2. It is shown in a later part of this section that Table A1.4.4.1 can also be regarded as a table of symmetry groups in Fourier space, in the Bienenstock–Ewald (1962) sense which was mentioned in Section 1.4.1. The section is concluded with a brief description of the correspondence between Bravais-lattice types in direct and reciprocal spaces.

1.4.4.2. Arrangement of the space-group tables

Table A1.4.4.1 is subdivided into point-group sections and space-group subsections, as outlined below.

(i) *The point-group heading.* This heading contains a short Hermann–Mauguin symbol of a point group, the crystal system and the symbol of the Laue group with which the point group is associated. Each point-group heading is followed by the set of space groups which are isomorphic to the point group indicated, the set being enclosed within a box.

(ii) *The space-group heading.* This heading contains, for each space group listed in Volume A (*IT* A, 1983), the short Hermann–Mauguin symbol of the space group, its conventional space-group number and (in parentheses) the serial number of its representation in Volume A; this is also the serial number of the explicit space-group symbol in Table A1.4.2.1 from which the entry was derived. Additional items are full space-group symbols, given only for the monoclinic space groups in their settings that are given in Volume A (*IT*, 1983), and self-explanatory comments as required.

(iii) *The table entry.* In the context of the analysis in Section 1.4.2.2, the format of a table entry is: $\mathbf{h}^T\boldsymbol{P}_n : -\mathbf{h}^T\mathbf{t}_n$, where $(\boldsymbol{P}_n, \mathbf{t}_n)$ is the nth space-group operator, and the phase shift $\mathbf{h}^T\mathbf{t}_n$ is expressed in units of 2π [see equations (1.4.2.3) and (1.4.2.5)]. More explicitly, the general format of a table entry is

$$(n)\, h_n k_n l_n : -p_n q_n r_n/m. \qquad (1.4.4.1)$$

In (1.4.4.1), n is the serial number of the space-group operation to which this entry pertains and is the same as the number of the general Wyckoff position generated by this operation and given in *IT* A (1983) for the space group appearing in the space-group heading. The first part of an entry, $h_n k_n l_n$:, contains the coordinates of the reciprocal-lattice vector that was generated from the reference vector (hkl) by the rotation part of the nth space-group operation. These rotation parts of the table entries, for a given space group, thus constitute the set of reciprocal-lattice points that are generated by the corresponding point group (*not Laue group*). The second part of an entry is an abbreviation of the phase shift which is associated with the nth operation and thus

$$-p_n q_n r_n/m \quad \text{denotes} \quad -2\pi(hp_n + kq_n + lr_n)/m, \qquad (1.4.4.2)$$

where the fractions p_n/m, q_n/m and r_n/m are the components of the translation part $\mathbf{t}_n$ of the nth space-group operation. The

phase-shift part of an entry is given only if $(p_n q_n r_n)$ is *not* a vector in the direct lattice, since such a vector would give rise to a trivial phase shift (an integer multiple of 2π).

1.4.4.3. Effect of direct-space transformations

The phase shifts given in Table A1.4.4.1 depend on the translation parts of the space-group operations and these translations are determined, all or in part, by the choice of the space-group origin. It is a fairly easy matter to find the phase shifts that correspond to a given shift of the space-group origin in direct space, directly from Table A1.4.4.1. Moreover, it is also possible to modify the table entries so that a more general transformation, including a change of crystal axes as well as a shift of the space-group origin, can be directly accounted for. We employ here the frequently used concise notation due to Seitz (1935) (see also *IT* A, 1983).

Let the direct-space transformation be given by

$$\mathbf{r}_{\rm new} = \boldsymbol{T}\mathbf{r}_{\rm old} + \mathbf{v}, \tag{1.4.4.3}$$

where $\boldsymbol{T}$ is a nonsingular 3×3 matrix describing the change of the coordinate system and $\mathbf{v}$ is an origin-shift vector. The components of $\boldsymbol{T}$ and $\mathbf{v}$ are referred to the old system, and $\mathbf{r}_{\rm new}$ ($\mathbf{r}_{\rm old}$) is the position vector of a point in the crystal, referred to the new (old) system, respectively. If we denote a space-group operation referred to the new and old systems by $(\boldsymbol{P}_{\rm new}, \mathbf{t}_{\rm new})$ and $(\boldsymbol{P}_{\rm old}, \mathbf{t}_{\rm old})$, respectively, we have

$$(\boldsymbol{P}_{\rm new}, \mathbf{t}_{\rm new}) = (\boldsymbol{T}, \mathbf{v})(\boldsymbol{P}_{\rm old}, \mathbf{t}_{\rm old})(\boldsymbol{T}, \mathbf{v})^{-1} \tag{1.4.4.4}$$

$$= (\boldsymbol{T}\boldsymbol{P}_{\rm old}\boldsymbol{T}^{-1}, \mathbf{v} - \boldsymbol{T}\boldsymbol{P}_{\rm old}\boldsymbol{T}^{-1}\mathbf{v} + \boldsymbol{T}\mathbf{t}_{\rm old}). \tag{1.4.4.5}$$

It follows from (1.4.4.2) and (1.4.4.5) that if the old entry of Table A1.4.4.1 is given by

$$(n)\,\mathbf{h}^T\boldsymbol{P} : -\mathbf{h}^T\mathbf{t},$$

the transformed entry becomes

$$(n)\,\mathbf{h}^T\boldsymbol{T}\boldsymbol{P}\boldsymbol{T}^{-1} : \mathbf{h}^T\boldsymbol{T}\boldsymbol{P}\boldsymbol{T}^{-1}\mathbf{v} - \mathbf{h}^T\mathbf{v} - \mathbf{h}^T\boldsymbol{T}\mathbf{t}, \tag{1.4.4.6}$$

and in the important special cases of a pure change of setting ($\mathbf{v} = 0$) or a pure shift of the space-group origin ($\boldsymbol{T}$ is the unit matrix $\boldsymbol{I}$), (1.4.4.6) reduces to

$$(n)\,\mathbf{h}^T\boldsymbol{T}\boldsymbol{P}\boldsymbol{T}^{-1} : -\mathbf{h}^T\boldsymbol{T}\mathbf{t} \tag{1.4.4.7}$$

or

$$(n)\,\mathbf{h}^T\boldsymbol{P} : \mathbf{h}^T\boldsymbol{P}\mathbf{v} - \mathbf{h}^T\mathbf{v} - \mathbf{h}^T\mathbf{t}, \tag{1.4.4.8}$$

respectively. The rotation matrices $\boldsymbol{P}$ are readily obtained by visual or programmed inspection of the old entries: if, for example, $\mathbf{h}^T\boldsymbol{P}$ is *khl*, we must have $P_{21} = 1$, $P_{12} = 1$ and $P_{33} = 1$, the remaining P_{ij}'s being equal to zero. Similarly, if $\mathbf{h}^T\boldsymbol{P}$ is *kil*, where $i = -h - k$, we have

$$(kil) = (k, -h-k, l) = (hkl)\begin{pmatrix} 0 & \bar{1} & 0 \\ 1 & \bar{1} & 0 \\ 0 & 0 & 1 \end{pmatrix}.$$

The rotation matrices can also be obtained by reference to Part 7 and Tables 11.2.2.1 and 11.2.2.2 in Volume A (*IT* A, 2005).

As an example, consider the phase shifts corresponding to the operation No. (16) of the space group $P4/nmm$ (No. 129) in its two origins given in Volume A (*IT* A, 1983). For an Origin 2-to-Origin 1 transformation we find there $\mathbf{v} = (\frac{1}{4}, -\frac{1}{4}, 0)$ and the old Origin 2 entry in Table A1.4.4.1 is (16) *khl* ($\mathbf{t}$ is zero). The appropriate entry for the Origin 1 description of this operation should therefore be $\mathbf{h}^T\boldsymbol{P}\mathbf{v} - \mathbf{h}^T\mathbf{v} = k/4 - h/4 - h/4 + k/4 = -h/2 + k/2$, as given by (1.4.4.8), or $-(h+k)/2$ if a trivial shift of 2π is subtracted. The (new) Origin 1 entry thus becomes: (16) *khl*: $-110/2$, as listed in Table A1.4.4.1.

1.4.4.4. Symmetry in Fourier space

As shown below, Table A1.4.4.1 can also be regarded as a collection of the general equivalent positions of the symmetry groups of Fourier space, in the sense of the treatment by Bienenstock & Ewald (1962). This interpretation of the table is, however, restricted to the underlying periodic function being real and positive (see the latter reference). The symmetry formalism can be treated with the aid of the original 4×4 matrix notation, but it appears that a concise Seitz-type notation suits better the present introductory interpretation.

The symmetry dependence of the fundamental relationship (1.4.2.5)

$$\varphi(\mathbf{h}^T\boldsymbol{P}_n) = \varphi(\mathbf{h}) - 2\pi\mathbf{h}^T\mathbf{t}_n$$

is given by a table entry of the form: $(n)\,\mathbf{h}^T\boldsymbol{P} : -\mathbf{h}^T\mathbf{t}$, where the phase shift is given in units of 2π, and the structure-dependent phase $\varphi(\mathbf{h})$ is omitted. Defining a combination law analogous to Seitz's product of two operators of affine transformation:

$$[\mathbf{a}^T : b](\boldsymbol{R}, \mathbf{r}) = [\mathbf{a}^T\boldsymbol{R} : \mathbf{a}^T\mathbf{r} + b], \tag{1.4.4.9}$$

where $\boldsymbol{R}$ is a 3×3 matrix, $\mathbf{a}^T$ is a row vector, $\mathbf{r}$ is a column vector and b is a scalar, we can write the general form of a table entry as

$$[\mathbf{h}^T : \delta](\boldsymbol{P}, -\mathbf{t}) = [\mathbf{h}^T\boldsymbol{P} : -\mathbf{h}^T\mathbf{t} + \delta], \tag{1.4.4.10}$$

where δ is a constant phase shift which we take as zero. The positions $[\mathbf{h}^T : 0]$ and $[\mathbf{h}^T\boldsymbol{P} : -\mathbf{h}^T\mathbf{t}]$ are now related by the operation $(\boldsymbol{P}, -\mathbf{t})$ *via* the combination law (1.4.4.9), which is a shorthand transcription of the 4×4 matrix notation of Bienenstock & Ewald (1962), with the appropriate sign of $\mathbf{t}$.

Let us evaluate the result of a successive application of two such operators, say $(\boldsymbol{P}, -\mathbf{t})$ and $(\boldsymbol{Q}, -\mathbf{v})$ to the reference position $[\mathbf{h}^T : 0]$ in Fourier space:

$$[\mathbf{h}^T : 0](\boldsymbol{P}, -\mathbf{t})(\boldsymbol{Q}, -\mathbf{v}) = [\mathbf{h}^T : 0](\boldsymbol{P}\boldsymbol{Q}, -\boldsymbol{P}\mathbf{v} - \mathbf{t})$$

$$= [\mathbf{h}^T\boldsymbol{P}\boldsymbol{Q} : -\mathbf{h}^T\boldsymbol{P}\mathbf{v} - \mathbf{h}^T\mathbf{t}], \tag{1.4.4.11}$$

and perform an inverse operation:

$$[\mathbf{h}^T\boldsymbol{P} : -\mathbf{h}^T\mathbf{t}](\boldsymbol{P}, -\mathbf{t})^{-1} = [\mathbf{h}^T\boldsymbol{P} : -\mathbf{h}^T\mathbf{t}](\boldsymbol{P}^{-1}, \boldsymbol{P}^{-1}\mathbf{t})$$

$$= [\mathbf{h}^T\boldsymbol{P}\boldsymbol{P}^{-1} : \mathbf{h}^T\boldsymbol{P}\boldsymbol{P}^{-1}\mathbf{t} - \mathbf{h}^T\mathbf{t}]$$

$$= [\mathbf{h}^T : 0]. \tag{1.4.4.12}$$

These equations confirm the validity of the shorthand notation (1.4.4.9) and illustrate the group nature of the operators $(\boldsymbol{P}, -\mathbf{t})$ in the present context.

Table 1.4.4.1. *Correspondence between types of centring in direct and reciprocal lattices*

Direct lattice		Reciprocal lattice		
Lattice type(s)	Centring translations	Lattice type(s)	Restriction on *hkl*	Multiple unit cell
P, *R*		*P*, *R*		$\mathbf{a}^*$, $\mathbf{b}^*$, $\mathbf{c}^*$
A	$0, \frac{1}{2}, \frac{1}{2}$	*A*	$k+l=2n$	$\mathbf{a}^*$, $2\mathbf{b}^*$, $2\mathbf{c}^*$
B	$\frac{1}{2}, 0, \frac{1}{2}$	*B*	$h+l=2n$	$2\mathbf{a}^*$, $\mathbf{b}^*$, $2\mathbf{c}^*$
C	$\frac{1}{2}, \frac{1}{2}, 0$	*C*	$h+k=2n$	$2\mathbf{a}^*$, $2\mathbf{b}^*$, $\mathbf{c}^*$
I	$\frac{1}{2}, \frac{1}{2}, \frac{1}{2}$	*F*	$h+k+l=2n$	$2\mathbf{a}^*$, $2\mathbf{b}^*$, $2\mathbf{c}^*$
F	$0, \frac{1}{2}, \frac{1}{2}$ $\frac{1}{2}, 0, \frac{1}{2}$ $\frac{1}{2}, \frac{1}{2}, 0$	*I*	$k+l=2n$ $h+l=2n$ $h+k=2n$	$2\mathbf{a}^*$, $2\mathbf{b}^*$, $2\mathbf{c}^*$
$R_{\rm hex}$	$\frac{2}{3}, \frac{1}{3}, \frac{1}{3}$ $\frac{1}{3}, \frac{2}{3}, \frac{2}{3}$	$R_{\rm hex}$	$-h+k+l=3n$	$3\mathbf{a}^*$, $3\mathbf{b}^*$, $3\mathbf{c}^*$

Following Bienenstock & Ewald, the operators $(\boldsymbol{P}, -\mathbf{t})$ are symmetry operators that act on the positions $[\mathbf{h}^T : 0]$ in Fourier space, provided they satisfy the following requirements: (i) the application of such an operator leaves the magnitude of the (generally) complex Fourier coefficient unchanged, and (ii) after g successive applications of an operator, where g is the order of its rotation part, the phase remains unchanged up to a shift by an integer multiple of 2π (a trivial phase shift, corresponding to a translation by a lattice vector in direct space).

If our function is the electron density in the crystal, the first requirement is obviously satisfied since $|F(\mathbf{h})| = |F(\mathbf{h}^T\boldsymbol{P})|$, where F is the structure factor [*cf.* equation (1.4.2.4)]. In order to make use of the second requirement in deriving permissible symmetry operators on Fourier space, all the relevant transformations, *i.e.* those which have rotation operators of the orders 1, 2, 3, 4 and 6, must be individually examined. A comprehensive example, covering most of the tetragonal system, can be found in Bienenstock & Ewald (1962).

It is of interest to illustrate the above process for a simple particular instance. Consider an operation, the rotation part of which involves a mirror plane, and assume that it is associated with the monoclinic system, in the second setting (unique axis b). We denote the operator by $(\boldsymbol{m}, -\mathbf{u})$, where $\mathbf{u}^T = (uvw)$, and the permissible values of u, v and w are to be determined. The operation is of order 2, and according to requirement (ii) above we have to evaluate

$$\begin{aligned}[\mathbf{h}^T : 0](\boldsymbol{m}, -\mathbf{u})^2 &= [\mathbf{h}^T : 0](\boldsymbol{I}, -\boldsymbol{m}\mathbf{u} - \mathbf{u}) \\ &= [\mathbf{h}^T : -\mathbf{h}^T(\boldsymbol{m} + \boldsymbol{I})\mathbf{u}] \\ &= [hkl : -2(hu + lw)], \end{aligned} \tag{1.4.4.13}$$

where

$$\boldsymbol{m} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & \bar{1} & 0 \\ 0 & 0 & 1 \end{pmatrix}$$

is the matrix representing the operation of reflection and $\boldsymbol{I}$ is the unit matrix. For $(\boldsymbol{m}, -\mathbf{u})$ to be an admissible symmetry operator, the phase-shift part of (1.4.4.13), *i.e.* $-2(hu + lw)$, must be an integer (multiple of 2π). The smallest non-negative values of u and w which satisfy this are the pairs: $u = w = 0$, $u = \frac{1}{2}$ and $w = 0$, $u = 0$ and $w = \frac{1}{2}$, and $u = w = \frac{1}{2}$. We have thus obtained four symmetry operators in Fourier space, which are identical (except for the sign of their translational parts) to those of the direct-space monoclinic mirror and glide-plane operations. The fact that the component v cancels out simply means that an arbitrary component of the phase shift can be added along the b^* axis; this is concurrent with arbitrary direct-space translations that appear in the characterization of individual types of space-group operations [see *e.g.* Koch & Fischer (2005)].

Each of the 230 space groups, which leaves invariant a (real and non-negative) function with the periodicity of the crystal, thus has its counterpart which determines the symmetry of the Fourier expansion coefficients of this function, with equivalent positions given in Table A1.4.4.1.

1.4.4.5. Relationships between direct and reciprocal Bravais lattices

Centred Bravais lattices in crystal space give rise to systematic absences of certain classes of reflections (*IT* I, 1952; *IT* A, 1983) and the corresponding points in the reciprocal lattice have accordingly zero weights. These absences are periodic in reciprocal space and their 'removal' from the reciprocal lattice results in a lattice which – like the direct one – must belong to one of the fourteen Bravais lattice types. This must be so since the point group of a crystal leaves its lattice – and also the associated reciprocal lattice – unchanged. The magnitudes of the structure factors (the weight functions) are also invariant under the operation of this point group.

The correspondence between the types of centring in direct and reciprocal lattices is given in Table 1.4.4.1.

Notes:

(i) The vectors $\mathbf{a}^*$, $\mathbf{b}^*$ and $\mathbf{c}^*$, appearing in the definition of the multiple unit cell in the reciprocal lattice, define this lattice *prior to the removal* of lattice points with zero weights (absences). All the restrictions on *hkl* pertain to indexing on $\mathbf{a}^*$, $\mathbf{b}^*$ and $\mathbf{c}^*$.

(ii) The centring type of the reciprocal lattice refers to the multiple unit cell given in the table.

(iii) The centring type denoted by $R_{\rm hex}$ is a representation of the rhombohedral lattice R by a triple hexagonal unit cell, in the obverse setting (*IT* I, 1952), *i.e.* according to the transformation

$$\begin{aligned} \mathbf{a} &= \mathbf{a}_R - \mathbf{b}_R \\ \mathbf{b} &= \mathbf{b}_R - \mathbf{c}_R \\ \mathbf{c} &= \mathbf{a}_R + \mathbf{b}_R + \mathbf{c}_R, \end{aligned} \tag{1.4.4.14}$$

where $\mathbf{a}_R$, $\mathbf{b}_R$ and $\mathbf{c}_R$ pertain to a primitive unit cell in the rhombohedral lattice R.

The corresponding multiple reciprocal cell, with centring denoted by $R_{\rm hex}$, contains nine lattice points with coordinates 000, 021, 012, 101, 202, 110, 220, 211 and 122 – indexed on the usual reciprocal to the triple hexagonal unit cell defined by (1.4.4.14). Detailed derivations of these correspondences are given by Buerger (1942), and an elementary proof of the reciprocity of I and F lattices can be found, *e.g.*, in pamphlet No. 4 of the Commission on Crystallographic Teaching (Authier, 1981).

Intuitive proofs follow directly from the restrictions on *hkl*, given in Table 1.4.4.1.

APPENDIX A1.4.1
Comments on the preparation and usage of the tables

By U. Shmueli

The straightforward but rather extensive calculations and text processing related to Tables A1.4.3.1 through A1.4.3.7 and Table A1.4.4.1 in Appendices 1.4.3 and 1.4.4, respectively, were performed with the aid of a combination of FORTRAN and REDUCE (Hearn, 1973) programs, designed so as to enable the author to produce the table entries directly from a space-group symbol and with a minimum amount of intermediate manual intervention. The first stage of the calculation, the generation of a space group (coordinates of the equivalent positions), was accomplished with the program *SPGRGEN*, the algorithm of which was described in some detail elsewhere (Shmueli, 1984). A complete list of computer-adapted space-group symbols, processed by *SPGRGEN* and not given in the latter reference, is presented in Table A1.4.2.1 of Appendix 1.4.2.

The generation of the space group is followed by a construction of symbolic expressions for the scalar products $\mathbf{h}^T(\boldsymbol{P}\mathbf{r}+\mathbf{t})$; *e.g.* for position No. (13) in the space group $P4_132$ (No. 213, *IT* I, 1952, *IT* A, 1983), this scalar product is given by $h(\frac{3}{4}+y)+k(\frac{1}{4}+x)+l(\frac{1}{4}-z)$. The construction of the various table entries consists of expanding the sines and cosines of these scalar products, performing the required summations, and simplifying the result where possible. The construction of the scalar products in a FORTRAN program is fairly easy and the extremely tedious trigonometric calculations required by equations (1.4.2.19) and (1.4.2.20) can be readily performed with the aid of one of several available computer-algebraic languages (for a review, see *Computers in the New Laboratory – a Nature Survey*, 1981); the REDUCE language was employed for the above purpose.

Since the REDUCE programs required for the summations in (1.4.2.19) and (1.4.2.20) for the various space groups were seen to have much in common, it was decided to construct a FORTRAN interface which would process the space-group input and prepare automatically REDUCE programs for the algebraic work. The least straightforward problem encountered during this work was the need to 'convince' the interface to generate *hkl* parity assignments which are appropriate to the space-group information input. This was solved for all the crystal families except the hexagonal by setting up a 'basis' of the form: $h/2, k/2, l/2, (k+l)/2, \ldots, (h+k+l)/4$ and representing the translation parts of the scalar products, $\mathbf{h}^T\mathbf{t}$, as sums of such 'basis functions'. A subsequent construction of an automatic parity routine proved to be easy and the interface could thus produce any number of REDUCE programs for the summations in (1.4.2.19) and (1.4.2.20) using a list of space-group symbols as the sole input. These included trigonal and hexagonal space groups with translation components of $\frac{1}{2}$. This approach seemed to be too awkward for some space groups containing threefold and sixfold screw axes, and these were treated individually.

There is little to say about the REDUCE programs, except that the output they generate is at the same level of trigonometric complexity as the expressions for A and B appearing in Volume I (*IT* I, 1952). This could have been improved by making use of the pattern-matching capabilities that are incorporated in REDUCE, but it was found more convenient to construct a FORTRAN interpreter which would detect in the REDUCE output the basic building blocks of the trigonometric structure factors (see Section 1.4.3.3) and perform the required transformations.

Tables A1.4.3.1–A1.4.3.7 were thus constructed with the aid of a chain composed of (i) a space-group generating routine, (ii) a FORTRAN interface, which processes the space-group input and 'writes' a complete REDUCE program, (iii) execution of the REDUCE program and (iv) a FORTRAN interpreter of the REDUCE output in terms of the abbreviated symbols to be used in the tables. The computation was at a 'one-group-at-a-time' basis and the automation of its repetition was performed by means of procedural constructs at the operating-system level. The construction of Table A1.4.4.1 involved only the preliminary stage of the processing of the space-group information by the FORTRAN interface. All the computations were carried out on a Cyber 170–855 at the Tel Aviv University Computation Center.

It is of some importance to comment on the recommended usage of the tables included in this chapter in automatic computations. If, for example, we wish to compute the expression: $A=-8(\mathrm{Escs}+\mathrm{Ossc})$, use can be made of the facility provided by most versions of FORTRAN of transferring subprogram names as parameters of a FUNCTION. We thus need only two FUNCTIONs for any calculation of A and B for a cubic space group, one FUNCTION for the block of even permutations of x, y and z:

```
      FUNCTION E(P,Q,R)
      EXTERNAL SIN,COS
      COMMON/TSF/TPH,TPK,TPL,X,Y,Z
      E = P(TPH * X) * Q(TPK * Y) * R(TPL * Z)
     1 + P(TPH * Z) * Q(TPK * X) * R(TPL * Y)
     2 + P(TPH * Y) * Q(TPK * Z) * R(TPL * X)
      RETURN
      END
```

where TPH, TPK and TPL denote $2\pi h$, $2\pi k$ and $2\pi l$, respectively, and a similar FUNCTION, say O(P,Q,R), for the block of odd permutations of x, y and z. The calling statement in the calling (sub)program can thus be:

```
A = -8 * (E(SIN,COS,SIN) + O(SIN,SIN,COS)).
```

A small number of such FUNCTIONs suffices for all the space-group-specific computations that involve trigonometric structure factors.

APPENDIX A1.4.2
Space-group symbols for numeric and symbolic computations

A1.4.2.1. Introduction

By U. Shmueli, S. R. Hall and R. W. Grosse-Kunstleve

This appendix lists two sets of computer-adapted space-group symbols which are implemented in existing crystallographic software and can be employed in the automated generation of space-group representations. The computer generation of space-group symmetry information is of well known importance in many crystallographic calculations, numeric as well as symbolic. A prerequisite for a computer program that generates this information is a set of computer-adapted space-group symbols which are based on the generating elements of the space group to be derived. The sets of symbols to be presented are:

(i) *Explicit symbols*. These symbols are based on the classification of crystallographic point groups and space groups by Zachariasen (1945). These symbols are termed *explicit* because they contain in an explicit manner the rotation and translation parts of the space-group generators of the space group to be derived and used. These computer-adapted explicit symbols were proposed by Shmueli (1984), who also describes in detail their implementation in the program *SPGRGEN*. This program was used for the automatic preparation of the structure-factor tables for the 17 plane groups and 230 space groups, listed in Appendix 1.4.3, and the 230 space groups in reciprocal space, listed in Appendix 1.4.4. The explicit symbols presented in this appendix are adapted to the 306 representations of the 230 space groups as presented in *IT* A (1983) with regard to the standard settings and choice of space-group origins.

The symmetry-generating algorithm underlying the explicit symbols, and their definition, are given in Section A1.4.2.2 of this appendix and the explicit symbols are listed in Table A1.4.2.1.

(ii) *Hall symbols*. These symbols are based on the implied-origin notation of Hall (1981*a*,*b*), who also describes in detail the algorithm implemented in the program *SGNAME* (Hall, 1981*a*). In the first edition of *IT* B (1993), the term 'concise space-group symbols' was used for this notation. In recent years, however, the term 'Hall symbols' has come into use in symmetry papers (Altermatt & Brown, 1987; Grosse-Kunstleve, 1999), software applications (Hovmöller, 1992; Grosse-Kunstleve, 1995; Larine *et al.*, 1995; Dowty, 1997) and data-handling approaches (Bourne *et al.*, 1998). This term has therefore been adopted for the second edition.

The main difference in the definition of the Hall symbols between this edition and the first edition of *IT* B is the generalization of the origin-shift vector to a full change-of-basis matrix. The examples have been expanded to show how this matrix is applied. The notation has also been made more consistent, and a typographical error in a default axis direction has been corrected.[1] The lattice centring symbol 'H' has been added to Table A1.4.2.2. In addition, Hall symbols are now provided for 530 settings to include all settings from Table 4.3.1 of *IT* A (1983). Namely, all nonstandard symbols for the monoclinic and orthorhombic space groups are included.

Some of the space-group symbols listed in Table A1.4.2.7 differ from those listed in Table B.6 (p. 119) of the first edition of *IT* B. This is because the symmetry of many space groups can be represented by more than one subset of 'generator' elements and these lead to different Hall symbols. The symbols listed in this edition have been selected after first sorting the symmetry elements into a strictly prescribed order based on the shape of their Seitz matrices, whereas those in Table B.6 were selected from symmetry elements in the order of *IT* I (1965). Software for selecting the Hall symbols listed in Table A1.4.2.7 is freely available (Hall, 1997). These symbols and their equivalents in the first edition of *IT* B will generate identical symmetry elements, but the former may be used as a reference table in a strict mapping procedure between different symmetry representations (Hall *et al.*, 2000).

The Hall symbols are defined in Section A1.4.2.3 of this appendix and are listed in Table A1.4.2.7.

A1.4.2.2. Explicit symbols

By U. Shmueli

As shown elsewhere (Shmueli, 1984), the set of representative operators of a crystallographic space group [*i.e.* the set that is listed for each space group in the symmetry tables of *IT* A (1983) and automatically regenerated for the purpose of compiling the symmetry tables in the present chapter] may have one of the following forms:

$$\begin{aligned} &\{(\mathbf{Q}, \mathbf{u})\}, \\ &\{(\mathbf{Q}, \mathbf{u})\} \times \{(\mathbf{R}, \mathbf{v})\}, \quad \text{or} \\ &\{(\mathbf{P}, \mathbf{t})\} \times [\{(\mathbf{Q}, \mathbf{u})\} \times \{(\mathbf{R}, \mathbf{v})\}], \end{aligned} \tag{A1.4.2.1}$$

where **P**, **Q** and **R** are point-group operators, and **t**, **u** and **v** are zero vectors or translations not belonging to the lattice-translations subgroup. Each of the forms in (A1.4.2.1), enclosed in braces, is evaluated as, *e.g.*,

$$\{(\mathbf{P}, \mathbf{t})\} = \{(\mathbf{I}, \mathbf{0}), (\mathbf{P}, \mathbf{t}), (\mathbf{P}, \mathbf{t})^2, \ldots, (\mathbf{P}, \mathbf{t})^{g-1}\}, \tag{A1.4.2.2}$$

where **I** is a unit operator and g is the order of the rotation operator **P** (*i.e.* $\mathbf{P}^g = \mathbf{I}$). The representative operations of the space group are evaluated by expanding the generators into cyclic groups, as in (A1.4.2.2), and forming, as needed, ordered products of the expanded groups as indicated in (A1.4.2.1) and explained in detail in the original article (Shmueli, 1984). The rotation and translation parts of the generators (**P**, **t**), (**Q**, **u**) and (**R**, **v**) presented here were adapted to the settings and choices of origin used in the main symmetry tables of *IT* A (1983).

The general structure of a three-generator symbol, corresponding to the last line of (A1.4.2.1), as represented in Table A1.4.2.1, is

$$\mathrm{LSC\$r_1Pt_1t_2t_3\$r_2Qu_1u_2u_3\$r_3Rv_1v_2v_3}, \tag{A1.4.2.3}$$

where

L – lattice type; can be P, A, B, C, I, F, or R. The symbol R is used only for the seven rhombohedral space groups in their representations in rhombohedral and hexagonal axes [obverse setting (*IT* I, 1952)].

S – crystal system; can be A (triclinic), M (monoclinic), O (orthorhombic), T (tetragonal), R (trigonal), H (hexagonal) or C (cubic).

C – status of centrosymmetry; can be C or N according as the space group is centrosymmetric or noncentrosymmetric, respectively.

$ – this character is followed by six characters that define a generator of the space group.

r_i – indicator of the type of rotation that follows: r_i is P or I according as the rotation part of the ith generator is proper or improper, respectively.

P, Q, R – two-character symbols of matrix representations of the point-group rotation operators **P**, **Q** and **R**, respectively (see below).

$t_1t_2t_3$, $u_1u_2u_3$, $v_1v_2v_3$ – components of the translation parts of the generators, given in units of $\frac{1}{12}$; *e.g.* the translation part $(0\ \frac{1}{2}\ \frac{3}{4})$ is given in Table A1.4.2.1 as 069. *An exception*: $(0\ 0\ \frac{5}{6})$ is denoted by 005 and not by 0010.

The two-character symbols for the matrices of rotation, which appear in the explicit space-group symbols in Table A1.4.2.1, are defined as follows:

[1] The correct default axis direction $\mathbf{a} - \mathbf{b}$ of an N preceded by 3 or 6 replaces $\mathbf{a} + \mathbf{b}$ on p. 117, right-hand column, line 4, in the first edition of *IT* B.

where only matrices of proper rotation are given (and required), since the corresponding matrices of improper rotation are created by the program for appropriate value of the r_i indicator. The first character of a symbol is the order of the axis of rotation and the second character specifies its orientation: in terms of direct-space lattice vectors, we have

$$\mathtt{A}=[100],\ \mathtt{B}=[010],\ \mathtt{C}=[001],\ \mathtt{D}=[110],$$
$$\mathtt{E}=[1\bar{1}0],\ \mathtt{F}=[100],\ \mathtt{G}=[210]\ \text{and}\ \mathtt{Q}=[111]$$

for the standard orientations of the axes of rotation. Note that the axes 2F, 2G, 3C and 6C appear in trigonal and hexagonal space groups.

In the above scheme a space group is determined by one, two or at most three generators [see (A1.4.2.1)]. It should be pointed out that a convenient way of achieving a representation of the space group in any setting and relative to any origin is to start from the standard generators in Table A1.4.2.1 and let the computer program perform the appropriate transformation of the generators only, as in equations (1.4.4.4) and (1.4.4.5). The subsequent expansion of the transformed generators and the formation of the required products [see (A1.4.2.1)

Table A1.4.2.2. *Lattice symbol L*

The lattice symbol L implies Seitz matrices for the lattice translations. For noncentrosymmetric lattices the rotation parts of the Seitz matrices are for *1* (see Table A1.4.2.4). For centrosymmetric lattices the rotation parts are *1* and *−1*. The translation parts in the fourth columns of the Seitz matrices are listed in the last column of the table. The total number of matrices implied by each symbol is given by **nS**.

Noncentrosymmetric		Centrosymmetric		
Symbol	**nS**	Symbol	**nS**	Implied lattice translation(s)
P	1	−P	2	$0,0,0$
A	2	−A	4	$0,0,0 \quad 0,\frac{1}{2},\frac{1}{2}$
B	2	−B	4	$0,0,0 \quad \frac{1}{2},0,\frac{1}{2}$
C	2	−C	4	$0,0,0 \quad \frac{1}{2},\frac{1}{2},0$
I	2	−I	4	$0,0,0 \quad \frac{1}{2},\frac{1}{2},\frac{1}{2}$
R	3	−R	6	$0,0,0 \quad \frac{2}{3},\frac{1}{3},\frac{1}{3} \quad \frac{1}{3},\frac{2}{3},\frac{2}{3}$
H	3	−H	6	$0,0,0 \quad \frac{2}{3},\frac{1}{3},0 \quad \frac{1}{3},\frac{2}{3},0$
F	4	−F	8	$0,0,0 \quad 0,\frac{1}{2},\frac{1}{2} \quad \frac{1}{2},0,\frac{1}{2} \quad \frac{1}{2},\frac{1}{2},0$

and (A1.4.2.2)] leads to the new representation of the space group.

In order to illustrate an explicit space-group symbol consider, for example, the symbol for the space group $Ia\bar{3}d$, as given in Table A1.4.2.1:

```
ICC$I3Q000$P4C393$P2D933.
```

The first three characters tell us that the Bravais lattice of this space group is of type I, that the space group is centrosymmetric and that it belongs to the cubic system. We then see that the generators are (i) an improper threefold axis along [111] (I3Q) with a zero translation part, (ii) a proper fourfold axis along [001] (P4C) with translation part (1/4, 3/4, 1/4) and (iii) a proper twofold axis along [110] (P2D) with translation part (3/4, 1/4, 1/4).

If we make use of the above-outlined interpretation of the explicit symbol (A1.4.2.3), the space-group symmetry transformations in direct space, corresponding to these three generators of the space group $Ia\bar{3}d$, become

$$\left[\begin{pmatrix} 0 & 0 & \bar{1} \\ \bar{1} & 0 & 0 \\ 0 & \bar{1} & 0 \end{pmatrix}\begin{pmatrix} x \\ y \\ z \end{pmatrix} + \begin{pmatrix} 0 \\ 0 \\ 0 \end{pmatrix}\right] = \begin{pmatrix} \bar{z} \\ \bar{x} \\ \bar{y} \end{pmatrix},$$

$$\left[\begin{pmatrix} 0 & \bar{1} & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 1 \end{pmatrix}\begin{pmatrix} x \\ y \\ z \end{pmatrix} + \begin{pmatrix} \frac{1}{4} \\ \frac{3}{4} \\ \frac{1}{4} \end{pmatrix}\right] = \begin{pmatrix} \frac{1}{4}-y \\ \frac{3}{4}+x \\ \frac{1}{4}+z \end{pmatrix},$$

$$\left[\begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & \bar{1} \end{pmatrix}\begin{pmatrix} x \\ y \\ z \end{pmatrix} + \begin{pmatrix} \frac{3}{4} \\ \frac{1}{4} \\ \frac{1}{4} \end{pmatrix}\right] = \begin{pmatrix} \frac{3}{4}+y \\ \frac{1}{4}+x \\ \frac{1}{4}-z \end{pmatrix}.$$

The corresponding symmetry transformations in reciprocal space, in the notation of Section 1.4.4, are

$$\left[(hkl)\begin{pmatrix} 0 & 0 & \bar{1} \\ \bar{1} & 0 & 0 \\ 0 & \bar{1} & 0 \end{pmatrix} : -(hkl)\begin{pmatrix} 0 \\ 0 \\ 0 \end{pmatrix}\right] = [\overline{klh} : 0];$$

similarly, $[k\bar{h}l : -131/4]$ and $[kh\bar{l} : -311/4]$ are obtained from the second and third generator of $Ia\bar{3}d$, respectively.

The first column of Table A1.4.2.1 lists the conventional space-group number. The second column shows the conventional short Hermann–Mauguin or international space-group symbol, and the third column, *Comments*, shows the full international space-group symbol *only* for the different settings of the monoclinic space groups that are given in the main space-group tables of *IT* A (1983). Other comments pertain to the choice of the space-group origin – where there are alternatives – and to axial systems. The fourth column shows the explicit space-group symbols described above for each of the settings considered in *IT* A (1983).

A1.4.2.3. Hall symbols

By S. R. Hall and R. W. Grosse-Kunstleve

The explicit-origin space-group notation proposed by Hall (1981*a*) is based on a subset of the symmetry operations, in the form of Seitz matrices, sufficient to uniquely define a space group. The concise unambiguous nature of this notation makes it well suited to handling symmetry in computing and database applications.

Table A1.4.2.7 lists space-group notation in several formats. The first column of Table A1.4.2.7 lists the space-group numbers with axis codes appended to identify the nonstandard settings. The second column lists the Hermann–Mauguin symbols in computer-entry format with appended codes to identify the origin and cell choice when there are alternatives. The general forms of the Hall notation are listed in the fourth column and the computer-entry representations of these symbols are listed in the third column. The computer-entry format is the general notation expressed as case-insensitive ASCII characters with the overline (bar) symbol replaced by a minus sign.

The Hall notation has the general form:

$$\mathbf{L}[\mathbf{N}_\mathbf{T}^\mathbf{A}]_\mathbf{1} \ldots [\mathbf{N}_\mathbf{T}^\mathbf{A}]_\mathbf{p}\mathbf{V}. \qquad \text{(A1.4.2.4)}$$

Table A1.4.2.3. *Translation symbol T*

The symbol T specifies the translation elements of a Seitz matrix. Alphabetical symbols (given in the first column) specify translations along a fixed direction. Numerical symbols (given in the third column) specify translations as a fraction of the rotation order |N| and in the direction of the implied or explicitly defined axis.

Translation symbol	Translation vector	Subscript symbol	Fractional translation
a	$\frac{1}{2},0,0$	*1* in 3_1	$\frac{1}{3}$
b	$0,\frac{1}{2},0$	*2* in 3_2	$\frac{2}{3}$
c	$0,0,\frac{1}{2}$	*1* in 4_1	$\frac{1}{4}$
n	$\frac{1}{2},\frac{1}{2},\frac{1}{2}$	*3* in 4_3	$\frac{3}{4}$
u	$\frac{1}{4},0,0$	*1* in 6_1	$\frac{1}{6}$
v	$0,\frac{1}{4},0$	*2* in 6_2	$\frac{1}{3}$
w	$0,0,\frac{1}{4}$	*4* in 6_4	$\frac{2}{3}$
d	$\frac{1}{4},\frac{1}{4},\frac{1}{4}$	*5* in 6_5	$\frac{5}{6}$

Table A1.4.2.4. *Rotation matrices for principal axes*

The 3 × 3 matrices for *proper* rotations along the three principal unit-cell directions are given below. The matrices for *improper* rotations (*−1*, *−2*, *−3*, *−4* and *−6*) are identical except that the signs of the elements are reversed.

Axis	Symbol A	Rotation order				
		1	*2*	*3*	*4*	*6*
a	*x*	$\begin{pmatrix}1&0&0\\0&1&0\\0&0&1\end{pmatrix}$	$\begin{pmatrix}1&0&0\\0&\bar{1}&0\\0&0&\bar{1}\end{pmatrix}$	$\begin{pmatrix}1&0&0\\0&0&\bar{1}\\0&1&\bar{1}\end{pmatrix}$	$\begin{pmatrix}1&0&0\\0&0&\bar{1}\\0&1&0\end{pmatrix}$	$\begin{pmatrix}1&0&0\\0&1&\bar{1}\\0&1&0\end{pmatrix}$
b	*y*	$\begin{pmatrix}1&0&0\\0&1&0\\0&0&1\end{pmatrix}$	$\begin{pmatrix}\bar{1}&0&0\\0&1&0\\0&0&\bar{1}\end{pmatrix}$	$\begin{pmatrix}\bar{1}&0&1\\0&1&0\\\bar{1}&0&0\end{pmatrix}$	$\begin{pmatrix}0&0&1\\0&1&0\\\bar{1}&0&0\end{pmatrix}$	$\begin{pmatrix}0&0&1\\0&1&0\\\bar{1}&0&1\end{pmatrix}$
c	*z*	$\begin{pmatrix}1&0&0\\0&1&0\\0&0&1\end{pmatrix}$	$\begin{pmatrix}\bar{1}&0&0\\0&\bar{1}&0\\0&0&1\end{pmatrix}$	$\begin{pmatrix}0&\bar{1}&0\\1&\bar{1}&0\\0&0&1\end{pmatrix}$	$\begin{pmatrix}0&\bar{1}&0\\1&0&0\\0&0&1\end{pmatrix}$	$\begin{pmatrix}1&\bar{1}&0\\1&0&0\\0&0&1\end{pmatrix}$

L is the symbol specifying the lattice translational symmetry (see Table A1.4.2.2). The integral translations are implicitly included in the set of generators. If **L** has a leading minus sign, it also specifies an inversion centre at the origin. $[\mathbf{N}^{\mathbf{A}}_{\mathbf{T}}]_{\mathbf{n}}$ specifies the 4 × 4 Seitz matrix $\mathbf{S}_{\mathbf{n}}$ of a symmetry element in the minimum set which defines the space-group symmetry (see Tables A1.4.2.3 to A1.4.2.6), and **p** is the number of elements in the set. **V** is a change-of-basis operator needed for less common descriptions of the space-group symmetry.

The matrix symbol $\mathbf{N}^{\mathbf{A}}_{\mathbf{T}}$ is composed of three parts: **N** is the symbol denoting the |N|-fold order of the rotation matrix (see Tables A1.4.2.4, A1.4.2.5 and A1.4.2.6), **T** is a subscript symbol denoting the *translation* vector (see Table A1.4.2.3) and **A** is a superscript symbol denoting the *axis* of rotation.

The computer-entry format of the Hall notation contains the rotation-order symbol **N** as positive integers *1*, *2*, *3*, *4*, or *6* for proper rotations and as negative integers *−1*, *−2*, *−3*, *−4* or *−6* for improper rotations. The **T** translation symbols *1*, *2*, *3*, *4*, *5*, *6*, *a*, *b*, *c*, *n*, *u*, *v*, *w*, *d* are described in Table A1.4.2.3. These translations apply additively [*e.g. ad* signifies a $(\frac{3}{4}, \frac{1}{4}, \frac{1}{4})$ translation]. The **A** axis symbols *x*, *y*, *z* denote rotations about the axes **a**, **b** and **c**, respectively (see Table A1.4.2.4). The axis symbols ″ and ′ signal rotations about the body-diagonal vectors **a** + **b** (or alternatively **b** + **c** or **c** + **a**) and **a** − **b** (or alternatively **b** − **c** or **c** − **a**) (see Table A1.4.2.5). The axis symbol * always refers to a threefold rotation along **a** + **b** + **c** (see Table A1.4.2.6).

The change-of-basis operator **V** has the general form (v_x, v_y, v_z). The vectors v_x, v_y and v_z are specified by

$$\begin{aligned} v_x &= r_{1,1}X + r_{1,2}Y + r_{1,3}Z + \mathbf{t}_1 \\ v_y &= r_{2,1}X + r_{2,2}Y + r_{2,3}Z + \mathbf{t}_2\,, \\ v_z &= r_{3,1}X + r_{3,2}Y + r_{3,3}Z + \mathbf{t}_3 \end{aligned}$$

where $r_{i,j}$ and $\mathbf{t}_i$ are fractions or real numbers. Terms in which $r_{i,j}$ or $\mathbf{t}_i$ are zero need not be specified. The 4 × 4 change-of-basis matrix operator **V** is defined as

$$\mathbf{V} = \begin{pmatrix} r_{1,1} & r_{1,2} & r_{1,3} & \mathbf{t}_1 \\ r_{2,1} & r_{2,2} & r_{2,3} & \mathbf{t}_2 \\ r_{3,1} & r_{3,2} & r_{3,3} & \mathbf{t}_3 \\ 0 & 0 & 0 & 1 \end{pmatrix}.$$

The transformed symmetry operations are derived from the specified Seitz matrices $\mathbf{S}_{\mathbf{n}}$ as

$$\mathbf{S}'_{\mathbf{n}} = \mathbf{V} \cdot \mathbf{S}_{\mathbf{n}} \cdot \mathbf{V}^{-1}$$

and from the integral translations **t**(1, 0, 0), **t**(0, 1, 0) and **t**(0, 0, 1) as

$$(\mathbf{t}'_{\mathbf{n}}, \mathbf{1})^T = \mathbf{V} \cdot (\mathbf{t}_{\mathbf{n}}, \mathbf{1})^T.$$

A shorthand form of **V** may be used when the change-of-basis operator only translates the origin of the basis system. In this form v_x, v_y and v_z are specified simply as shifts in twelfths, implying the matrix operator

Table A1.4.2.5. *Rotation matrices for face-diagonal axes*

The symbols for face-diagonal twofold rotations are *2′* and *2″*. The face-diagonal axis direction is determined by the axis of the preceding rotation N^x, N^y or N^z. Note that the single prime ′ is the default and may be omitted.

Preceding rotation	Rotation	Axis	Matrix
N^x	*2′*	**b** − **c**	$\begin{pmatrix}\bar{1}&0&0\\0&0&\bar{1}\\0&\bar{1}&0\end{pmatrix}$
	2″	**b** + **c**	$\begin{pmatrix}\bar{1}&0&0\\0&0&1\\0&1&0\end{pmatrix}$
N^y	*2′*	**a** − **c**	$\begin{pmatrix}0&0&\bar{1}\\0&\bar{1}&0\\\bar{1}&0&0\end{pmatrix}$
	2″	**a** + **c**	$\begin{pmatrix}0&0&1\\0&\bar{1}&0\\1&0&0\end{pmatrix}$
N^z	*2′*	**a** − **b**	$\begin{pmatrix}0&\bar{1}&0\\\bar{1}&0&0\\0&0&\bar{1}\end{pmatrix}$
	2″	**a** + **b**	$\begin{pmatrix}0&1&0\\1&0&0\\0&0&\bar{1}\end{pmatrix}$

Table A1.4.2.6. *Rotation matrix for the body-diagonal axis*

The symbol for the threefold rotation in the **a** + **b** + **c** direction is *3**. Note that for cubic space groups the body-diagonal axis is implied and the asterisk * may be omitted.

Axis	Rotation	Matrix
a + **b** + **c**	*3**	$\begin{pmatrix}0&0&1\\1&0&0\\0&1&0\end{pmatrix}$

$$\mathbf{V} = \begin{pmatrix} 1 & 0 & 0 & v_x/12 \\ 0 & 1 & 0 & v_y/12 \\ 0 & 0 & 1 & v_z/12 \\ 0 & 0 & 0 & 1 \end{pmatrix}.$$

In the shorthand form of **V**, the commas separating the vectors may be omitted.

A1.4.2.3.1. Default axes

For most symbols the rotation axes applicable to each **N** are implied and an explicit axis symbol **A** is not needed. The rules for *default* axis directions are:

(i) the *first* rotation or roto-inversion has an axis direction of **c**;

(ii) the *second* rotation (if |N| is 2) has an axis direction of **a** if preceded by an |N| of 2 or 4, **a**−**b** if preceded by an |N| of 3 or 6;

(iii) the *third* rotation (if |N| is 3) has an axis direction of **a** + **b** + **c**.

A1.4.2.3.2. Example matrices

The following examples show how the notation expands to Seitz matrices.

The notation $\bar{2}_c^x$ represents an improper twofold rotation along **a** and a **c**/2 translation:

$$-2\text{xc} = \begin{pmatrix} -1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & \frac{1}{2} \\ 0 & 0 & 0 & 1 \end{pmatrix}.$$

The notation 3^* represents a threefold rotation along **a** + **b** + **c**:

$$3^* = \begin{pmatrix} 0 & 0 & 1 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}.$$

The notation 4_{vw} represents a fourfold rotation along **c** (implied) and translation of **b**/4 and **c**/4:

$$4\text{vw} = \begin{pmatrix} 0 & -1 & 0 & 0 \\ 1 & 0 & 0 & \frac{1}{4} \\ 0 & 0 & 1 & \frac{1}{4} \\ 0 & 0 & 0 & 1 \end{pmatrix}.$$

The notation 6_1 2 (0 0 −1) represents a 6_1 screw along **c**, a twofold rotation along **a** − **b** and an origin shift of −**c**/12. Note that the 6_1 matrix is unchanged by the shifted origin whereas the *2* matrix is changed by −**c**/6.

$$\begin{aligned} &61\,2\,(0\,0\,-1) \\ &\quad = \begin{pmatrix} 1 & -1 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & \frac{1}{6} \\ 0 & 0 & 0 & 1 \end{pmatrix}, \begin{pmatrix} 0 & -1 & 0 & 0 \\ -1 & 0 & 0 & 0 \\ 0 & 0 & -1 & \frac{5}{6} \\ 0 & 0 & 0 & 1 \end{pmatrix}. \end{aligned}$$

The change-of-basis vector (0 0 −1) could also be entered as $(x, y, z - 1/12)$.

The *reverse setting of the R-centred lattice* (hexagonal axes) is specified using a change-of-basis transformation applied to the standard *obverse setting* (see Table A1.4.2.2). The obverse Seitz matrices are

$$\text{R}\,3 = \begin{pmatrix} 1 & 0 & 0 & \frac{1}{3} \\ 0 & 1 & 0 & \frac{2}{3} \\ 0 & 0 & 1 & \frac{2}{3} \\ 0 & 0 & 0 & 1 \end{pmatrix}, \begin{pmatrix} 1 & 0 & 0 & \frac{2}{3} \\ 0 & 1 & 0 & \frac{1}{3} \\ 0 & 0 & 1 & \frac{1}{3} \\ 0 & 0 & 0 & 1 \end{pmatrix}, \begin{pmatrix} 0 & -1 & 0 & 0 \\ 1 & -1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}.$$

The reverse-setting Seitz matrices are

$$\begin{aligned} &\text{R}\,3\,(-\text{x}, -\text{y}, \text{z}) \\ &\quad = \begin{pmatrix} 1 & 0 & 0 & \frac{1}{3} \\ 0 & 1 & 0 & \frac{2}{3} \\ 0 & 0 & 1 & \frac{1}{3} \\ 0 & 0 & 0 & 1 \end{pmatrix}, \begin{pmatrix} 1 & 0 & 0 & \frac{2}{3} \\ 0 & 1 & 0 & \frac{1}{3} \\ 0 & 0 & 1 & \frac{2}{3} \\ 0 & 0 & 0 & 1 \end{pmatrix}, \begin{pmatrix} 0 & -1 & 0 & 0 \\ 1 & -1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}. \end{aligned}$$

The conventional primitive hexagonal lattice may be transformed to a *C-centred orthohexagonal setting* using the change-of-basis operator

$$\text{P}\,6\,(\text{x} - 1/2\text{y}, 1/2\text{y}, \text{z}) = \begin{pmatrix} \frac{1}{2} & -\frac{3}{2} & 0 & 0 \\ \frac{1}{2} & \frac{1}{2} & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}.$$

In this case the lattice translation for the *C* centring is obtained by transforming the integral translation **t**(0, 1, 0):

$$\begin{aligned} \boldsymbol{V} \cdot \begin{pmatrix} 0 & 1 & 0 & 1 \end{pmatrix}^T &= \begin{pmatrix} 1 & -\frac{1}{2} & 0 & 0 \\ 0 & \frac{1}{2} & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} 0 \\ 1 \\ 0 \\ 1 \end{pmatrix} \\ &= \begin{pmatrix} -\frac{1}{2} & \frac{1}{2} & 0 & 1 \end{pmatrix}^T. \end{aligned}$$

The standard setting of an *I*-centred tetragonal space group may be transformed to a primitive setting using the change-of-basis operator

$$\text{I}\,4\,(\text{y} + \text{z}, \text{x} + \text{z}, \text{x} + \text{y}) = \begin{pmatrix} 0 & 1 & 0 & 0 \\ 0 & 1 & -1 & 0 \\ -1 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}.$$

Note that in the primitive setting, the fourfold axis is along **a** + **b**.

Table A1.4.2.7. *Hall symbols*

The first column, n:c, lists the space-group numbers and axis codes† separated by a colon. The second column lists the Hermann–Mauguin symbols in computer-entry format. The third column lists the Hall symbols in computer-entry format and the fourth column lists the Hall symbols as described in Tables A1.4.2.2–A1.4.2.6.

n:c	H–M entry	Hall entry	Hall symbol
1	P 1	p 1	P 1

The codes appended to the space-group numbers listed in the first column identify the relationship between the symmetry elements and the crystal cell. Where no code is given the first choice listed below applies. *Monoclinic*. Code = *<unique axis><cell choice>*: unique axis choices [*cf. IT* A (2005) Table 4.3.2.1] b, -b, c, -c, a, -a; cell choices [*cf. IT* A (2005) Table 4.3.2.1] 1, 2, 3. *Orthorhombic*. Code = *<origin choice><setting>*: origin choices 1, 2; setting choices [*cf. IT* A (2005) Table 4.3.2.1] abc, ba-c, cab, -cba, bca, a-cb. *Tetragonal, cubic*. Code = *<origin choice>*: origin choices 1, 2. *Trigonal*. Code = *<cell choice>*: cell choices h (hexagonal), r (rhombohedral).

APPENDIX A1.4.3
Structure-factor tables

Table A1.4.3.1. *Plane groups*

The symbols appearing in this table are explained in Section 1.4.3 and in Tables A1.4.3.3 (monoclinic), A1.4.3.5 (tetragonal) and A1.4.3.6 (trigonal and hexagonal).

System	No.	Symbol	Parity	A	B
Oblique	1	$p1$		c(hk)	s(hk)
	2	$p2$		2c(hk)	0
Rectangular	3	pm		2c(hx)c(ky)	2c(hx)s(ky)
	4	pg	$k = 2n$	2c(hx)c(ky)	2c(hx)s(ky)
			$k = 2n + 1$	−2s(hx)s(ky)	2s(hx)c(ky)
	5	cm		4c(hx)c(ky)	4c(hx)s(ky)
	6	$p2mm$		4c(hx)c(ky)	0
	7	$p2mg$	$h = 2n$	4c(hx)c(ky)	0
			$h = 2n + 1$	−4s(hx)s(ky)	0
	8	$p2gg$	$h + k = 2n$	4c(hx)c(ky)	0
			$h + k = 2n + 1$	−4s(hx)s(ky)	0
	9	$c2mm$		8c(hx)c(ky)	0
Square	10	$p4$		2[P(cc) − M(ss)]	0
	11	$p4mm$		4P(cc)	0
	12	$p4gm$	$h + k = 2n$	4P(cc)	0
			$h + k = 2n + 1$	−4M(ss)	0
Hexagonal	13	$p3$		C(hki)	S(hki)
	14	$p3m1$		PH(cc)	MH(ss)
	15	$p31m$		PH(cc)	PH(ss)
	16	$p6$		2C(hki)	0
	17	$p6mm$		2PH(cc)	0

Table A1.4.3.2. *Triclinic space groups*

For the definition of the triple products ccc, csc *etc*., see Table A1.4.3.4.

$P1$ [No. 1]

hkl	A	B
All	$\cos 2\pi(hx + ky + lz)$ = ccc − css − scs − ssc	$\sin 2\pi(hx + ky + lz)$ = scc + csc + ccs − sss

$P\bar{1}$ [No. 2]

hkl	A	B
All	2(ccc − css − scs − ssc)	0

Table A1.4.3.3. *Monoclinic space groups*

Each expression for A or B in the monoclinic system and for the space-group settings chosen in *IT* A is represented in terms of one of the following symbols:

$$\begin{aligned}
&\mathrm{c}(hl)\mathrm{c}(ky) = \cos[2\pi(hx+lz)]\cos(2\pi ky), \quad && \mathrm{c}(hk)\mathrm{c}(lz) = \cos[2\pi(hx+ky)]\cos(2\pi lz),\\
&\mathrm{c}(hl)\mathrm{s}(ky) = \cos[2\pi(hx+lz)]\sin(2\pi ky), \quad && \mathrm{c}(hk)\mathrm{s}(lz) = \cos[2\pi(hx+ky)]\sin(2\pi lz),\\
&\mathrm{s}(hl)\mathrm{c}(ky) = \sin[2\pi(hx+lz)]\cos(2\pi ky), \quad && \mathrm{s}(hk)\mathrm{c}(lz) = \sin[2\pi(hx+ky)]\cos(2\pi lz),\\
&\mathrm{s}(hl)\mathrm{s}(ky) = \sin[2\pi(hx+lz)]\sin(2\pi ky), \quad && \mathrm{s}(hk)\mathrm{s}(lz) = \sin[2\pi(hx+ky)]\sin(2\pi lz), \qquad \text{(A1.4.3.1)}
\end{aligned}$$

where the left-hand column of expressions corresponds to space-group representations in the second setting, with b taken as the unique axis, and the right-hand column corresponds to representations in the first setting, with c taken as the unique axis.

The lattice types in this table are P, A, B, C and I, and are all explicit in the full space-group symbol only (see below). Note that s(hl), s(hk), s(ky) and s(lz) are zero for $h = l = 0$, $h = k = 0$, $k = 0$ and $l = 0$, respectively.

No.	Group symbol		Parity	A	B	Unique axis
	Short	Full

Table A1.4.3.4. *Orthorhombic space groups*

The expressions for A and B for the orthorhombic space groups in their standard settings [as in *IT* A (2005)] contain one, two or four terms of the form

$$\mathrm{pqr} = \mathrm{p}(2\pi hx)\mathrm{q}(2\pi ky)\mathrm{r}(2\pi lz) \qquad \text{(A1.4.3.2)}$$

preceded by a signed numerical constant, where p, q and r can each be either a sine or a cosine function, and the arguments of the functions in any product of the form (A1.4.3.2) are ordered as in (A1.4.3.2). These products are given in this table as ccc, ccs, csc, scc, ssc, scs, css and/or sss, where c and s are abbreviations for 'sin' and 'cos', respectively.

Note that pqr vanishes if at least one of p, q and r is a sine, and the corresponding index h, k or l is zero.

Table A1.4.3.5. *Tetragonal space groups*

The symbols appearing in this table are based on the factorization of the scalar product appearing in equations (1.4.2.19) and (1.4.2.20) into its plane-group and unique-axis components. The symbols are

$$\begin{aligned} \mathrm{P(pq)} &= \mathrm{p}(2\pi hx)\mathrm{q}(2\pi ky) + \mathrm{p}(2\pi hy)\mathrm{q}(2\pi kx) \\ \mathrm{M(pq)} &= \mathrm{p}(2\pi hx)\mathrm{q}(2\pi ky) - \mathrm{p}(2\pi hy)\mathrm{q}(2\pi kx), \end{aligned} \tag{A1.4.3.3}$$

where p and q can each be a sine or a cosine.

Explicit trigonometric functions given in the table follow the convention

$$\mathrm{c}(u) = \cos(2\pi u) \quad \mathrm{s}(u) = \sin(2\pi u).$$

Conditions for vanishing symbols:

$$\begin{gathered} \mathrm{P(ss)} = \mathrm{M(ss)} = 0 \text{ if } h = 0 \text{ or } k = 0, \\ \mathrm{P(sc)} = \mathrm{M(sc)} = 0 \text{ if } h = 0, \\ \mathrm{P(cs)} = \mathrm{M(cs)} = 0 \text{ if } k = 0, \\ \mathrm{M(cc)} = \mathrm{M(ss)} = 0 \text{ if } h = k \text{ or } h = -k, \end{gathered}$$

and any explicit sine function vanishes if all the indices (h and k, or l) appearing in its argument are zero.

Table A1.4.3.6. *Trigonal and hexagonal space groups*

The table lists the expressions for A and B for the space groups belonging to the hexagonal family. For the space groups that are referred to hexagonal axes the expressions are given in terms of symbols related to the decomposition of the scalar products into their plane-group and unique-axis components [*cf.* equations (1.4.3.10)–(1.4.3.12)]. The symbols for the seven rhombohedral space groups in their rhombohedral-axes representation are the same as those used for the cubic space groups [*cf.* equations (1.4.3.4) and (1.4.3.5), and the notes at the start of Table A1.4.3.7]. Factors of the forms $\cos(2\pi x)$ and $\sin(2\pi x)$ are abbreviated by $\mathrm{c}(x)$ and $\mathrm{s}(x)$, respectively. All the symbols used in this table are repeated below. Most expressions are given in terms of

$$\begin{aligned}
\mathrm{C}(hki) &= \mathrm{c}(p_1) + \mathrm{c}(p_2) + \mathrm{c}(p_3),\\
\mathrm{C}(khi) &= \mathrm{c}(q_1) + \mathrm{c}(q_2) + \mathrm{c}(q_3) \text{ and}\\
\mathrm{S}(hki) &= \mathrm{s}(p_1) + \mathrm{s}(p_2) + \mathrm{s}(p_3),\\
\mathrm{S}(khi) &= \mathrm{s}(q_1) + \mathrm{s}(q_2) + \mathrm{s}(q_3),
\end{aligned} \tag{A1.4.3.4}$$

where

$$\begin{aligned}
p_1 &= hx + ky,\ p_2 = kx + iy,\ p_3 = ix + hy,\\
q_1 &= kx + hy,\ q_2 = hx + iy,\ q_3 = ix + ky,
\end{aligned} \tag{A1.4.3.5}$$

and the abbreviations

$$\begin{aligned}
\mathrm{PH(cc)} &= \mathrm{C}(hki) + \mathrm{C}(khi),\\
\mathrm{PH(ss)} &= \mathrm{S}(hki) + \mathrm{S}(khi),\\
\mathrm{MH(cc)} &= \mathrm{C}(hki) - \mathrm{C}(khi) \text{ and}\\
\mathrm{MH(ss)} &= \mathrm{S}(hki) - \mathrm{S}(khi).
\end{aligned} \tag{A1.4.3.6}$$

In addition, the following abbreviations are employed for some space groups:

$$u_1 = lz,\ u_2 = lz + \tfrac{1}{3} \text{ and } u_3 = lz - \tfrac{1}{3}.$$

Conditons for vanishing symbols:

$$\begin{aligned}
&\mathrm{S}(hki) = \mathrm{S}(khi) = 0 \text{ if } h = k = 0,\\
&\mathrm{PH(ss)} = 0 \text{ if } h = -k \text{ (or } k = -i \text{ or } i = -h),\\
&\mathrm{MH(cc)} = 0 \text{ if } |h| = |k| \text{ (or } |k| = |i| \text{ or } |i| = |h|)
\end{aligned}$$

and any explicit sine function vanishes if all the indices (h and k, or l) appearing in its argument are zero.

Table A1.4.3.7. *Cubic space groups*

The symbols appearing in this table are related to the pqr representation used with the orthorhombic space groups as follows: Each of the symbols defined below is a sum of three pqr terms, where the order of *hkl* is fixed in each of the three terms and that of *xyz* is permuted.

This table and parts of Table A1.4.3.6 (rhombohedral space groups referred to rhombohedral axes) are given in terms of the following two symbols:

$$\mathrm{Epqr} = \mathrm{p}(hx)\mathrm{q}(ky)\mathrm{r}(lz) + \mathrm{p}(hy)\mathrm{q}(kz)\mathrm{r}(lx) + \mathrm{p}(hz)\mathrm{q}(kx)\mathrm{r}(ly) \tag{A1.4.3.7}$$

and

$$\mathrm{Opqr} = \mathrm{p}(hx)\mathrm{q}(kz)\mathrm{r}(ly) + \mathrm{p}(hz)\mathrm{q}(ky)\mathrm{r}(lx) + \mathrm{p}(hy)\mathrm{q}(kx)\mathrm{r}(lz), \tag{A1.4.3.8}$$

where p, q and r can each be a sine or a cosine, and the factor 2π has been absorbed in the abbreviations (see text). As in Tables A1.4.3.1–A1.4.3.6, cosine and sine are abbreviated by c and s, respectively. The permutation of the coordinates is even in Epqr and odd in Opqr.

Conditions for vanishing symbols:

Epqr = Opqr = 0 if at least one of p, q, r is a sine and the index h, k or l in its argument is zero,

$$\mathrm{Eccc} - \mathrm{Occc} = 0 \text{ if } |h| = |k| \text{ (or } |k| = |l| \text{ or } |l| = |h|),$$
$$\mathrm{Esss} - \mathrm{Osss} = 0 \text{ if } |h| = |k| \text{ (or } |k| = |l| \text{ or } |l| = |h|),$$
$$\mathrm{Ecss} - \mathrm{Ocss} = \mathrm{Escc} - \mathrm{Oscc} = 0 \text{ if } |k| = |l|,$$
$$\mathrm{Escs} - \mathrm{Oscs} = \mathrm{Ecsc} - \mathrm{Ocsc} = 0 \text{ if } |l| = |h| \text{ and}$$
$$\mathrm{Essc} - \mathrm{Ossc} = \mathrm{Eccs} - \mathrm{Occs} = 0 \text{ if } |h| = |k|.$$

APPENDIX A1.4.4
Crystallographic space groups in reciprocal space

Table A1.4.4.1. *Crystallographic space groups in reciprocal space*

The table entries are described in detail in Section 1.4.4.1. The general format of an entry is

$$(n)\,\mathbf{h}^T\boldsymbol{P}_n : -\mathbf{h}^T\mathbf{t}_n$$

or

$$(n)\,\mathbf{h}^T\boldsymbol{P}_n :,$$

according as the phase-shift part of the entry is nonzero or zero modolo 2π, respectively.

Notes:

(1) For centrosymmetric space groups with the centre located at the unit-cell origin only those entries are given which correspond to symmetry operations not related by inversion. If the origin in such space groups is chosen elsewhere, all the entries corresponding to the operations of the point group are presented.

(2) For trigonal and hexagonal space groups referred to hexagonal axes the Miller–Bravais indices *hkil* are employed, and for the rhombohedral space groups referred to rhombohedral axes the indices are denoted by *hkl* (*cf. IT* I, 1952).

1.5. Crystallographic viewpoints in the classification of space-group representations

By M. I. Aroyo and H. Wondratschek

1.5.1. List of abbreviations and symbols

BC	Bradley & Cracknell (1972)
CDML	Cracknell, Davies, Miller & Love (1979)
IT A	*International Tables for Crystallography*, Volume A (2005)
irreps	Irreducible representations
L; $\mathbf{L}^*$	Vector lattice of a space group $\mathcal{G}$; reciprocal lattice of $\mathcal{G}$
t	Vector of the lattice **L** of $\mathcal{G}$
k	Vector of the reciprocal space
K	Vector of the reciprocal lattice $\mathbf{L}^*$ [see Note (1)]
a, **b**, **c**; $\mathbf{a}^*$, $\mathbf{b}^*$, $\mathbf{c}^*$	Basis vectors of the crystal lattice; basis vectors of the reciprocal lattice
$(\mathbf{a})^T$	Row of basis vectors [see Note (2)]
$(\mathbf{a}^*)$	Column of basis vectors of the reciprocal lattice $\mathbf{L}^*$
X	Point of point space
x, y, z; k_x, k_y, k_z	Point coordinates; vector coefficients
$\boldsymbol{x}$; $\boldsymbol{r}$	Column of point coordinates; column of vector coefficients
$(\boldsymbol{k})^T$	Row of coefficients of a reciprocal-space vector [see Note (2)]
a, b, c	Lengths of the basis vectors of the lattice
α, β, γ	Parameters of **k**-vector coefficients in CDML
a^*, b^*, c^*	Lengths of the basis vectors of the reciprocal lattice
$\boldsymbol{M}$, $\boldsymbol{R}$, $\boldsymbol{D}$, $\boldsymbol{S}$	Matrices
$\boldsymbol{W}$	Matrix part of a mapping
$\boldsymbol{w}$	Column part of a mapping
$(\boldsymbol{A}, \boldsymbol{a})$, $(\boldsymbol{W}, \boldsymbol{w})$	Matrix–column pairs
$\mathcal{G}$; $\mathcal{G}_0$; $(\mathcal{G})^*$	Group or space group; symmorphic space group; reciprocal-space group
$\mathcal{T}$	Translation subgroup of $\mathcal{G}$
$\mathcal{P}$ or $\overline{\mathcal{G}}$; $\mathcal{Q}$	Point group; holohedral point group
$\mathcal{S}$	Site-symmetry group
$\overline{\mathcal{G}}^{\mathbf{k}}$; $\mathcal{L}^{\mathbf{k}}$	Little co-group of **k**; little group of **k**
g, h, e	Group elements of $\mathcal{G}$
2, 3, m	Symmetry operations
$\Gamma(\mathcal{G})$	(Matrix) representation of the group $\mathcal{G}$

Notes: (1) In crystallography, vectors are designated by lower-case bold-face letters. With **K** we make an exception in order to follow the tradition of physics. A crystallographic alternative could be $\mathbf{t}^*$. (2) In crystallography, point coordinates or vector coefficients are written as columns. Therefore, columns are taken as 'normal'. In order to distinguish rows from columns (the coefficients k_i of vectors in reciprocal space, *i.e.* the Miller indices, and the basis of the crystal lattice are written as rows), rows are regarded as transposed columns and are thus marked by $(\ldots)^T$.

1.5.2. Introduction

This chapter on representations widens the scope of the general topics of reciprocal space treated in this volume.

Space-group representations play a growing role in physical applications of crystal symmetry. They are treated in a number of papers and books but comparison of the terms and the listed data is difficult. The main reason for this is the lack of standards in the classification and nomenclature of representations. As a result, the reader is confronted with barely comparable notations used by the different authors, see *e.g.* Stokes & Hatch (1988), Table 7.

The **k** vectors, which can be described as vectors in reciprocal space, play a decisive role in the description and classification of space-group representations. Their symmetry properties are determined by the so-called *reciprocal-space group* $(\mathcal{G})^*$ which is always isomorphic to a symmorphic space group $\mathcal{G}_0$. The different symmetries of **k** vectors correspond to the different kinds of point orbits in the symmorphic space groups $\mathcal{G}_0$. The classification of point orbits into Wyckoff positions in *International Tables for Crystallography* Volume A (*IT* A) (2005) can be used directly to classify the irreducible representations of a space group, abbreviated *irreps*; the Wyckoff positions of the symmorphic space groups $\mathcal{G}_0$ form a basis for a *natural* classification of the irreps. This was first discovered by Wintgen (1941). Similar results have been obtained independently by Raghavacharyulu (1961), who introduced the term reciprocal-space group. In this chapter a classification of irreps is provided which is based on Wintgen's idea.

Although this idea is now more than 60 years old, it has been utilized only rarely and has not yet found proper recognition in the literature and in the existing tables of space-group irreps. Slater (1962) described the correspondence between the special **k** vectors of the Brillouin zone and the Wyckoff positions of space group $Pm\overline{3}m$. Similarly, Jan (1972) compared Wyckoff positions with points of the Brillouin zone when describing the symmetry $Pm\overline{3}$ of the Fermi surface for the pyrite structure. However, the widespread tables of Miller & Love (1967), Zak *et al.* (1969), Bradley & Cracknell (1972) (abbreviated as BC), Cracknell *et al.* (1979) (abbreviated as CDML), and Kovalev (1986) have not made use of this kind of classification and its possibilities, and existing tables are unnecessarily complicated, *cf.* Boyle (1986).

In addition, historical reasons have obscured the classification of irreps and impeded their application. The first considerations of irreps dealt only with space groups of translation lattices (Bouckaert *et al.*, 1936). Later, other space groups were taken into consideration as well. Instead of treating these (lower) symmetries as such, their irreps were derived and classified by starting from the irreps of lattice space groups and proceeding to those of lower symmetry. This procedure has two consequences:

(1) those **k** vectors that are special in a lattice space group are also correspondingly listed in the low-symmetry space group even if they have lost their special properties due to the symmetry reduction;

(2) during the symmetry reduction unnecessary new symbols of **k** vectors are introduced.

The use of the reciprocal-space group $(\mathcal{G})^*$ avoids both these detours.

The relations between the special **k** vectors as listed by CDML and the Wyckoff positions of the space groups of *IT* A have been derived and displayed in figures and tables for a few space groups by Aroyo & Wondratschek (1995). The **k**-vector classification scheme based on Wintgen's (1941) reciprocal-space group approach has been applied meanwhile to all space groups. The compilation of Brillouin-zone figures and **k**-vector correlation tables for the 230 space groups constitutes the wavevector database of the Bilbao Crystallographic Server (1998), a website of crystallographic databases and programs that can be used free

Copyright © 2010 International Union of Crystallography

of charge from any computer with a web browser *via* the Internet (Aroyo, Perez-Mato *et al.*, 2006; Aroyo, Kirov *et al.*, 2006). Simple retrieval tools give direct access to the figures and tables for any space group. The wavevector database available on the server forms the background of the description and classification of the space-group irreps calculated and applied by different programs of the server.

This chapter is a modification of Chapter 1.5 of the second edition of *International Tables for Crystallography*, Volume B, published in 2001. As in the previous edition, we consider in more detail the reciprocal-space group approach and show that widely used crystallographic conventions can be adopted for the classification of space-group representations. Some basic concepts are developed in Section 1.5.3. Possible conventions are discussed in Section 1.5.4. In contrast to Chapter 1.5 in the second edition of *IT* B, the consequences and advantages of the reciprocal-space group approach are demonstrated and discussed in Section 1.5.5 using examples from the database of the Bilbao Crystallographic Server (1998).

1.5.3. Basic concepts

The aim of this section is to give a brief overview of some of the basic concepts related to groups and their representations. Its content should be of some help to readers who wish to refresh their knowledge of space groups and representations, and to familiarize themselves with the kind of description in this chapter. However, it can not serve as an introductory text for these subjects. The interested reader is referred to books dealing with space-group theory, representations of space groups and their applications in solid-state physics: see BC or Chapter 1.2 of *International Tables for Crystallography* Volume D by Janssen (2003).

1.5.3.1. Representations of finite groups

Group theory is the proper tool for studying symmetry in science. The elements of the crystallographic groups are rigid motions (isometries) with regard to performing one after another. The set of all isometries that map an object onto itself always fulfils the group postulates and is called the symmetry or the symmetry group of that object; the isometry itself is called a symmetry operation. Symmetry groups of crystals are dealt with in this chapter. In addition, groups of matrices with regard to matrix multiplication (matrix groups) are considered frequently. Such groups will sometimes be called realizations or representations of abstract groups.

Many applications of group theory to physical problems are closely related to representation theory, *cf.* Rosen (1981) and references therein. In this section, matrix representations Γ of finite groups $\mathcal{G}$ are considered. The concepts of *homomorphism* and *matrix groups* are of essential importance.

A group $\mathcal{B}$ is a homomorphic image of a group $\mathcal{A}$ if there exists a mapping of the elements a_i of $\mathcal{A}$ onto the elements b_k of $\mathcal{B}$ that preserves the multiplication relation (in general several elements of $\mathcal{A}$ are mapped onto one element of $\mathcal{B}$): if $\mathsf{a}_i \rightarrow \mathsf{b}_i$ and $\mathsf{a}_k \rightarrow \mathsf{b}_k$, then $\mathsf{a}_i\mathsf{a}_k \rightarrow \mathsf{b}_i\mathsf{b}_k$ holds for all elements of $\mathcal{A}$ and $\mathcal{B}$ (the image of the product is equal to the product of the images). In the special case of a one-to-one mapping, the homomorphism is called an *isomorphism*.

A matrix group is a group whose elements are non-singular square matrices. The law of combination is matrix multiplication and the group inverse is the inverse matrix. In the following we will be concerned with some basic properties of finite matrix groups relevant to representations.

Let $\mathcal{M}_1$ and $\mathcal{M}_2$ be two matrix groups whose matrices are of the same dimension. They are said to be equivalent if there exists a (non-singular) matrix $\boldsymbol{S}$ such that $\mathcal{M}_2 = \boldsymbol{S}^{-1}\mathcal{M}_1\boldsymbol{S}$ holds. Equivalence implies isomorphism but the inverse is not true: two matrix groups may be isomorphic without being equivalent. According to the theorem of Schur-Auerbach, every finite matrix group is equivalent to a unitary matrix group (by a unitary matrix group we understand a matrix group consisting entirely of unitary matrices).

A matrix group $\mathcal{M}$ is *reducible* if it is equivalent to a matrix group in which every matrix $\boldsymbol{M}$ is of the form

$$\boldsymbol{R} = \begin{pmatrix} \boldsymbol{D}_1 & \boldsymbol{X} \\ \boldsymbol{O} & \boldsymbol{D}_2 \end{pmatrix},$$

see *e.g.* Lomont (1959), p. 47. The group $\mathcal{M}$ is *completely reducible* if it is equivalent to a matrix group in which for all matrices $\boldsymbol{R}$ the submatrices $\boldsymbol{X}$ are $\boldsymbol{O}$ matrices (consisting of zeros only). According to the theorem of Maschke, a finite matrix group is completely reducible if it is reducible. A matrix group is *irreducible* if it is not reducible.

A (matrix) representation $\Gamma(\mathcal{G})$ of a group $\mathcal{G}$ is a homomorphic mapping of $\mathcal{G}$ onto a matrix group $\mathcal{M}(\mathcal{G})$. In a representation Γ every element $\mathsf{g} \in \mathcal{G}$ is associated with a matrix $\boldsymbol{M}(\mathsf{g})$. The dimension of the matrices is called the dimension of the representation.

The above-mentioned theorems on finite matrix groups can be applied directly to representations: we can restrict the considerations to unitary representations only. Further, since every finite matrix group is either completely reducible into irreducible constituents or irreducible, it follows that the infinite set of all matrix representations of a group is known in principle once the irreps are known. Naturally, the question of how to construct all nonequivalent irreps of a finite group and how to classify them arises.

Linear representations are especially important for applications. In this chapter only linear representations of space groups will be considered. Realizations and representations are homomorphic images of abstract groups, but not all of them are linear. In particular, the action of space groups on point space is a nonlinear realization of the abstract space groups because isometries and thus symmetry operations of space groups $\mathcal{G}$ are nonlinear operations. The same holds for their description by matrix-column pairs $(\boldsymbol{W}, \boldsymbol{w})$,[1] by the general position, or by augmented (4×4) matrices, see *IT* A, Part 8. Therefore, the isomorphic matrix representation of a space group, mostly used by crystallographers and listed in the space-group tables of *IT* A as the general position, is not linear.

1.5.3.2. Space groups

In crystallography one deals with real crystals. In many cases the treatment of the crystal is much simpler, but nevertheless describes the crystal and its properties very well, if the real crystal is replaced by an 'ideal crystal'. The real crystal is then considered to be a finite piece of an undisturbed, periodic, and thus infinitely extended arrangement of particles or their centres: ideal crystals are periodic objects in three-dimensional point space E^3, also called direct space. Periodicity means that there are translations among the symmetry operations of ideal crystals. The symmetry group of an ideal crystal is called its space group $\mathcal{G}$.

Space groups $\mathcal{G}$ are of special interest for our problem because:

(1) their irreps are the subject of the classification to be discussed;

(2) this classification makes use of the isomorphism of certain groups to the so-called symmorphic space groups $\mathcal{G}_0$.

Therefore, space groups are introduced here in a slightly more detailed manner than the other concepts. In doing this we follow the definitions and symbolism of *IT* A, Part 8.

[1] In physics written as the Seitz symbol $(\boldsymbol{W}|\boldsymbol{w})$.

To each space group $\mathcal{G}$ belongs an infinite set $\mathcal{T}$ of translations, the *translation subgroup* of $\mathcal{G}$. The group $\mathcal{T}$ forms an infinite Abelian invariant subgroup of $\mathcal{G}$. For each translation its translation vector is defined. The set of all translation vectors is called the *vector lattice* $\mathbf{L}$ of $\mathcal{G}$. Because of the finite size of the atoms constituting the real crystal, the lengths of the translation vectors of the ideal crystal cannot be arbitrarily small; rather there is a lower limit $\delta > 0$ for their length in the range of a few Å.

When referred to a coordinate system $(O, \mathbf{a}_1, \mathbf{a}_2, \mathbf{a}_3)$, consisting of an origin O and a basis $\mathbf{a}_k$, the symmetry operations, *i.e.* the elements $\mathsf{g}: \tilde{\boldsymbol{x}} = \boldsymbol{W}\boldsymbol{x} + \boldsymbol{w}$ of the space group $\mathcal{G}$, are described by matrix–column pairs $(\boldsymbol{W}, \boldsymbol{w})$ with matrix part $\boldsymbol{W}$ and column part $\boldsymbol{w}$. The translations of $\mathcal{G}$ are represented by pairs $(\boldsymbol{I}, \boldsymbol{t}_i)$, where $\boldsymbol{I}$ is the (3×3) unit matrix and $\boldsymbol{t}_i$ is the column of coefficients of the translation vector $\mathbf{t}_i \in \mathbf{L}$. The basis can always be chosen such that all columns $\boldsymbol{t}_i$ and no other columns of translations consist of integers. Such a basis $\mathbf{p}_1, \mathbf{p}_2, \mathbf{p}_3$ is called a *primitive basis*. For each vector lattice $\mathbf{L}$ there exists an infinite number of primitive bases.

The space group $\mathcal{G}$ can be decomposed into right cosets relative to $\mathcal{T}$:

$$\mathcal{G} = \mathcal{T} \cup \mathcal{T}(\boldsymbol{W}_2, \boldsymbol{w}_2) \cup \ldots \cup \mathcal{T}(\boldsymbol{W}_i, \boldsymbol{w}_i) \cup \ldots \cup \mathcal{T}(\boldsymbol{W}_n, \boldsymbol{w}_n). \quad (1.5.3.1)$$

The coset representatives form the finite set $\mathrm{V} = \{(\boldsymbol{W}_v, \boldsymbol{w}_v)\}$, $v = 1, \ldots, n$, with $(\boldsymbol{W}_1, \boldsymbol{w}_1) = (\boldsymbol{I}, \boldsymbol{o})$, where $\boldsymbol{I}$ is the unit matrix and $\boldsymbol{o}$ is the column consisting of zeros only. The factor group $\mathcal{G}/\mathcal{T}$ is isomorphic to the *point group* $\mathcal{P}$ of $\mathcal{G}$ (called $\overline{\mathcal{G}}$ in books on representation theory) describing the symmetry of the external shape of the macroscopic crystal and being represented by the matrices $\boldsymbol{W}_1, \boldsymbol{W}_2, \ldots, \boldsymbol{W}_n$, $\mathcal{P} = \{\boldsymbol{W}_i\}$. If V can be chosen such that all $\boldsymbol{w}_v = \boldsymbol{o}$, then $\mathcal{G}$ is called a *symmorphic space group* $\mathcal{G}_0$. A symmorphic space group can be recognized easily from its conventional Hermann–Mauguin symbol which does not contain any screw or glide component. In terms of group theory, a symmorphic space group is the semidirect product of $\mathcal{T}$ and $\mathcal{P}$, *cf.* BC, p. 44. In symmorphic space groups $\mathcal{G}_0$ (and in no others) there are site-symmetry groups which are isomorphic to the point group $\mathcal{P}$ of $\mathcal{G}_0$. (For the term 'site-symmetry group', see Section 1.5.4.2.)

Space groups can be classified into 219 (*affine*) *space-group types* either by isomorphism or by affine equivalence; the 230 *crystallographic* space-group types are obtained by restricting the transformations available for affine equivalence to those with positive determinant, *cf. IT* A, Section 8.2.1. Many important properties of space groups are shared by all space groups of a type. In such a case one speaks of *properties of the type.* For example, if a space group is symmorphic, then all space groups of its type are symmorphic, so that one normally speaks of a symmorphic space-group type.

With the concept of symmorphic space groups one can also define the arithmetic crystal classes: Let $\mathcal{G}_0$ be a symmorphic space group referred to a primitive basis and $\mathrm{V} = \{(\boldsymbol{W}_v, \boldsymbol{w}_v)\}$ its set of coset representatives with $\boldsymbol{w}_v = \boldsymbol{o}$ for all columns. To $\mathcal{G}_0$ all those space groups $\mathcal{G}$ can be assigned for which a primitive basis can be found such that the matrix parts $\boldsymbol{W}_v$ of their sets V are the same as those of $\mathcal{G}_0$, only the columns $\boldsymbol{w}_v$ may differ. In this way, to a type of symmorphic space groups $\mathcal{G}_0$, other types of space groups are assigned, *i.e.* the space-group types are classified according to the symmorphic space-group types. These classes are called *arithmetic crystal classes* of space groups or of space-group types.

There are 73 arithmetic crystal classes corresponding to the 73 types of symmorphic space groups; between 1 and 16 space-group types belong to an arithmetic crystal class. A matrix-algebraic definition of arithmetic crystal classes and a proposal for their nomenclature can be found in *IT* A, Section 8.2.3; see also Section 8.3.4 and Table 8.3.4.1.

1.5.3.3. Representations of the translation group $\mathcal{T}$ and the reciprocal lattice

For representation theory we follow the terminology of BC and CDML.

Let $\mathcal{G}$ be referred to a primitive basis. For the following, the infinite set of translations, based on discrete cyclic groups of infinite order, will be replaced by a (very large) finite set in the usual way, assuming the Born–von Karman boundary conditions

$$(\boldsymbol{I}, \boldsymbol{t}_{bi})^{N_i} = (\boldsymbol{I}, N_i) = (\boldsymbol{I}, \boldsymbol{o}) \quad (1.5.3.2)$$

to hold, where $\boldsymbol{t}_{bi} = (1, 0, 0)$, $(0, 1, 0)$ or $(0, 0, 1)$ and N_i is a large integer for $i = 1$, 2 or 3, respectively. Then for any lattice translation $(\boldsymbol{I}, \boldsymbol{t})$,

$$(\boldsymbol{I}, \boldsymbol{N}\boldsymbol{t}) = (\boldsymbol{I}, \boldsymbol{o}) \quad (1.5.3.3)$$

holds, where $\boldsymbol{N}\boldsymbol{t}$ is the column $(N_1 t_1, N_2 t_2, N_3 t_3)$. If the (infinitely many) translations mapped in this way onto $(\boldsymbol{I}, \boldsymbol{o})$ form a normal subgroup $\mathcal{T}_1$ of $\mathcal{G}$, then the mapping described by (1.5.3.3) is a homomorphism. There exists a factor group $\mathcal{G}' = \mathcal{G}/\mathcal{T}_1$ of $\mathcal{G}$ relative to $\mathcal{T}_1$ with translation subgroup $\mathcal{T}' = \mathcal{T}/\mathcal{T}_1$ which is finite and is sometimes called the *finite space group*.

Only the irreps of these finite space groups will be considered. The definitions of space-group type, symmorphic space group *etc.* can be transferred to these groups. Because $\mathcal{T}$ is Abelian, $\mathcal{T}'$ is also Abelian. Replacing the space group $\mathcal{G}$ by $\mathcal{G}'$ means that the especially well developed theory of representations of finite groups can be applied, *cf.* Lomont (1959), Jansen & Boon (1967). For convenience, the prime $'$ will be omitted and the symbol $\mathcal{G}$ will be used instead of $\mathcal{G}'$; $\mathcal{T}'$ will be denoted by $\mathcal{T}$ in the following.

Because $\mathcal{T}$ (formerly $\mathcal{T}'$) is Abelian, its irreps $\Gamma(\mathcal{T})$ are one-dimensional and consist of (complex) roots of unity. Owing to equations (1.5.3.2) and (1.5.3.3), the irreps $\Gamma^{q_1 q_2 q_3}[(\boldsymbol{I}, \boldsymbol{t})]$ of $\mathcal{T}$ have the form

$$\Gamma^{q_1 q_2 q_3}[(\boldsymbol{I}, \boldsymbol{t})] = \exp\left[-2\pi i\left(q_1 \frac{t_1}{N_1} + q_2 \frac{t_2}{N_2} + q_3 \frac{t_3}{N_3}\right)\right], \quad (1.5.3.4)$$

where $\boldsymbol{t}$ is the column (t_1, t_2, t_3), $q_j = 0, 1, 2, \ldots, N_j - 1$, $j = 1, 2, 3$, and t_k and q_j are integers.

Given a primitive basis $\mathbf{a}_1, \mathbf{a}_2, \mathbf{a}_3$ of $\mathbf{L}$, mathematicians and crystallographers define the *basis of the dual or reciprocal lattice* $\mathbf{L}^*$ by

$$\mathbf{a}_i \cdot \mathbf{a}_j^* = \delta_{ij}, \quad (1.5.3.5)$$

where $\mathbf{a} \cdot \mathbf{a}^*$ is the scalar product between the vectors and δ_{ij} is the unit matrix (see *e.g.* Chapter 1.1, Section 1.1.3). Texts on the physics of solids redefine the basis $\mathbf{a}_1^*, \mathbf{a}_2^*, \mathbf{a}_3^*$ of the *reciprocal lattice* $\mathbf{L}^*$, lengthening each of the basis vectors $\mathbf{a}_j^*$ by the factor 2π. Therefore, in the physicist's convention the relation between the bases of direct and reciprocal lattice reads (*cf.* BC, p. 86):

$$\mathbf{a}_i \cdot \mathbf{a}_j^* = 2\pi\delta_{ij}. \quad (1.5.3.6)$$

In the present chapter only the physicist's basis of the reciprocal lattice is employed, and hence the use of $\mathbf{a}_i^*$ should not lead to misunderstandings. The set of all vectors $\mathbf{K}$,[2]

$$\mathbf{K} = k_1\mathbf{a}_1^* + k_2\mathbf{a}_2^* + k_3\mathbf{a}_3^*, \quad (1.5.3.7)$$

k_i integer, is called the lattice reciprocal to $\mathbf{L}$ or the *reciprocal lattice* $\mathbf{L}^*$.[3]

If one adopts the notation of *IT* A, Part 5, the basis of direct space is denoted by a row $(\mathbf{a}_1, \mathbf{a}_2, \mathbf{a}_3)^T$, where $(\,)^T$ means trans-

[2] See Note (1) in Section 1.5.1.

[3] The lattice $\mathbf{L}$ is often called the *direct lattice*. These names are historically introduced and cannot be changed, although equations (1.5.3.5) and (1.5.3.6) show that essentially neither of the lattices is preferred: they form a pair of *mutually reciprocal* lattices.

posed. For reciprocal space, the basis is described by a column $(\mathbf{a}_1^*, \mathbf{a}_2^*, \mathbf{a}_3^*)$.

To each lattice generated from a basis $(\mathbf{a}_i)^T$ a reciprocal lattice is generated from the basis $(\mathbf{a}_j^*)$. Both lattices, $\mathbf{L}$ and $\mathbf{L}^*$, can be compared most easily by referring the direct lattice $\mathbf{L}$ to its *conventional* basis $(\mathbf{a}_i)^T$ as defined in Chapters 2.1 and 9.1 of *IT* A. In this case, the lattice $\mathbf{L}$ may be primitive or centred. If $(\mathbf{a}_i)^T$ forms a primitive basis of $\mathbf{L}$, *i.e.* if $\mathbf{L}$ is primitive, then the basis $(\mathbf{a}_j^*)$ forms a primitive basis of $\mathbf{L}^*$. If $\mathbf{L}$ is centred, *i.e.* $(\mathbf{a}_i)^T$ is not a primitive basis of $\mathbf{L}$, then there exists a centring matrix $\boldsymbol{P}$, $0 < \det(\boldsymbol{P}) < 1$, by which three linearly independent vectors of $\mathbf{L}$ with rational coefficients are generated from those with integer coefficients, *cf. IT* A, Table 5.1.3.1.

Moreover, $\boldsymbol{P}$ can be chosen such that the set of vectors

$$(\mathbf{p}_1, \mathbf{p}_2, \mathbf{p}_3)^T = (\mathbf{a}_1, \mathbf{a}_2, \mathbf{a}_3)^T \boldsymbol{P} \qquad (1.5.3.8)$$

forms a primitive basis of $\mathbf{L}$. Then the basis vectors $(\mathbf{p}_1^*, \mathbf{p}_2^*, \mathbf{p}_3^*)$ of the lattice reciprocal to the lattice generated by $(\mathbf{p}_1, \mathbf{p}_2, \mathbf{p}_3)^T$ are determined by

$$(\mathbf{p}_1^*, \mathbf{p}_2^*, \mathbf{p}_3^*) = \boldsymbol{P}^{-1}(\mathbf{a}_1^*, \mathbf{a}_2^*, \mathbf{a}_3^*) \qquad (1.5.3.9)$$

and form a primitive basis of $\mathbf{L}^*$.

Because $\det(\boldsymbol{P}^{-1}) > 1$, not all vectors $\mathbf{K}$ of the form (1.5.3.7) belong to $\mathbf{L}^*$. If k_1, k_2, k_3 are the (integer) coefficients of these vectors $\mathbf{K}$ referred to $(\mathbf{a}_j^*)$ and $k_{p1}\mathbf{p}_1^* + k_{p2}\mathbf{p}_2^* + k_{p3}\mathbf{p}_3^*$ are the vectors of $\mathbf{L}^*$, then $\mathbf{K} = (k_j)^T(\mathbf{a}_j^*) = (k_j)^T\boldsymbol{P}(\mathbf{p}_i^*) = (k_{pi})^T(\mathbf{p}_i^*)$ is a vector of $\mathbf{L}^*$ if and only if the coefficients

$$(k_{p1}, k_{p2}, k_{p3})^T = (k_1, k_2, k_3)^T \boldsymbol{P} \qquad (1.5.3.10)$$

are integers. In other words, $(k_1, k_2, k_3)^T$ has to fulfil the equation

$$(k_1, k_2, k_3)^T = (k_{p1}, k_{p2}, k_{p3})^T \boldsymbol{P}^{-1}. \qquad (1.5.3.11)$$

As is well known, the Bravais type of the reciprocal lattice $\mathbf{L}^*$ is not necessarily the same as that of its direct lattice $\mathbf{L}$. If $\boldsymbol{W}$ is the matrix of a (point-) symmetry operation of the direct lattice, referred to its basis $(\mathbf{a}_i)^T$, then $\boldsymbol{W}^{-1}$ is the matrix of the same symmetry operation of the reciprocal lattice but referred to the dual basis $(\mathbf{a}_i^*)$. This does not affect the symmetry because in a (symmetry) group the inverse of each element in the group also belongs to the group. Therefore, the (point) symmetries of a lattice and its reciprocal lattice are always the same. However, there may be differences in the matrix descriptions due to the different orientations of $\mathbf{L}$ and $\mathbf{L}^*$ relative to the symmetry elements of $\overline{\mathcal{G}}$ and due to the reference to the different bases $(\mathbf{a}_i)^T$ and $(\mathbf{a}_i^*)$. For example, if $\mathbf{L}$ has the point symmetry (Hermann–Mauguin symbol) $\overline{3}m1$, then the symbol for the point symmetry of $\mathbf{L}^*$ is $\overline{3}1m$ and *vice versa*.

1.5.3.4. Irreducible representations of space groups and the reciprocal-space group

Let $(\mathbf{a}_i)^T$ be a conventional basis of the lattice $\mathbf{L}$ of the space group $\mathcal{G}$. From (1.5.3.6), $k_i = q_i/N_i$ and $\mathbf{k} = \sum_{k=1}^{3} k_i \mathbf{a}_i^*$, equation (1.5.3.4) can be written

$$\Gamma^{q_1 q_2 q_3}[(\boldsymbol{I}, \boldsymbol{t})] = \Gamma^{\mathbf{k}}[(\boldsymbol{I}, \boldsymbol{t})] = \exp[-i\mathbf{k} \cdot \mathbf{t}]. \qquad (1.5.3.12)$$

Equation (1.5.3.12) has the same form if a primitive basis $(\mathbf{p}_i)^T$ of $\mathbf{L}$ has been chosen. In this case, the vector $\mathbf{k}$ is given by $\mathbf{k} = \sum_{i=1}^{3} k_{pi}\mathbf{p}_i^*$ with rational coefficients k_{pi}.

Let a primitive basis $(\mathbf{p}_i)^T$ be chosen for the lattice $\mathbf{L}$. The set of all vectors $\mathbf{k}$ (known as wavevectors) forms a discontinuous array. Consider two wavevectors $\mathbf{k}$ and $\mathbf{k}' = \mathbf{k} + \mathbf{K}$, where $\mathbf{K}$ is a vector of the reciprocal lattice $\mathbf{L}^*$. Obviously, $\mathbf{k}$ and $\mathbf{k}'$ describe the same irrep of $\mathcal{T}$. Therefore, to determine all irreps of $\mathcal{T}$ it is necessary to consider only the wavevectors of a small region of the reciprocal space, where the translation of this region by all vectors of $\mathbf{L}^*$ fills the reciprocal space without gap or overlap. Such a region is called a *fundamental region* of $\mathbf{L}^*$. (The nomenclature in literature is not quite uniform. We follow here widely adopted definitions.)

The fundamental region of $\mathbf{L}^*$ is not uniquely determined. Two types of fundamental regions are of interest in this chapter:

(1) The *first Brillouin zone* is that range of $\mathbf{k}$ space around $\mathbf{o}$ for which $|\mathbf{k}| \leq |\mathbf{K} - \mathbf{k}|$ holds for any vector $\mathbf{K} \in \mathbf{L}^*$ (*Wigner–Seitz cell* or *domain of influence* in $\mathbf{k}$ space). Visually, it is the region of endpoints of the $\mathbf{k}$ vectors that are nearer to the origin than to any other point of the reciprocal lattice. The Brillouin zone is a centrosymmetric body bounded by centrosymmetric planes which bisect perpendicularly the connecting lines from the origin to the neighbouring reciprocal-lattice points. The Brillouin zone is used in books and articles on irreps of space groups.

(2) The *crystallographic unit cell in reciprocal space*, for short *unit cell*, is the set of all $\mathbf{k}$ vectors with $0 \leq k_i < 1$. It corresponds to the unit cell used in crystallography for the description of crystal structures in direct space.

Let $\mathbf{k}$ be some vector according to (1.5.3.12) and $\boldsymbol{W}$ be the matrices of $\overline{\mathcal{G}}$. The following definitions are useful:

Definition. The set of all vectors $\mathbf{k}'$ fulfilling the condition

$$\mathbf{k}' = \mathbf{k}\boldsymbol{W} + \mathbf{K}, \quad \boldsymbol{W} \in \overline{\mathcal{G}}, \quad \mathbf{K} \in \mathbf{L}^* \qquad (1.5.3.13)$$

is called *the orbit of* $\mathbf{k}$.

Definition. The set of all matrices $\boldsymbol{W} \in \overline{\mathcal{G}}$ for which

$$\mathbf{k} = \mathbf{k}\boldsymbol{W} + \mathbf{K}, \quad \mathbf{K} \in \mathbf{L}^* \qquad (1.5.3.14)$$

forms a group which is called the *little co-group* $\overline{\mathcal{G}}^{\mathbf{k}}$ of $\mathbf{k}$. The vector $\mathbf{k}$ is called *general* if $\overline{\mathcal{G}}^{\mathbf{k}} = \{\boldsymbol{I}\}$; otherwise $\overline{\mathcal{G}}^{\mathbf{k}} > \{\boldsymbol{I}\}$ and $\mathbf{k}$ is called *special*.

In words: The $\mathbf{k}$ vector is called *general* if its little co-group $\overline{\mathcal{G}}^{\mathbf{k}}$ is the identity of $\overline{\mathcal{G}}$. Otherwise, $\overline{\mathcal{G}}^{\mathbf{k}}$ is a non-trivial subgroup of the point group $\overline{\mathcal{G}}$ of $\mathcal{G}$, $\overline{\mathcal{G}} > \overline{\mathcal{G}}^{\mathbf{k}}$, and $\mathbf{k}$ is called a *special vector* of the reciprocal space.

Equation (1.5.3.14) for $\mathbf{k}$ resembles the equation

$$\boldsymbol{x} = \boldsymbol{W}\boldsymbol{x} + \boldsymbol{t}, \quad \mathbf{t} \in \mathbf{L} \qquad (1.5.3.15)$$

by which the fixed points of the symmetry operation $(\boldsymbol{W}, \boldsymbol{t})$ of a symmorphic space group $\mathcal{G}_0$ are determined. Indeed, the orbits of $\mathbf{k}$ defined by (1.5.3.13) correspond to the point orbits of $\mathcal{G}_0$, the little co-group $\overline{\mathcal{G}}^{\mathbf{k}}$ of $\mathbf{k}$ corresponds to the site-symmetry group of that point $\boldsymbol{X}$ whose coordinates (x_i) have the same values as the vector coefficients $(k_i)^T$ of $\mathbf{k}$.

Consider the coset decomposition of $\overline{\mathcal{G}}$ relative to $\overline{\mathcal{G}}^{\mathbf{k}}$.

Definition. If $\{\boldsymbol{W}_m\}$ is a set of coset representatives of $\overline{\mathcal{G}}$ relative to $\overline{\mathcal{G}}^{\mathbf{k}}$, then the set $\{\mathbf{k}\boldsymbol{W}_m\}$ is called the *star* of $\mathbf{k}$ and the vectors $\mathbf{k}\boldsymbol{W}_m$ are called the *arms of the star*.

The number of arms of the star of $\mathbf{k}$ is equal to the order $|\overline{\mathcal{G}}|$ of the point group $\overline{\mathcal{G}}$ divided by the order $|\overline{\mathcal{G}}^{\mathbf{k}}|$ of the symmetry group $\overline{\mathcal{G}}^{\mathbf{k}}$ of $\mathbf{k}$. If $\mathbf{k}$ is general, then there are $|\overline{\mathcal{G}}|$ vectors from the orbit of $\mathbf{k}$ in each fundamental region and $|\overline{\mathcal{G}}|$ arms of the star. If $\mathbf{k}$ is special with little co-group $\overline{\mathcal{G}}^{\mathbf{k}}$, then the number of arms of the star of $\mathbf{k}$ and the number of $\mathbf{k}$ vectors in the fundamental region from the orbit of $\mathbf{k}$ is $|\overline{\mathcal{G}}|/|\overline{\mathcal{G}}^{\mathbf{k}}|$.

Definition. The group of all elements $(\boldsymbol{W}, \boldsymbol{w}) \in \mathcal{G}$ for which $\boldsymbol{W} \in \overline{\mathcal{G}}^{\mathbf{k}}$ is called the *little group* $\mathcal{L}^{\mathbf{k}}$ *of* $\mathbf{k}$.

The analogue of the little group $\mathcal{L}^{\mathbf{k}}$ is rarely considered in crystallography.

All symmetry operations of $\mathcal{G}_0$ may be obtained as combinations of an operation that leaves the origin fixed with a transla-

tion of $\mathbf{L}$, *i.e.* are of the kind $(\boldsymbol{W}, \boldsymbol{t}) = (\boldsymbol{I}, \boldsymbol{t})(\boldsymbol{W}, \boldsymbol{o})$. We now define the analogous group for the $\mathbf{k}$ vectors. Whereas $\mathcal{G}_0$ is a realization of the corresponding abstract group in direct (point) space, the group to be defined will be a realization of it in reciprocal (vector) space.

Definition. The group $(\mathcal{G})^*$ which is the semidirect product of the point group $\overline{\mathcal{G}}$ and the translation group of the reciprocal lattice $\mathbf{L}^*$ of $\mathcal{G}$ is called the *reciprocal-space group of* $\mathcal{G}$.

By this definition, the reciprocal-space group $(\mathcal{G})^*$ is isomorphic to a symmorphic space group $\mathcal{G}_0$. The elements of $\mathcal{G}_0$ are the operations $(\boldsymbol{W}, \boldsymbol{t}_{\boldsymbol{K}}) = (\boldsymbol{I}, \boldsymbol{t}_{\boldsymbol{K}})(\boldsymbol{W}, \boldsymbol{o})$ with $\boldsymbol{W} \in \overline{\mathcal{G}}$ and $\boldsymbol{t}_{\boldsymbol{K}} \in \mathbf{L}$ with the coefficients of $\mathbf{K}$. In order to emphasize that $(\mathcal{G})^*$ is a group acting on reciprocal space and not the inverse of a space group (whatever that may mean) we insert a hyphen '-' between 'reciprocal' and 'space'.

From the definition of $(\mathcal{G})^*$ it follows that space groups of the same type define the same type of reciprocal-space group $(\mathcal{G})^*$. Moreover, as $(\mathcal{G})^*$ does not depend on the column parts of the space-group operations, all space groups of the same arithmetic crystal class determine the same type of $(\mathcal{G})^*$; for arithmetic crystal class see Section 1.5.3.2. Following Wintgen (1941), the types of reciprocal-space groups $(\mathcal{G})^*$ are listed for the arithmetic crystal classes of space groups, *i.e.* for all space groups $\mathcal{G}$, in Appendix A1.5.1.

1.5.4. Conventions in the classification of space-group irreps

Because of the isomorphism between the reciprocal-space groups $(\mathcal{G})^*$ and the symmorphic space groups $\mathcal{G}_0$ one can introduce crystallographic conventions in the classification of space-group irreps. These conventions will be compared with those which have mainly been used up to now. Illustrative examples to the following more theoretical considerations are discussed in Section 1.5.5.

1.5.4.1. Fundamental regions

Different types of regions of reciprocal space may be chosen as fundamental regions, see Section 1.5.3.4. The most frequently used type is the first Brillouin zone, which is the Wigner–Seitz cell (or Voronoi region, Dirichlet domain, domain of influence; *cf. IT* A, Chapter 9.1) of the reciprocal lattice. The Brillouin zone has the property of including the star of each $\mathbf{k}$ vector that belongs to it. Such a choice has three advantages:

(1) the Brillouin zone manifests the point symmetry of the reciprocal lattice $\mathbf{L}^*$ of $\mathcal{G}$;

(2) only $\mathbf{k}$ vectors of the boundary of the Brillouin zone may have little-group representations which are obtained from projective representations of the little co-group $\overline{\mathcal{G}}^{\mathbf{k}}$, see *e.g.* BC, p. 156;

(3) for physical reasons, the Brillouin zone may be the most convenient fundamental region.

Of these advantages only the third may be essential. For the classification of irreps the minimal domains, see Section 1.5.4.2, are much more important than the fundamental regions. The minimal domain does not display the point-group symmetry anyway and the distinguished $\mathbf{k}$ vectors always belong to its boundary however the minimal domain may be chosen.

The serious disadvantage of the Brillouin zone is its often complicated shape which, moreover, depends on the lattice parameters of $\mathbf{L}^*$, *cf.* Section 1.5.5.3. The body that represents the Brillouin zone belongs to one of the five Fedorov polyhedra (more or less distorted versions of the cubic forms cube, rhombdodecahedron or cuboctahedron, of the hexagonal prism, or of the tetragonal elongated rhombdodecahedron). A more detailed description is that by the 24 *symmetrische Sorten* (Delaunay sorts) of Delaunay (1933*a*,*b*), Figs. 11 and 12. According to this classification, the Brillouin zone may display three types of polyhedra of cubic, one type of hexagonal, two of rhombohedral, three of tetragonal, six of orthorhombic, six of monoclinic, and three types of triclinic symmetry.

For low symmetries the shape of the Brillouin zone is so variable that BC, p. 90 *ff.* chose a primitive unit cell of $\mathbf{L}^*$ for the fundamental regions of triclinic and monoclinic crystals. This cell also reflects the point symmetry of $\mathbf{L}^*$, it has six faces only, and although its shape varies with the lattice parameters all cells are affinely equivalent. For space groups of higher symmetry, BC and most other authors prefer the Brillouin zone.

Considering $\mathbf{L}^*$ as a lattice, one can refer it to its conventional crystallographic lattice basis. Referred to this basis, the *unit cell of* $\mathbf{L}^*$ is always an alternative to the Brillouin zone. With the exception of the hexagonal lattice, the unit cell of $\mathbf{L}^*$ reflects the point symmetry, it has only six faces and its shape is always affinely equivalent for varying lattice parameters. For a space group $\mathcal{G}$ with a primitive lattice, the above-defined conventional unit cell of $\mathbf{L}^*$ is also primitive. If $\mathcal{G}$ has a centred lattice, then $\mathbf{L}^*$ also belongs to a type of centred lattice and the *conventional* cell of $\mathbf{L}^*$ [not to be confused with the cell spanned by the basis $(\mathbf{a}_j^*)$ dual to the basis $(\mathbf{a}_i)^T$] is larger than necessary. However, this is not disturbing because in this context the fundamental region is an auxiliary construction only for the definition of the minimal domain; see Section 1.5.4.2.

1.5.4.2. Minimal domains

One can show that all irreps of $\mathcal{G}$ can be built up from the irreps $\Gamma^{\mathbf{k}}$ of $\mathcal{T}$. Moreover, to find all irreps of $\mathcal{G}$ it is only necessary to consider one $\mathbf{k}$ vector from each orbit of $\mathbf{k}$, *cf.* CDML, p. 31.

Definition. A simply connected part of the fundamental region which contains *exactly one* $\mathbf{k}$ vector of each orbit of $\mathbf{k}$ is called a *minimal domain* Φ.

The choice of the minimal domain is by no means unique. One of the difficulties in comparing the published data on irreps of space groups is due to the different minimal domains found in the literature.

The number of $\mathbf{k}$ vectors of each general $\mathbf{k}$ orbit in a fundamental region is always equal to the order of the point group $\overline{\mathcal{G}}$ of $\mathcal{G}$; see Section 1.5.3.4. Therefore, the volume of the minimal domain Φ in reciprocal space is $1/|\overline{\mathcal{G}}|$ of the volume of the fundamental region. Now we can restrict the search for all irreps of $\mathcal{G}$ to the $\mathbf{k}$ vectors within a minimal domain Φ.

In general, in representation theory of space groups the Brillouin zone is taken as the fundamental region and Φ is called a *representation domain*.[4] Again, the volume of a representation domain in reciprocal space is $1/|\overline{\mathcal{G}}|$ of the volume of the Brillouin zone. In addition, as the Brillouin zone contains for each $\mathbf{k}$ vector all $\mathbf{k}$ vectors of the star of $\mathbf{k}$, by application of all symmetry operations $\boldsymbol{W} \in \overline{\mathcal{G}}$ to Φ one obtains the Brillouin zone; *cf.* BC, p. 147. As the Brillouin zone may change its geometrical type depending on the lattice parameters, the type of the representation domain may also vary with varying lattice parameters; see the examples of Section 1.5.5.

The simplest crystal structures are the lattice-like structures that are built up of translationally equivalent points (centres of particles) only. For such a structure the point group $\overline{\mathcal{G}}$ of the space group $\mathcal{G}$ is equal to the point group $\mathcal{Q}$ of its lattice $\mathbf{L}$. Such point groups are called *holohedral*, the space group $\mathcal{G}$ is called *holo-*

[4] From definition 3.7.1 on p. 147 of BC, it does not follow that a representation domain contains *exactly one* $\mathbf{k}$ vector from each star. The condition 'The intersection of the representation domain with its symmetrically equivalent domains is empty' is missing. Lines 14 to 11 from the bottom of p. 149, however, state that such a property of the representation domain is intended. The representation domains of CDML, Figs. 3.15–3.29 contain *at least one* $\mathbf{k}$ vector of each star (Vol. 1, pp. 31, 57 and 65). On pp. 66, 67 a procedure is described for eliminating those $\mathbf{k}$ vectors from the representation domain which occur more than once. In the definition of Altmann (1977), p. 204, the representation domain contains *exactly one* arm (prong) per star.

symmetric. There are seven holohedral point groups of three dimensions: $\overline{1}, 2/m, mmm, 4/mmm, \overline{3}m, 6/mmm$ and $m\overline{3}m$. For the non-holosymmetric space groups $\mathcal{G}, \overline{\mathcal{G}} < \mathcal{Q}$ holds. [The group $\mathcal{Q}$ may have *accidentally higher symmetry* in addition, *e.g.* if the lattice of a monoclinic crystal structure is orthorhombic at a certain temperature, pressure and composition. In Section 8.2.6 of *IT* A it is shown how such accidental symmetry can be treated.]

In books on representation theory of space groups, holosymmetric space groups play a distinguished role. Their representation domains are called *basic domains* Ω. For holosymmetric space groups $\Omega = \Phi$ holds. If $\mathcal{G}$ is non-holosymmetric, *i.e.* $\overline{\mathcal{G}} < \mathcal{Q}$ holds, Ω is defined by $\mathcal{Q}$ and is smaller than the representation domain Φ by a factor which is equal to the index of $\overline{\mathcal{G}}$ in $\mathcal{Q}$. In the literature these basic domains are considered to be of primary importance. In Miller & Love (1967) only the irreps for the $\mathbf{k}$ vectors of the basic domains Ω are listed. Section 5.5 of BC and Davies & Cracknell (1976) state that such a listing is not sufficient for the non-holosymmetric space groups because $\Omega < \Phi$. Section 5.5 of BC shows how to overcome this deficiency; Chapter 4 of CDML introduces new labels of $\mathbf{k}$ vectors for the parts of Φ not belonging to Ω.

The crystallographic analogue of the representation domain in direct space is the *asymmetric unit*, *cf. IT* A. According to its definition it is a simply connected smallest part of space from which by application of all symmetry operations of the space group the whole space is exactly filled. For each space-group type the asymmetric units of *IT* A belong to the same topological type independent of the lattice parameters. They are chosen as 'simple' bodies by inspection rather than by applying clearly stated rules. Among the asymmetric units of the 73 symmorphic space-group types $\mathcal{G}_0$ there are 31 parallelepipeds, 27 prisms (13 trigonal, 6 tetragonal and 8 pentagonal) for the non-cubic, and 15 pyramids (11 trigonal and 4 tetragonal) for the cubic $\mathcal{G}_0$.

The asymmetric units of *IT* A – transferred to the groups $(\mathcal{G})^*$ of reciprocal space – are alternatives for the representation domains of the literature. They are formulated as closed bodies. Therefore, for inner points $\mathbf{k}$, the asymmetric units of *IT* A fulfil the condition that each star of $\mathbf{k}$ is represented exactly once. For the surface, however, these conditions either have to be worked out or one gives up the condition of uniqueness and replaces *exactly* by *at least* in the definition of the minimal domain (see preceding footnote). The examples of Section 1.5.5 show that the conditions for the boundary of the asymmetric unit and its special points, lines and planes are in many cases much easier to formulate than those for the representation domain. The asymmetric units used here are not always those of *IT* A. They may have been chosen differently in order to make them more convenient for our purpose or to adapt them more or less to the representation domains of CDML.

The $\mathbf{k}$*-vector coefficients.* For each $\mathbf{k}$ vector one can derive a set of irreps of the space group $\mathcal{G}$. Different $\mathbf{k}$ vectors of a $\mathbf{k}$ orbit give rise to equivalent irreps. Thus, for the calculation of the irreps of the space groups it is essential to identify the orbits of $\mathbf{k}$ vectors in reciprocal space. This means finding the sets of all $\mathbf{k}$ vectors that are related by the operations of the reciprocal-space group $(\mathcal{G})^*$ according to equation (1.5.3.13). The classification of these $\mathbf{k}$ orbits can be done in analogy to that of the point orbits of the symmorphic space groups, as is apparent from the comparison of equations (1.5.3.14) and (1.5.3.15).

The classes of point orbits in direct space under a space group $\mathcal{G}$ are well known and are listed in the space-group tables of *IT* A. They are labelled by *Wyckoff letters*. The stabilizer $\mathcal{S}_{\mathcal{G}}(X)$ of a point X is called the *site-symmetry group* of X, and a *Wyckoff position* consists of all orbits for which the site-symmetry groups are conjugate subgroups of $\mathcal{G}$. Let $\mathcal{G}$ be a symmorphic space group $\mathcal{G}_0$. Owing to the isomorphism between the reciprocal-space groups $(\mathcal{G})^*$ and the symmorphic space groups $\mathcal{G}_0$, the complete list of special $\mathbf{k}$ vectors of $(\mathcal{G})^*$ is provided by the Wyckoff positions of $\mathcal{G}_0$. The groups $\mathcal{S}_{\mathcal{G}_0}(X)$ and $\overline{\mathcal{G}}^{\mathbf{k}}$ correspond to each other and the multiplicity of the Wyckoff position (divided by the number of centring vectors per unit cell for centred lattices) equals the number of arms of the star of $\mathbf{k}$. Let the vectors $\mathbf{t}$ of $\mathbf{L}$ be referred to the conventional basis $(\mathbf{a}_i)^T$ of the space-group tables of *IT* A, as defined in Chapters 2.1 and 9.1 of *IT* A. Then, for the construction of the irreps $\Gamma^{\mathbf{k}}$ of $\mathcal{T}$ the coefficients of the $\mathbf{k}$ vectors must be referred to the basis $(\mathbf{a}_j^*)$ of reciprocal space dual to $(\mathbf{a}_i)^T$ in direct space. These $\mathbf{k}$-vector coefficients may be different from the conventional coordinates of $\mathcal{G}_0$ listed in the Wyckoff positions of *IT* A.

Example

Let $\mathcal{G}$ be a space group with an *I*-centred cubic lattice $\mathbf{L}$, conventional basis $(\mathbf{a}_i)^T$. Then $\mathbf{L}^*$ is an *F*-centred lattice. If referred to the conventional basis $(\mathbf{a}_j^*)$ with $\mathbf{a}_i \cdot \mathbf{a}_j^* = 2\pi\delta_{ij}$, the $\mathbf{k}$ vectors with coefficients 1 0 0, 0 1 0 and 0 0 1 do not belong to $\mathbf{L}^*$ due to the 'extinction laws' well known in X-ray crystallography. However, in the standard basis of $\mathcal{G}_0$, isomorphic to $(\mathcal{G})^*$, the vectors 1 0 0, 0 1 0 and 0 0 1 point to the vertices of the face-centred cube and thus correspond to 2 0 0, 0 2 0 and 0 0 2 referred to the conventional basis $(\mathbf{a}_j^*)$.

In the following, three bases and, therefore, three kinds of coefficients of $\mathbf{k}$ will be distinguished:

(1) Coefficients referred to the conventional basis $(\mathbf{a}_j^*)$ in reciprocal space, dual to the conventional basis $(\mathbf{a}_i)^T$ in direct space. The corresponding $\mathbf{k}$-vector coefficients, $(k_j)^T$, will be called *conventional* coefficients.

(2) Coefficients of $\mathbf{k}$ referred to a primitive basis $(\mathbf{a}_{pi}^*)$ in reciprocal space (which is dual to a primitive basis in direct space). The corresponding coefficients will be called *primitive* coefficients $(k_{pi})^T$. For a centred lattice the coefficients $(k_{pi})^T$ are different from the conventional coefficients $(k_i)^T$. In most of the physics literature related to space-group representations these primitive coefficients are used, *e.g.* by CDML.

(3) The coefficients of $\mathbf{k}$ referred to the conventional basis of $\mathcal{G}_0$. These coefficients will be called *adjusted* coefficients $(k_{ai})^T$.

The relations between conventional and adjusted coefficients are listed for the different Bravais types of reciprocal lattices in Table 1.5.4.1, and those between adjusted and primitive coordinates in Table 1.5.4.2. If adjusted coefficients are used, then *IT* A is as suitable for dealing with irreps as it is for handling space-group symmetry.

1.5.4.3. Wintgen positions

In order to avoid confusion, in the following the analogues to the Wyckoff positions of $\mathcal{G}_0$ will be called *Wintgen positions* of $(\mathcal{G})^*$; the *coordinates* of the Wyckoff position are replaced by the $\mathbf{k}$*-vector coefficients* of the Wintgen position, the *Wyckoff letter* will be called the *Wintgen letter*, and the symbols for the *site symmetries* of $\mathcal{G}_0$ are to be read as the symbols for the *little cogroups* $\overline{\mathcal{G}}^{\mathbf{k}}$ of the $\mathbf{k}$ vectors in $(\mathcal{G})^*$. The *multiplicity* of a Wyckoff position is retained in the Wintgen symbol in order to facilitate the use of *IT* A for the description of symmetry in $\mathbf{k}$ space. However, it is equal to the *multiplicity of the star of* $\mathbf{k}$ only in the case of primitive lattices $\mathbf{L}^*$.

In analogy to a Wyckoff position, a Wintgen position is a set of orbits of $\mathbf{k}$ vectors. Each orbit as well as each star of $\mathbf{k}$ can be represented by any one of its $\mathbf{k}$ vectors. The zero, one or two free parameters in the $\mathbf{k}$-vector coefficients correspond to special $\mathbf{k}$ vectors, *i.e.*, they define *symmetry points*, *symmetry lines* or *symmetry planes*. Three free parameters indicate general $\mathbf{k}$ vectors. The different stars of a Wintgen position are obtained by varying the free parameters.

For convenience, we call the set of all $\mathbf{k}$ vectors of a Wintgen position a $\mathbf{k}$*-vector type*. A $\mathbf{k}$-vector type consists of complete orbits of $\mathbf{k}$ vectors and thus of full stars of $\mathbf{k}$ vectors; the different orbits of a $\mathbf{k}$-vector type are distinguished by the value(s) of the variable parameter(s) of their $\mathbf{k}$ vectors. Correspondingly, the

tI	$-k_{a1}+k_{a3}$	$k_{a1}+k_{a3}$	$k_{a2}-k_{a3}$
hP	$k_{a1}-k_{a2}$	k_{a2}	k_{a3}
hR (hexagonal)	$k_{a1}+k_{a3}$	$-k_{a1}+k_{a2}+k_{a3}$	$-k_{a2}+k_{a3}$

irreps belonging to a **k** vector are specified by these parameters and the irreps belonging to a **k**-vector type form a *type of irreps*, Boyle (1986).

It may be advantageous to describe the different stars belonging to a Wintgen position in a *uniform* way. For this purpose one can define:

Definition. Two **k** vectors of a Wintgen position are *uni-arm* if one can be obtained from the other by parameter variation. The *description of the stars* of a Wintgen position is *uni-arm* if the **k** vectors representing these stars are uni-arm.

The uni-arm description is particularly useful to check whether different sets of **k** vectors belong to the same **k**-vector type or not. Because of the shape of the representation domain or of the asymmetric unit, a **k**-vector type may be split into different parts which belong to different arms of different **k**-vector stars. A uni-arm description may be obtained by the introduction of flagpoles and wings, see Section 1.5.5.1.

For the uni-arm description of a Wintgen position it is easy to check whether the parameter ranges for the general or special constituents of the representation domain or asymmetric unit have been stated correctly. For this purpose one may define the *field of* **k** as the parameter space (point, line, plane or space) of a Wintgen position. For the check one determines that part of the field of **k** which is in the unit cell. The order of the little co-group $\overline{\mathcal{G}}^{\mathbf{k}}$ ($\overline{\mathcal{G}}^{\mathbf{k}}$ represents those operations which leave the field of **k** *fixed pointwise*) is divided by the order of the stabilizer of the field in $(\mathcal{G})^*$ [which is the set of all symmetry operations mod (integer translations) which leave the field *invariant as a whole*]. The result gives the independent fraction of the volume of the unit cell or the area of the plane or length of the line.

If the description is not uni-arm, the uni-arm parameter range will be split into the parameter ranges of the different arms. These parameter ranges of the different arms are not necessarily equal, for examples see Section 1.5.5.

Remark. One should avoid the term *equivalent* for the relation between **k** vectors of the same type but with different parameters, as used by Stokes *et al.* (1993) for Λ and *F* or *B*, *C* and *J* of $m\bar{3}mI$, see examples (1) and (2) in Section 1.5.5.4.4. To belong to the same **k**-vector type is only a necessary, not a sufficient, condition for **k**-vector equivalence. On p. 95 of BC is the following definition: 'Two **k** vectors $\mathbf{k}_1$ and $\mathbf{k}_2$ are equivalent if $\mathbf{k}_1 = \mathbf{k}_2 + \mathbf{K}$, where $\mathbf{K} \in \mathbf{L}^*$'. One can express this by saying: 'Two **k** vectors are equivalent if their difference is a vector **K** of the (reciprocal) lattice'. We prefer to extend this equivalence by saying: 'Two **k** vectors $\mathbf{k}_1$ and $\mathbf{k}_2$ are equivalent if and only if they belong to the same orbit of **k**', *i.e* if there is a matrix part $\boldsymbol{W}$ and a vector $\mathbf{K} \in \mathbf{L}^*$ belonging to $\mathcal{G}$ such that $\mathbf{k}_2 = \mathbf{W}\mathbf{k}_1 + \mathbf{K}$, see equation (1.5.3.13). The **k** vectors of Stokes *et al.* (1993) are not equivalent under this definition, see Davies & Dirl (1987). If the representatives of the **k**-vector stars are chosen uni-arm, their non-equivalence is evident.

It must be mentioned that two **k** vectors of the same type are only called equivalent here if they belong to the same *orbit* of **k** vectors, *i.e.* a **k**-vector type is *not* an equivalence class with respect to the definition of equivalence stated in this remark.

There are two main reasons why **k** vectors of the same type split and then have different labels in CDML:

(1) The higher the symmetry of the point group $\overline{\mathcal{G}}$ of $\mathcal{G}$, the higher is the symmetry of the lattice $\mathbf{L}(\mathcal{G})$ and of the reciprocal lattice $\mathbf{L}^*$, and thus of the Brillouin zone of $\mathcal{G}$. As the symmetry of the Brillouin zone increases, the choice of the boundaries of the representation domain and any other minimal domain becomes more and more restricted. This is because a symmetry element (rotation or rotoinversion axis, plane of reflection, centre of inversion) cannot occur in the interior of the minimal domain but only on its boundary. For the arithmetic crystal class $m\bar{3}mI$, for example, all boundary planes, lines and points are fixed, such that all possible minimal domains are equivalent.

For lower point-group symmetries of the fundamental regions, the choice of the minimal domain is less restricted but the Brillouin zones may become more complicated and may even belong to different topological types depending on the ratios of the lattice parameters. Faces and lines on the surface of the Brillouin zone may appear or disappear or change their relative sizes depending on the lattice parameters, causing different descriptions of Wintgen positions.

This does not happen in unit cells or their asymmetric units. Therefore, as already mentioned in Section 1.5.4.1, BC and CDML preferred to replace the different complicated bodies of the Brillouin zones for the possible values of the lattice parameters of the triclinic and monoclinic lattices by the simple primitive unit cells of the reciprocal lattice and to choose the representation domain correspondingly.

(2) For non-holosymmetric space groups the representation domain Φ is a multiple of the basic domain Ω. CDML introduce new letters for **k** vectors which do not belong to Ω. The more symmetry a space group has lost compared to its holosymmetric space group, the more letters of **k** vectors are introduced. The symbols of the basic domain Ω are kept in the names referred to the representation domain Φ. In most cases one can make the new **k** vectors uni-arm to **k** vectors of the basic domain Ω by an appropriate choice of Ω and Φ. Then these **k** vectors belong to the same **k**-vector type and the additional labels can be avoided by *extension of the parameter range* in the **k**-vector space (Boyle, 1986).

Examples where new letters can be avoided by the extension of the parameter range are common, see, *e.g.*, the examples of Section 1.5.5.

In the following example, the introduction of a new name in the transition from a holosymmetric space group to a non-holosymmetric one cannot be avoided because the Wintgen position splits into two positions. We consider the **k** label $Z, \alpha, \frac{1}{2}, 0$ of CDML for the arithmetic crystal class $m\bar{3}mP$, reciprocal-space group $(\mathcal{G})^* = (Pm\bar{3}m)^*$, isomorphic to $Pm\bar{3}m$, Wyckoff position 12 *h* *mm*2 $x, \frac{1}{2}, 0$. In the subgroup $(Pm\bar{3})^*$, this Wintgen position splits into the two positions $\alpha, \frac{1}{2}, 0$ and $\frac{1}{2}, \alpha, 0$, called *Z* and *ZA* by CDML. In the description of *IT* A they are 6 *g* *mm*2 $x, \frac{1}{2}, 0$ and 6 *f* *mm*2 $\frac{1}{2}, x, 0$. In $Pm\bar{3}$, they form two different Wyckoff positions and thus need two different names, as do their Wintgen positions.

1.5.5. Examples and discussion

The comparison of the crystallographic classification scheme with the traditional one is illustrated by four examples from the Bilbao Crystallographic Server (1998). The examples are designated by the arithmetic crystal classes.

To each arithmetic crystal class of space groups, *cf.* Section 1.5.3.2, there belongs exactly one reciprocal-space group $(\mathcal{G})^*$ which is isomorphic to a type of symmorphic space groups $\mathcal{G}_0$, *cf.* Sections 1.5.3.2 and 1.5.3.4.

(1) **k**-vector types of the arithmetic crystal class $m\bar{3}mI$ (space groups $Im\bar{3}m$ and $Ia\bar{3}d$), reciprocal-space group $(\mathcal{G})^*$ isomorphic to $Fm\bar{3}m$. The representation domain $\Phi = \Omega$ is equal to the asymmetric unit, see Fig. 1.5.5.1 and Table 1.5.5.1.

(2) **k**-vector types of the arithmetic crystal class $m\bar{3}I$ (space groups $Im\bar{3}$ and $Ia\bar{3}$), reciprocal-space group $(\mathcal{G})^*$ isomorphic to $Fm\bar{3}$. The representation domain $\Phi > \Omega$ is equal to the asymmetric unit; see Fig. 1.5.5.2 and Table 1.5.5.2.

(3) **k**-vector types of the arithmetic crystal class $4/mmmI$ ($I4/mmm$, $I4/mcm$, $I4_1/amd$ and $I4_1/acd$), reciprocal-space group $(\mathcal{G})^*$ isomorphic to $I4/mmm$. The representation domains $\Phi = \Omega$ are topologically different for different ratios of the lattice parameters a and c whereas the asymmetric units are affinely equivalent; see Figs. 1.5.5.3 and 1.5.5.4 and Tables 1.5.5.3 and 1.5.5.4.

(4) **k**-vector types of the arithmetic crystal class $mm2F$ ($Fmm2$ and $Fdd2$), reciprocal-space group $(\mathcal{G})^*$ isomorphic to $Imm2$. The representation domains $\Phi > \Omega$ are topologically different for different ratios of the lattice parameters a, b and c whereas the asymmetric units are affinely equivalent; see Figs. 1.5.5.5, 1.5.5.6 and 1.5.5.7, and Tables 1.5.5.5, 1.5.5.6 and 1.5.5.7.

These examples consist essentially of figures and tables. The Brillouin zones with the representation domains of CDML together with the asymmetric units are displayed in the figures. In the synoptic tables the correlation between the **k**-vector tables of CDML and the tables of (Wyckoff) positions in *IT* A is presented. One can thus compare the different descriptions and recognize the relations between them. In addition, the parameter ranges of the **k**-vector types in the asymmetric unit are stated. If a **k**-vector type is listed in the table more than once, then the equivalence relations between the **k** vectors are added such that exactly one representative may be selected for each **k**-vector orbit.

1.5.5.1. Guide to the figures

Each figure caption gives the name of the arithmetic crystal class of space groups to which the Brillouin zone belongs. If there is more than one figure for this arithmetic crystal class, then these figures refer to different geometric conditions for the lattice. Therefore, for each of the figures the arithmetic crystal class is followed by the specific conditions for the lattice parameters of this figure, *e.g.* '$c/a < 1$' for Fig. 1.5.5.3 or '$a^{-2} < b^{-2} + c^{-2}$, $b^{-2} < c^{-2} + a^{-2}$ and $c^{-2} < a^{-2} + b^{-2}$' for Fig. 1.5.5.5.

Then the space groups of the arithmetic crystal class are listed with their Hermann–Mauguin symbols, their Schoenflies symbols and their space-group numbers in *IT* A in parentheses. Following this the type of the reciprocal-space group is denoted, *e.g.* '$(Imm2)^*$, No. 44' for the arithmetic crystal class $mm2F$ in Fig. 1.5.5.5, together with the conditions for the lattice parameters of the reciprocal lattice, if any, and the number of the corresponding table.

The Brillouin zones are objects in reciprocal space. They are displayed in the figures. The reciprocal space is a vector space and its elements are the **k** vectors. Thus the Brillouin zone is a construction in vector space. Because the Brillouin zones are visualized by drawings consisting of vertices, lines and planes, one usually speaks of points, lines and planes in or on the border of the Brillouin zone, not of vectors. Here we follow this tradition.

The Brillouin zones are projected onto the drawing plane by a clinographic projection which may be found *e.g.* in Smith (1982), pp. 61 *f*. The coordinate axes are designated k_x, k_y and k_z; the k_z-coordinate axis points upwards in the projection plane. The diagrams of the Brillouin zones follow those of CDML in order to facilitate the comparison of the data. The origin O with coordinates 0, 0, 0 always forms the centre of the Brillouin zone and is called Γ.

A minimal domain is the smallest fraction of the Brillouin zone which contains *exactly* one wavevector **k** from each orbit. In these examples, the representation domain of CDML is compared with the minimal domain, called 'asymmetric unit', of the Bilbao Crystallographic Server. This asymmetric unit is a simple body and is often chosen in analogy to that of *IT* A. It may coincide with the representation domain of Table 3.10 in CDML, but is mostly rather different. Other than the representation domains of CDML, the asymmetric unit is often *not* fully contained in the Brillouin zone but protrudes from it, in particular by flagpoles and wings, *cf.* the end of this section.

In the figures the edges of the chosen asymmetric unit are drawn into the frame of the Brillouin zone. The names of points, lines and planes of CDML are retained in this listing. New names have been given to points and lines which are not listed in CDML.

The shape of the Brillouin zone depends on the lattice relations. Therefore, there may be vertices of the Brillouin zone with a variable coordinate. If such a point is displayed and designated in a figure by an upper-case letter, then the label of its variable coordinate in the corresponding table is the same letter but lower case. Thus, the variable coordinate of the point G_0 is g_0, of Λ_0 is λ_0 *etc*.

In CDML, the same letter may designate items of different quality in different figures and tables. For example, there is a point H in Fig. 1.5.5.1 and Table 1.5.5.1 but a line H in Fig. 1.5.5.5 and Table 1.5.5.5. In the figures and tables of these examples not only lines and points but also their equivalent objects are listed and the parameter ranges of the lines are described. Therefore, the endpoints of the line H, the points equivalent to a point H as well as the lines equivalent to a line H may be also designated by the letter H but distinguished by indices. In order to recognize points and lines easily, the indices of points are always even: H_0, H_2, H_4; those of lines are always odd: H_1, H_3.

A point is marked in a figure by its name and by a black circle filled with white if it is listed in the corresponding **k**-vector table but is not a point of special symmetry. The same designation is used for the auxiliary points that have been added in order to facilitate the comparison between the two descriptions of the **k**-vector types. Non-coloured parts of the coordinate axes, of the edges of the Brillouin zone or auxiliary lines are displayed by thin solid black lines. Such lines are dashed or omitted if they are not visible, *i.e.* are hidden by the body of the Brillouin zone or of the asymmetric unit.

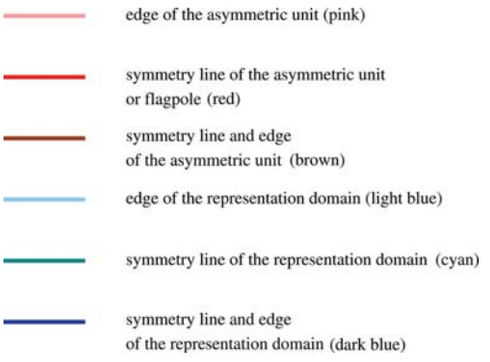
The representatives for the orbits of symmetry points or of symmetry lines, as well as the edges of the representation domain of CDML and of the chosen asymmetric unit are shown in colour.

(*a*) A representative point of each orbit of symmetry points is designated by a red- or cyan-filled circle with its name also in red or cyan if it belongs to the asymmetric unit or to the representation domain of CDML. If both colours could be used, *e.g.* if the asymmetric unit coincides with the representation domain, the colour is red.

Note that a point is coloured red or cyan only if it is really a symmetry *point*, *i.e.* its little co-group is a proper supergroup of the little co-groups of all points in its neighbourhood. Such a point has no variable parameters in its coordinates. Points listed by CDML are not coloured if they are part of a symmetry line or symmetry plane only.

(*b*) Coloured lines are always broad. They are solid lines if they are 'visible', *i.e.* if they are not hidden by the Brillouin zone or by the asymmetric unit. A hidden symmetry line or edge of the asymmetric unit is not suppressed but is coloured as a *dashed line*.

(*c*) The meanings of the different coloured lines and the names used for them in the text are as follows:



edge of the asymmetric unit (pink)
symmetry line of the asymmetric unit or flagpole (red)
symmetry line and edge of the asymmetric unit (brown)
edge of the representation domain (light blue)
symmetry line of the representation domain (cyan)
symmetry line and edge of the representation domain (dark blue)

Notes:

(1) The colour of the line is pink for an edge of the asymmetric unit which is not a symmetry line.

(2) The colour is red for a symmetry line of the asymmetric unit, with the name also in red.

(3) The colour of the line is brown with the name in red for a line which is a symmetry line as well as an edge of the asymmetric unit.

The representation domain of CDML is displayed in the same figure.

(1) The edges of the representation domain are coloured light blue.

(2) The symmetry points and lines with their letters are coloured cyan.

(3) Edges of the representation domain or common edges of the representation domain and the asymmetric unit are coloured dark blue with the letters in cyan if they are symmetry lines of the representation domain but not of the asymmetric unit.

Common edges of an asymmetric unit and a representation domain are coloured pink if they are not symmetry lines simultaneously.

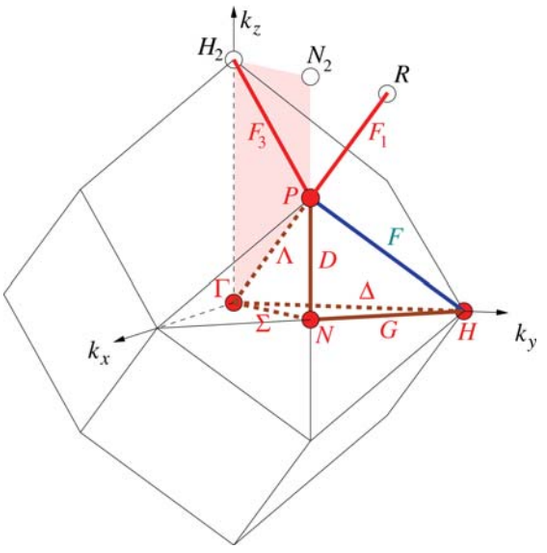


Fig. 1.5.5.1. Brillouin zone with asymmetric unit and representation domain of CDML for arithmetic crystal class $m\bar{3}mI$. Space groups: $Im\bar{3}m - O_h^9$ (229), $Ia\bar{3}d - O_h^{10}$ (230). Reciprocal-space group $(Fm\bar{3}m)$*, No. 225 (see Table 1.5.5.1). The representation domain of CDML is identical with the asymmetric unit. Auxiliary points: R: $\frac{1}{2},\frac{1}{2},\frac{1}{2}$; N_2: $\frac{1}{4},\frac{1}{4},\frac{1}{2}$; H_2: $0,0,\frac{1}{2}$. Flagpole: $F_1 = [P\,R]$ $\quad x,x,x$: $\frac{1}{4} < x < \frac{1}{2}$. Wing: $B_1 \cup J_1 = [\Gamma\,P\,N_2\,H_2]\backslash[F_3]$ $\quad x,x,z$: $0 < x < \frac{1}{4}$; $x < z < \frac{1}{2}$ with $z \neq \frac{1}{2} - x$.

Exactly one element of each point orbit, line orbit or orbit of planes is contained in the asymmetric unit. Exceptionally, *different* elements of the *same* orbit have been coloured because of their special meaning. In these cases the different elements are connected in the corresponding table by the equivalence sign $\sim$, see, *e.g.* the lines $F \sim F_1 = [P\,R]$ or the planes $B \sim B_1 = [P\,N_2\,H_2]$ in Table 1.5.5.1.

To enable a uni-arm description, symmetry lines outside the asymmetric unit may be selected as orbit representatives. Such a piece of a line is called a *flagpole*. Flagpoles are always coloured red, see, *e.g.*, the line F_1 in Fig. 1.5.5.1.

Symmetry planes are not distinguished in the figures. However, in analogy to the flagpoles, symmetry planes outside the asym-

metric unit may be selected as orbit representatives. Such a piece of a plane is called a *wing*. Wings are always coloured pink, see, *e.g.*, Fig. 1.5.5.1.

Within the caption of each figure the following data are listed:

(i) a statement of whether the representation domain and the asymmetric unit are identical or not;

(ii) the coordinates of auxiliary points if not specified in the corresponding table;

(iii) the parameter descriptions of the flagpoles and the wings.

1.5.5.2. Guide to the **k***-vector tables*

Each figure is followed by a table with the same number. As for the figures, each table caption gives the name of the arithmetic crystal class of space groups. If there is more than one table for this arithmetic crystal class, then the symbol for the arithmetic crystal class is followed by the specific conditions for the lattice parameters, as for the figures.

Column 1. Label of the **k** vectors in CDML, Tables 3.9 and 3.11 and parameter description of CDML for the set of **k** vectors which belong to the label. No ranges for the parameters are listed in CDML.

If two **k** vectors belong to the same type of **k** vectors, then their little co-groups are conjugate under the reciprocal-space group $(\mathcal{G})^*$ and they correspond to the same Wyckoff position. Different **k** vectors with the *same* CDML label always belong to the same **k**-vector type. **k** vectors with *different* CDML labels may either belong to the same or to different types of **k** vectors. If such **k** vectors belong to the same type, the corresponding Wyckoff-position descriptions are preceded by the letters '*ex*'. Frequently, such **k** vectors have been transformed (sign '$\sim$' in these tables) to equivalent ones in order to make the **k** vectors uni-arm, see the tables in this section.

The parameter range of a region may be described by the vertices of that region in brackets [...]. One point in brackets, *e.g.* [*P*], means the point *P*. Two points within the brackets, *e.g.* [*A B*] means the line from *A* to *B*. Three points within the brackets, *e.g.* [*A B C*] means the triangular region of a plane with the vertices *A*, *B* and *C*. Four or more points may mean a region of a plane or a three-dimensional body, depending on the positions of the points. The meaning can be recognized by studying the corresponding figure. Commas between the points, *e.g.* [*A*, *B*, *C*] indicate the set {*A*, *B*, *C*} of the three points *A*, *B* and *C*.

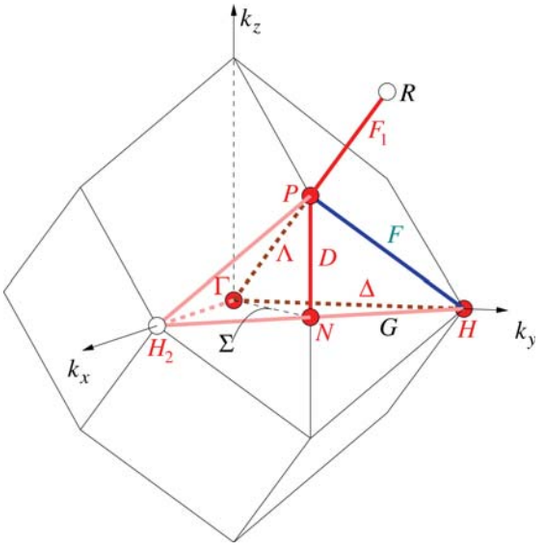

Fig. 1.5.5.2. Brillouin zone with asymmetric unit and representation domain of CDML for arithmetic crystal class $m\bar{3}I$. Space groups $Im\bar{3}-T_h^5$ (204), $Ia\bar{3}-T_h^7$ (206). Reciprocal-space group $(Fm\bar{3})^*$, No. 202 (see Table 1.5.5.2). The representation domain of CDML is identical with the asymmetric unit. Auxiliary points: R: $\frac{1}{2},\frac{1}{2},\frac{1}{2}$; H_2: $\frac{1}{2},0,0$. Flagpole: $F_1=[P\,R]$ x,x,x: $\frac{1}{4}<x<\frac{1}{2}$.

A symbol [...] does not indicate whether the vertices, boundary lines or boundary planes of the region are themselves included or not. All or part of them may belong to the region, all or part of them may not. In the parameter description of the region in Column 3 the inclusion or exclusion is stated by the symbols $\leq$ or $<$.

The backslash '\' is used to indicate included parts not belonging to the described region, see *e.g.* the regions $[\Gamma\,R]\backslash[P]$ and $[\Gamma\,N\,N_2\,H_2]\backslash[\Lambda,\ F_3]$ in Table 1.5.5.1.

Column 2. This column describes the Wyckoff positions (given as the multiplicity, the Wyckoff letter and the site symmetry) of that symmorphic space group $\mathcal{G}_0$ of *IT* A which is isomorphic to the reciprocal-space group $(\mathcal{G})^*$. Each Wyckoff position of $\mathcal{G}_0$ corresponds to a Wintgen position of $(\mathcal{G})^*$, *i.e.* to a type of **k** vectors of $(\mathcal{G})^*$ and *vice versa*.

'Multiplicity' is the number of points in the conventional unit cell of *IT* A. Here it is the number of arms of the star of the **k**

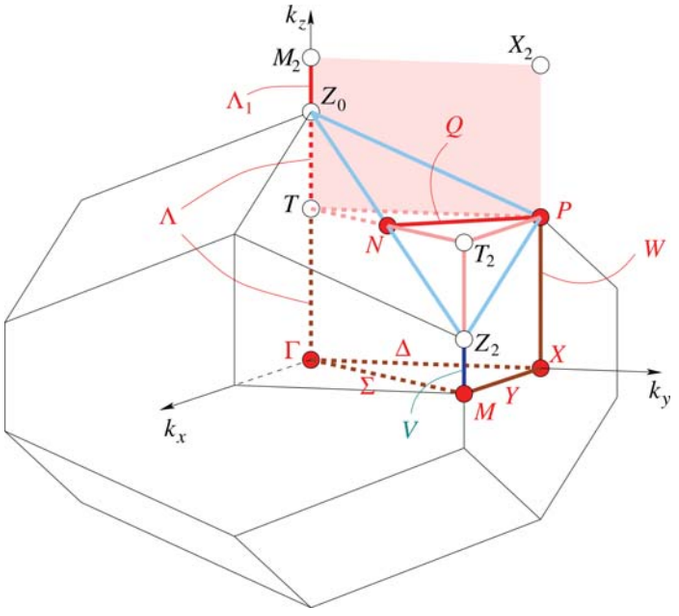

Fig. 1.5.5.3. Brillouin zone with asymmetric unit and representation domain of CDML for arithmetic crystal class $4/mmmI$: $c/a<1$. Space groups $I4/mmm-D_{4h}^{17}$ (139) to $I4_1/acd-D_{4h}^{20}$ (142). Reciprocal-space group $(I4/mmm)$*, No. 139: $c^*/a^*>1$ (see Table 1.5.5.3). The representation domain of CDML is different from the asymmetric unit. Auxiliary points: T: $0,0,\frac{1}{4}$; T_2: $\frac{1}{2},\frac{1}{2},\frac{1}{4}$; X_2: $0,\frac{1}{2},\frac{1}{2}$. Flagpole: $[T\,M_2]$ $\quad 0,0,z$: $\frac{1}{4}<z<\frac{1}{2}$. Wing: $[T\,P\,X_2\,M_2]$ $\quad 0,y,z$: $0<y<\frac{1}{2}$, $\frac{1}{4}<z<\frac{1}{2}$.

vector, multiplied by the number of centring vectors of the conventional unit cell in *IT* A.

Unlike in *IT* A, each table starts with the Wyckoff letter *a* for a Wyckoff position of highest site symmetry and proceeds in alphabetical order until the general position *GP* is reached. The sequence of the CDML labels is not that of CDML but is determined essentially by the alphabetical sequence of the Wyckoff positions.

The symbol for the site symmetry is 'oriented', as given in the space-group tables of *IT* A. For the nomenclature, see Section 2.2.12 of *IT* A.

Column 3. These are the parameters of that Wyckoff position of $\mathcal{G}_0$ which corresponds to the **k**-vector label in CDML, see Column 1. The *parameter description* and the *parameter range* are listed. This range is chosen such that each orbit of the Wyckoff position of *IT* A, *i.e.* also each **k**-vector orbit, is listed exactly once.

The following designation is used for the parameter ranges:

(1) The statement $0<x,\ y<\frac{1}{2}$ means that x and y may vary independently from 0 to $\frac{1}{2}$, 0 and $\frac{1}{2}$ both excluded.

(2) The statement

$$GP \quad \alpha,\beta,\gamma \quad 48\ h\ 1 \quad x,y,z\colon 0\le z<x<y<\tfrac{1}{2} \ \cup \ \cup\ x,\tfrac{1}{2},z\colon 0<z<x<\tfrac{1}{2}$$

means that the description of the asymmetric unit is split into two adjacent regions, a body and a plane. The boundary plane $z=0$ of the body is included, all other boundaries are excluded. Together the regions contain exactly one representative for each **k**-vector orbit of the general position *GP* of the reciprocal-space group.

(3) The statement $x,\frac{1}{2},z\colon -x<z\le x,\ z\ne 0$ means that z may assume any value between $-x$ and $+x$, $z=x$ included but $z=-x$ and $z=0$ excluded.

(4) Occasionally the parameter description becomes too clumsy. Then the data listed are abbreviated by replacing the parametrical data by the designation of the corresponding region.

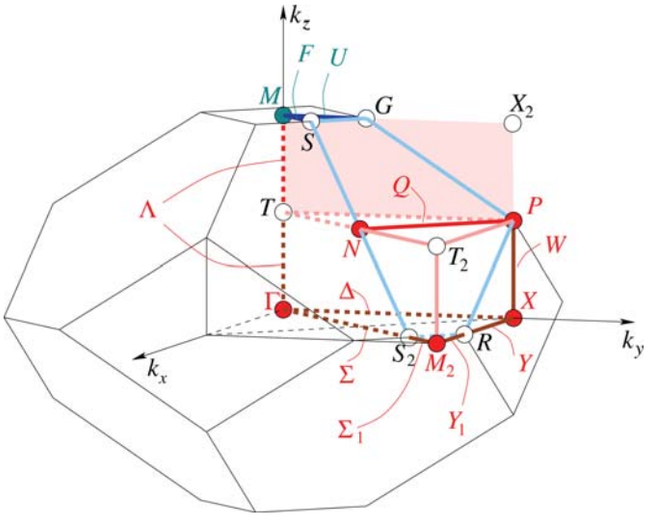

Fig. 1.5.5.4. Brillouin zone with asymmetric unit and representation domain of CDML for arithmetic crystal class $4/mmmI$: $c/a>1$. Space groups $I4/mmm-D_{4h}^{17}$ (139) to $I4_1/acd-D_{4h}^{20}$ (142). Reciprocal-space group $(I4/mmm)$*, No. 139: $c^*/a^*<1$ (see Table 1.5.5.4). The representation domain of CDML is different from the asymmetric unit. Auxiliary points: X_2: $0,\frac{1}{2},\frac{1}{2}$; T: $0,0,\frac{1}{4}$; T_2: $\frac{1}{2},\frac{1}{2},\frac{1}{4}$. Flagpole: $[T\,M]$ $0,0,z$: $\frac{1}{4}<z<\frac{1}{2}$. Wing: $[T\,P\,X_2\,M]$ $0,y,z$: $0<y<\frac{1}{2}, \frac{1}{4}<z<\frac{1}{2}$.

Example. In Table 1.5.5.3 one finds for the arithmetic crystal class $4/mmmI$ of space groups:

$$B\quad \alpha,\beta,-\alpha\quad 16\ m\ ..m\quad x,x,z\text{: }[\Gamma\,M\,Z_2\,Z_0]$$

The parameter description would be:

$$x,x,z\text{: }0<x<\tfrac{1}{2},\ 0<z\le z_0-2x(2z_0-\tfrac{1}{2})$$

Horizontal lines. The horizontal lines extending across the tables separate blocks with different numbers of free parameters. Decisive for this subdivision is the number of free parameters of the Wyckoff position to which the Wintgen position is assigned, not the number of free parameters of CDML.

Example. Arithmetic crystal class mm2F, see Table 1.5.5.5

The **k**-vector labels 'Γ $0,0,0$' and 'Z $\frac{1}{2},\frac{1}{2},0$' of CDML have no free parameter. However, they correspond to the Wyckoff position '2 *a mm*2 $0,0,z$', which has one free parameter. Therefore, Γ and Z are listed together with 'Λ $\alpha,\alpha,0$' and 'LE $-\alpha,-\alpha,0$' in the block for the symmetry lines, *i.e.* for the **k** vectors with one free parameter: in $(Imm2)$* there is no parameter-free Wintgen position at all. The **k**-vector labels 'Σ $0,\alpha,\alpha$' and 'A $\frac{1}{2},\frac{1}{2}+\alpha,\alpha$' of CDML have one free parameter each. However, they correspond together with other **k**-vector labels to the Wyckoff position '4 *c .m.* $x,0,z$'. Therefore, Σ and A are listed together with 'J $\alpha,\alpha+\beta,\beta$' and '$JA$ $-\alpha,-\alpha+\beta,\beta$' and others in the block for the planes, *i.e.* for the **k** vectors with two free parameters.

In general the sequence of the Wyckoff letters in *IT* A follows the falling number of free parameters. In the few cases where the sequence in *IT* A is different, the Wyckoff letters are exchanged. The exchange is noted at the top of the table.

Example. In the arithmetic crystal class $4/mmmI$, $c/a < 1$, see Table 1.5.5.3, Wyckoff position *e* has one free parameter, whereas Wyckoff position *f* has constant parameters, *i.e.* no free parameter. Therefore, *f* is listed above the horizontal line, *e* is listed below, see Table 1.5.5.3. The note at the top of the table states 'Wyckoff positions *e* and *f* exchanged'.

Parameter relations. The relations between the parameters of CDML and the parameters referred to the asymmetric unit are listed at the top of the table, *e.g.* for $m\bar{3}mI$ in Table 1.5.5.1: 'Parameter relations: $x = \frac{1}{2}\beta + \frac{1}{2}\gamma$, $y = \frac{1}{2}\alpha + \frac{1}{2}\gamma$, $z = \frac{1}{2}\alpha + \frac{1}{2}\beta$'. These relations may be modified to more convenient parameters without notice, as for the plane *B* of $m\bar{3}mI$ in Table 1.5.5.1:

$$B \quad \alpha+\beta, -\alpha+\beta, \tfrac{1}{2}-\beta \quad ex\ 96\ k\ ..m \quad x, \tfrac{1}{2}-x, z\colon\ 0 < z < x < \tfrac{1}{4}$$

instead of

$$\ldots \tfrac{1}{4} - \tfrac{1}{2}\alpha, \tfrac{1}{4} + \tfrac{1}{2}\alpha, \beta\colon\ 0 < \alpha < \tfrac{1}{2} - 2\beta < \tfrac{1}{2}.$$

1.5.5.3. Figures and tables

Arithmetic crystal classes $m\bar{3}mI$ *and* $m\bar{3}I$: The reciprocal lattice of a cubic lattice *I* is a cubic lattice *F*. Its Brillouin zone is a rhombic dodecahedron and has 12 faces, 24 edges and 14 apices, the coordinates of which are the six permutations of $\pm\frac{1}{2}, 0, 0$ and the eight coordinate triplets of $\pm\frac{1}{4}, \pm\frac{1}{4}, \pm\frac{1}{4}$. Eleven of these 14 points are visible in the applied projection.

The figure for arithmetic crystal class $m\bar{3}mI$ is shown in Fig. 1.5.5.1 and the corresponding table is Table 1.5.5.1. The figure for arithmetic crystal class $m\bar{3}I$ is shown in Fig. 1.5.5.2 and the corresponding table is Table 1.5.5.2.

Arithmetic crystal class $4/mmmI$: There are two different types of Brillouin zones for the tetragonal *I* lattice, one for $c < a$ (Fig. 1.5.5.3, Table 1.5.5.3) and one for $c > a$ (Fig. 1.5.5.4, Table 1.5.5.4). The first type of Brillouin zone, Fig. 1.5.5.3, is a tetragonal elongated rhombdodecahedron with 12 faces, four of them being hexagons. There are 18 apices; 14 of them are visible. The Brillouin zone of Fig. 1.5.5.4 is a tetragonally deformed cuboctahedron with 14 faces. There are 24 apices; 18 of them are visible.

Arithmetic crystal class mm2F: Depending on the lattice ratios *a*:*b*:*c*, there are four figures in CDML for the Brillouin zone of an orthorhombic crystal with an *F* lattice, see Fig. 3.6 on p. 26 in CDML. Only three of them are really necessary. Therefore, the case $b^{-2} > c^{-2} + a^{-2}$ of Fig. 3.6(c) of CDML has been omitted in these examples; it is obtained from $a^{-2} > c^{-2} + b^{-2}$ of Figure 3.6(d) by a rotation by 90° about the *c** axis. The three remaining

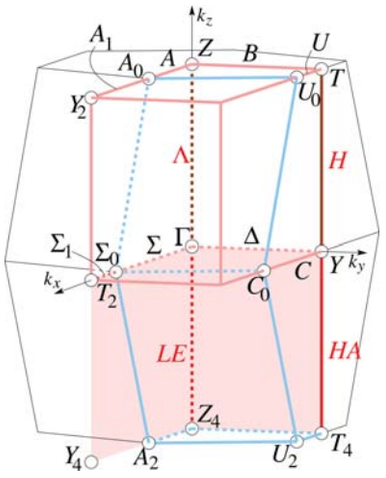

Fig. 1.5.5.7. Brillouin zone with asymmetric unit and representation domain of CDML for arithmetic crystal class *mm2F*: $a^{-2} > b^{-2} + c^{-2}$. Space groups $Fmm2 - C_{2v}^{18}$ (42), $Fdd2 - C_{2v}^{19}$ (43). Reciprocal-space group $(Imm2)^*$, No. 44: $a^{*2} > b^{*2} + c^{*2}$ (see Table 1.5.5.7). The representation domain of CDML is different from the asymmetric unit. Auxiliary points: T_4: $0, \frac{1}{2}, -\frac{1}{2}$; Y_4: $\frac{1}{2}, 0, -\frac{1}{2}$; Z_4: $0, 0, -\frac{1}{2}$. Flagpoles: $LE = [Z_4\,\Gamma]$ $0, 0, z$: $-\frac{1}{2} < z < 0$; $HA = [T_4\,Y]$ $0, \frac{1}{2}, z$: $-\frac{1}{2} < z < 0$. Wings: $JA \cup J_3 = [\Gamma\,T_2\,Y_4\,Z_4]$ $x, 0, z$: $0 < x < \frac{1}{2}, -\frac{1}{2} < z < 0$; $EA = [\Gamma\,Z_4\,T_4\,Y]$ $0, y, z$: $0 < y < \frac{1}{2}, -\frac{1}{2} < z < 0$.

Brillouin zones are displayed in Fig. 1.5.5.5 (see also Table 1.5.5.5), Fig. 1.5.5.6 (see also Table 1.5.5.6) and Fig. 1.5.5.7 (see also Table 1.5.5.7). Fig. 1.5.5.5 is a distorted cuboctahedron with 14 faces, 36 edges and 24 apices, 18 of which are visible. The Brillouin zones of Figs. 1.5.5.6 and 1.5.5.7 are distorted elongated rhombdodecahedra. There are 12 faces, 28 edges and 18 apices; 14 of them are visible.

1.5.5.4. Discussion

1.5.5.4.1. Representation domains and asymmetric units

When the symmetry of the reciprocal lattice allows, the shape of the asymmetric unit may be chosen to be much simpler than that of the representation domain.

Examples

(1) Arithmetic crystal class $4/mmmI$. The parameter ranges for the special lines and planes of the asymmetric unit and for general **k** vectors of the reciprocal-space group $(F4/mmm)^*$ [setting $(I4/mmm)^*$] are listed in Tables 1.5.5.3 and 1.5.5.4. One can describe the corresponding conditions of the representation domain by the boundary plane $x, y, z = \{1 + (c/a)^2[1 - 2(x + y)]\}/4$ which for $c/a < 1$ forms the triangle $[Z_0\,Z_2\,P]$ in Fig. 1.5.5.3 but for $c/a > 1$ the pentagon $[S_2\,R\,P\,G\,S]$ in Fig. 1.5.5.4. The inner points of this boundary plane are points of the general position *GP* with the exception of the line $Q = x, \frac{1}{2} - x, \frac{1}{4}$, which is a twofold rotation axis. The boundary conditions for the representation domain depend on c/a; they are much more complicated than those, $x, y, z = \frac{1}{4}$, for the asymmetric unit.

(2) Arithmetic crystal class *mm2F*, see Figs. 1.5.5.5 to 1.5.5.7. In the reciprocal-space group $(Imm2)^*$ the lines Λ and *LE* belong to Wintgen position 2 *a mm*2, as do the lines *Q*, *QA*, Λ_1 and Λ_3 if present. The lines *H* and *HA* belong to the Wintgen position 2 *b mm*2; as do the lines *G*, *GA*, H_1 and H_3 if present. The lines Σ, Σ_1, *A*, A_1, *C* and *U* belong to the plane $x, 0, z$; the lines Δ, *B*, B_1 and *D* belong to the plane $0, y, z$. The decisive boundary plane of the representation domain is $xa^{*2} + yb^{*2} + zc^{*2} = d^{*2}/4$, where $d^{*2} = a^{*2} + b^{*2} + c^{*2}$; it is a hexagon for Fig. 1.5.5.5 and a parallelogram for Figs. 1.5.5.6 and 1.5.5.7. There is no relation of the lattice parameters for which all the above-mentioned lines are realized on the surface of the representation domain simultaneously; either two or

Table 1.5.5.7. *List of* **k***-vector types for arithmetic crystal class mm2F:* $a^{-2} > b^{-2} + c^{-2}$

See Fig. 1.5.5.7. Parameter relations: $x = -\frac{1}{2}\alpha + \frac{1}{2}\beta + \frac{1}{2}\gamma$, $y = \frac{1}{2}\alpha - \frac{1}{2}\beta + \frac{1}{2}\gamma$, $z = \frac{1}{2}\alpha + \frac{1}{2}\beta - \frac{1}{2}\gamma$.

GP α, β, γ		8	*e*	1	x, y, z: $0 < x, y < \frac{1}{2}, 0 \leq z < \frac{1}{2}$

three of them do not appear and the length of the others depends on the boundary plane, see Tables and Figs. 1.5.5.5 to 1.5.5.7.

The boundary conditions for the asymmetric unit are independent of the lattice parameters and the boundary plane is always represented by the simple equation $x, y, \frac{1}{2}$: $0 < x, y < \frac{1}{2}$. By introducing flagpoles and wings, the description may become uni-arm.

1.5.5.4.2. Splitting of **k**-vector types

The Brillouin zone as well as the unit cell are always convex bodies; the same holds for the representation domain of CDML and for the choice of the asymmetric unit. It is thus sometimes unavoidable that the **k**-vector types are split and that the different parts belong to different arms and to different stars of **k** vectors. Sometimes this splitting of **k**-vector types may be avoided by an appropriate choice of the asymmetric unit; sometimes the introduction of flagpoles and wings is necessary to make the **k**-vector types uni-arm.

Examples

(1) In the reciprocal-space group $(\mathcal{G})^* = (Fm\bar{3}m)^*$, No. 225 of the arithmetic crystal class $m\bar{3}mI$ there are the lines of **k** vectors Λ (α, α, α) and F $(\frac{1}{2} - \alpha, -\frac{1}{2} + 3\alpha, \frac{1}{2} - \alpha)$ of CDML, p. 41. By Figure 1.5.5.1 one sees that the line Λ connects the points Γ and P, the line F connects the points P and H. One takes from the corresponding Table 1.5.5.1 the coefficients of $P = \frac{1}{4}, \frac{1}{4}, \frac{1}{4}$ and $H = 0, \frac{1}{2}, 0$. From these points or from the transformation listed at the top of Table 1.5.5.1 as 'Parameter relations' the coefficients of the line F are obtained as $F = x, \frac{1}{2} - x, x$; $0 < x < \frac{1}{4}$.

The inspection of the symmetry diagram of $Fm\bar{3}m$, No. 225, in *IT* A shows that a twofold rotation 2 (represented by the 4_2 $\frac{1}{4}, y, \frac{1}{4}$ screw-rotation axis) leaves the point P invariant, whereas the point H is mapped onto the point R $\frac{1}{2}, \frac{1}{2}, \frac{1}{2}$. More formally: the rotation is described by $x, \frac{1}{2} - x, x \rightarrow \frac{1}{2} - x, \frac{1}{2} - x, \frac{1}{2} - x$, where $0 < x < \frac{1}{4}$. The result is the line $F_1 = [R\,P]$. It is uni-arm to the line $\Lambda = x, x, x$ and the union $\Lambda \cup F_1$ forms the Wintgen position 32 *f* 3*m*. An analoguous result is obtained for the same lines in the arithmetic crystal class $m\bar{3}I$.

(2) In the following example the splitting of a Wintgen position happens if a representation domain of the Brillouin zone is chosen. The splitting can be avoided by the choice of the asymmetric unit. We consider the plane $x, y, 0$ in the arithmetic crystal class $4/mmmI$, see Fig. 1.5.5.4 and Table 1.5.5.4. In CDML this plane is split into the parts $C = [\Gamma\,S_2\,R\,X]$ and $D = [M\,S\,G] \sim [M_2\,S_2\,R]$. By the choice of the asymmetric unit the independent region of the Wintgen position is uni-arm: $[\Gamma M_2 X] = 16\ l\ m..\ x, y, 0$: $0 < x < y < \frac{1}{2}$.

(3) The splitting of a Wintgen position can be avoided if flagpoles and wings are admitted, *i.e.* if the minimal domain is described by a non-convex body. If one chooses in the first example of the arithmetic crystal classes $m\bar{3}mI$ and $m\bar{3}I$ the union $\Lambda \cup F_1$ for the line x, x, x, then $F_1 = [P\,R]$ forms a flagpole, whereas Λ forms an edge of the asymmetric unit, see Figs. 1.5.5.1 and 1.5.5.2.

The same holds for the Wintgen position 96 *k* ..*m* x, x, z of $m\bar{3}mI$. In the representation domain which is simultaneously the asymmetric unit, this Wintgen position is split into three parts *B*, *C* and *J*, which form three of the four walls of the (tetrahedral) minimal domain. By proper symmetry operations these three parts can be made uni-arm to the part *C*, such that their union $C \cup B_1 \cup J_1$ describes the independent part of that Wintgen position, see Fig. 1.5.5.1. The part *C* forms a wall of the asymmetric unit; the part $B_1 \cup J_1$ forms a wing, see Fig. 1.5.5.1.

1.5.5.4.3. **k**-vector types for non-holosymmetric space groups

The **k**-vector labels of CDML are primarily listed for the holosymmetric space groups. These lists are kept and supplemented for the non-holosymmetric space groups. In this way many superfluous **k**-vector labels are introduced.

Examples

(1) Arithmetic crystal class $m\bar{3}I$. In its reciprocal-space group $(Fm\bar{3})^*$, the introduction of the plane $AA = [\Gamma\,H_2\,N]$ is unnecessary because the plane $A = [\Gamma\,N\,H]$ of Wintgen position 96 *j* *m*.. of $(Fm\bar{3}m)^*$ can be extended to $A \cup AA = [\Gamma\,H_2\,H]$ in the reciprocal-space group $(Fm\bar{3})^*$, *cf.* Fig. 1.5.5.2 and Table 1.5.5.2. In $(Fm\bar{3})^*$, both planes, *A* and *AA*, belong to Wintgen position 48 *h* *m*... The parameter description is extended from $x, y, 0$: $0 < x < y < \frac{1}{2} - x (< \frac{1}{4})$ to $0 < y < \frac{1}{2} - x < \frac{1}{2}$.

(2) In the previous example, during the transition from the group $(Fm\bar{3}m)^*$ to the subgroup $(Fm\bar{3})^*$ the order of the little co-group of the special **k** vectors of $(Fm\bar{3}m)^*$ was not changed. In other cases, the little co-group may be reduced to a subgroup. Such **k** vectors may then be incorporated into a more general Wintgen position and described by an extension of the parameter range.

Arithmetic crystal class $m\bar{3}mI$, plane $[\Gamma\,H\,N] = x, y, 0$. In $(Fm\bar{3}m)^*$, see Fig. 1.5.5.1, all points (Γ, H, N) and lines (Δ, Σ, G) of the boundary of the asymmetric unit are special. In $(Fm\bar{3})^*$, see Fig. 1.5.5.2, the lines Δ and $[\Gamma\,H_2] \sim \Delta$ are special but Σ, *G* and $[N\,H_2] \sim G$ belong to the plane $(A \cup AA)$. The free parameter range on the line *G* is $0 < y < \frac{1}{4}$. Therefore, the parameter ranges of $(A \cup AA \cup G \cup \Sigma)$ in $x, y, 0$ can be taken as: $0 < x < \frac{1}{2} - y < \frac{1}{2}$ for $A \cup AA \cup \Sigma$ and $0 < y = \frac{1}{2} - x < \frac{1}{4}$ for *G*.

1.5.5.4.4. Ranges of independent parameters

In Section 1.5.4.3 a method for the determination of the parameter ranges was described. A few examples shall display the procedure.

(1) Arithmetic crystal class $m\bar{3}mI$, line $\Lambda \cup F_1$: In the reciprocal-space group $(Fm\bar{3}m)^*$ of the arithmetic crystal class $m\bar{3}mI$, the line x, x, x has stabilizer $\bar{3}m$ and little co-group $\overline{\mathcal{G}}^{\mathbf{k}} = 3m$. Therefore, the divisor is 12:6 = 2 and x is running from 0 to $\frac{1}{2}$.

The same result holds for the line $\Lambda \cup F_1$ in the reciprocal-space group $(Fm\bar{3})^*$ of the arithmetic crystal class $m\bar{3}I$: the stabilizer generated by $\bar{3}$ is of order 6, $|\overline{\mathcal{G}}^{\mathbf{k}}| = |\{\bar{3}\}| = 3$, the quotient is again $\frac{1}{2}$, the parameter range is the same as for $(Fm\bar{3}m)^*$.

(2) Arithmetic crystal class $m\bar{3}mI$, plane $B_1 \cup C \cup J_1$: In $(Fm\bar{3}m)^*$, the stabilizer of x, x, z is generated by *m*.*mm* and the centring translation $t(\frac{1}{2}, \frac{1}{2}, 0)$ mod (integer translations). They generate a group of order 16; $\overline{\mathcal{G}}^{\mathbf{k}}$ is ..*m* of order 2. The fraction of the plane is $\frac{2}{16} = \frac{1}{8}$ of the area $\sqrt{2}a^{*2}$ in the (centred) unit cell, as expressed by the parameter ranges $0 < x < \frac{1}{4}, 0 < z < \frac{1}{2}$. There are six arms of the star of x, x, z: x, x, z; $\bar{x}, x, z$; x, y, x; $x, y, \bar{x}$; x, y, y; $x, \bar{y}, y$. Three of them (x, x, z, $\bar{x}, x, z$ and x, y, x) are represented in the boundaries of the representation domain: $C = [\Gamma\,N\,P]$, $B = [H\,N\,P]$ and $J = [\Gamma\,H\,P]$, see Fig. 1.5.5.1. The areas of their parameter ranges are $\frac{1}{32}, \frac{1}{32}$ and $\frac{1}{16}$, respectively; the sum is $\frac{1}{8}$.

Arithmetic crystal class $m\bar{3}I$, the same result holds in the reciprocal-space group $(Fm\bar{3})^*$. The stabilizer generated by $2/m$.. and by the centring translation $t(\frac{1}{2}, \frac{1}{2}, 0)$ mod (integer translations) forms a group of order 8; the order of the little co-group $|\overline{\mathcal{G}}^{\mathbf{k}}| = |\{1\}| = 1$. The quotient is again $\frac{1}{8}$, the parameter range is the same as for $(Fm\bar{3}m)^*$ but the plane belongs to the general position *GP* because the little co-group is trivial.

(3) Arithmetic crystal class $m\bar{3}mI$, reciprocal-space group $(Fm\bar{3}m)^*$, plane $x, y, 0$: the stabilizer of the plane *A* is generated by $4/mmm$ and $t(\frac{1}{2}, \frac{1}{2}, 0)$, order 32, $\overline{\mathcal{G}}^{\mathbf{k}}$ (site-symmetry group) *m*..,

order 2. Consequently, $[\Gamma\ H\ N]$ is $\frac{1}{16}$ of the unit square a^{*2}: $0 < x < y < \frac{1}{2} - x$. In $(Fm\overline{3})^*$, the stabilizer of $x, y, 0$, here $A \cup AA$, is mmm. and $t(\frac{1}{2}, \frac{1}{2}, 0)$, order 16, with the same group $\overline{\mathcal{G}}^{\mathbf{k}} = m..$ of order 2. Therefore, $[\Gamma\ H_2\ H]$ is $\frac{1}{8}$ of the unit square a^{*2} in $(Fm\overline{3})^*$; $0 < y < \frac{1}{2} - x < \frac{1}{2}$.

(4) Arithmetic crystal class $m\overline{3}mI$, line $x, x, 0$: In $(Fm\overline{3}m)^*$ the stabilizer is generated by $m.mm$ and $t(\frac{1}{2}, \frac{1}{2}, 0)$ mod (integer translations), order 16, $\overline{\mathcal{G}}^{\mathbf{k}}$ is $m.2m$ of order 4. The divisor is 4 and thus $0 < x < \frac{1}{4}$. In $(Fm\overline{3})^*$ the stabilizer is generated by $2/m..$ and $t(\frac{1}{2}, \frac{1}{2}, 0)$ mod (integer translations), order 8, and $\overline{\mathcal{G}}^{\mathbf{k}} = m..$, order 2; the divisor is 4 again and $0 < x < \frac{1}{4}$ is restricted to the same range.

In the way just described the *inner* part of the parameter range can be fixed. The *boundaries* of the parameter range must be determined in addition:

(1) Arithmetic crystal classes $m\overline{3}mI$ and $m\overline{3}I$, *i.e.* $(Fm\overline{3}m)^*$ and $(Fm\overline{3})^*$, line x, x, x: The points $0, 0, 0$; $\frac{1}{2}, \frac{1}{2}, \frac{1}{2}$ (and $\frac{1}{4}, \frac{1}{4}, \frac{1}{4}$) are special points; the parameter ranges are open: $0 < x < \frac{1}{4}$, $\frac{1}{4} < x < \frac{1}{2}$.

(2) Arithmetic crystal class $m\overline{3}mI$, plane x, x, z: In $(Fm\overline{3}m)^*$ all corners Γ, N, N_2, H_2 and all edges are special points or lines. Therefore, the parameter ranges are open: x, x, z: $0 < x < \frac{1}{4}, 0 < z < \frac{1}{2}$, where the lines x, x, x: $0 < x < \frac{1}{4}$ and $x, x, \frac{1}{2} - x$: $0 < x < \frac{1}{4}$ are special lines and thus excepted.

(3) Arithmetic crystal classes $m\overline{3}mI$ and $m\overline{3}I$, plane $x, y, 0$: In both reciprocal-space groups, $(Fm\overline{3}m)^*$ and $(Fm\overline{3})^*$, $0 < x$ and $0 < y$ holds. The line $0, y, 0 = \Delta$ is a special line, its $\mathbf{k}$ vectors have little co-groups of higher order than that of the planes $x, y, 0$ and the boundaries of both planes are open. The same holds for the boundary $x, 0, 0 \sim 0, y, 0$ for $(Fm\overline{3})^*$. The $\mathbf{k}$ vectors of the lines $x, x, 0$ and $x, \frac{1}{2} - x, 0$, Σ and G, also have little co-groups of higher order and belong to other Wintgen positions in the representation domain (or asymmetric unit) of $(Fm\overline{3}m)^*$. Therefore, for the arithmetic crystal class $m\overline{3}mI$, the plane $A = x, y, 0$ is open at its boundaries $x, x, 0$ and $x, \frac{1}{2} - x, 0$ in the range $0 < x < \frac{1}{4}$. In the asymmetric unit of $(Fm\overline{3})^*$ the lines $x, x, 0$: $0 < x < \frac{1}{4}$ and $x, \frac{1}{2} - x, 0$: $0 < x < \frac{1}{4}$ belong to the plane, and the boundary of the plane A is here closed. The boundary line $x, \frac{1}{2} - x, 0$: $\frac{1}{4} < x < \frac{1}{2}$ of the plane AA is equivalent to the range $0 < x < \frac{1}{4}$ of the part A and thus does not belong to the asymmetric unit; here the boundary of the plane $A \cup AA$ is open.

1.5.6. Conclusions

International Tables for Crystallography Volume A can serve as a basis for the classification of irreps of space groups by using the concept of reciprocal-space groups. The main features of the crystallographic classification scheme are as follows.

(i) The asymmetric units of the conventional crystallographic unit cells are minimal domains of $\mathbf{k}$ space which are in many cases simpler than the representation domains of the Brillouin zones.

(ii) All $\mathbf{k}$-vector stars giving rise to the same type of irreps belong to the same Wintgen position and *vice versa*. They can be collected in one entry (uni-arm description) and are designated by the same Wintgen letter if flagpoles and wings are admitted.

(iii) The Wyckoff positions of *IT* A, interpreted as Wintgen positions, provide a complete list of the special $\mathbf{k}$ vectors in the Brillouin zone; the site symmetry of *IT* A is the little co-group $\overline{\mathcal{G}}^{\mathbf{k}}$ of $\mathbf{k}$; the multiplicity per primitive unit cell is the number of arms of the star of $\mathbf{k}$. The Wintgen positions with 0, 1, 2, or 3 variable parameters correspond to special $\mathbf{k}$-vector points, $\mathbf{k}$-vector lines, $\mathbf{k}$-vector planes or to the set of all general $\mathbf{k}$ vectors, respectively.

The complete set of types of irreps is obtained by considering the irreps of one $\mathbf{k}$ vector per Wintgen position in the uni-arm description. A complete set of inequivalent irreps of $\mathcal{G}$ is obtained from these irreps by varying the parameters within their ranges.

Data on the independent parameter ranges are essential to make sure that exactly one $\mathbf{k}$ vector per orbit is represented in the representation domain Φ or in the asymmetric unit. Such data are often much easier to calculate for the asymmetric unit of the unit cell than for the representation domain of the Brillouin zone, in particular if a uni-arm description has been chosen, *cf.* Section 1.5.5. Such data can not be found in the cited tables of irreps.

The uni-arm description unmasks those $\mathbf{k}$ vectors which lie on the boundary of the Brillouin zone but belong to a Wintgen position which also contains inner $\mathbf{k}$ vectors, see the example of the lines Λ and F in $(Fm\overline{3}m)^*$ and $(Fm\overline{3})^*$. Such $\mathbf{k}$ vectors can not give rise to little-group representations obtained from projective representations of the little co-group $\overline{\mathcal{G}}^{\mathbf{k}}$.

The consideration of the basic domain Ω in relation to the representation domain Φ is unnecessary. It may even be misleading because special $\mathbf{k}$-vector subspaces of Ω frequently belong to more general types of $\mathbf{k}$ vectors in Φ. Space groups $\mathcal{G}$ with non-holohedral point groups can be referred to their reciprocal-space groups $(\mathcal{G})^*$ directly without reference to the types of irreps of the corresponding holosymmetric space group.

In principle both approaches are equivalent: the *traditional* one by Brillouin zone, basic domain and representation domain and the *crystallographic* one by unit cell and asymmetric unit. Moreover, it is not difficult to relate one approach to the other, see Figs. and Tables 1.5.5.1 to 1.5.5.7. The conclusions show that the crystallographic approach for the description of irreps of space groups has several advantages as compared with the traditional approach. Owing to these advantages, CDML have already accepted the crystallographic approach for triclinic and monoclinic space groups. However, the advantages are not restricted to such low symmetries. In particular, the simple boundary conditions and shapes of the asymmetric units result in simple equations for the boundaries and shapes of volume elements and facilitate numerical calculations, integrations *etc.* If there are special reasons to prefer $\mathbf{k}$ vectors inside or on the boundary of the Brillouin zone to those outside, then the advantages and disadvantages of both approaches have to be compared in order to find the optimal way to solve the problem.

The crystallographic approach may be realized in three different ways:

(1) In the *uni-arm description* one lists each $\mathbf{k}$-vector star exactly once by indicating the parameter field of the representing $\mathbf{k}$ vector. Advantages are the transparency of the presentation and the relatively small effort for the derivation of the list. A disadvantage may be that there are protruding flagpoles or wings. Points of flagpoles or wings are no longer neighbours of inner points (an inner point has a full three-dimensional sphere of neighbours which belong to the asymmetric unit).

(2) In the *compact description* one lists each $\mathbf{k}$ vector exactly once such that each point of the asymmetric unit is either an inner point itself or has inner points as neighbours. Such a description may not be uni-arm for some Wintgen positions, and the determination of the parameter ranges may become less straightforward.

(3) In the *non-unique description* one gives up the condition that each $\mathbf{k}$ vector is listed exactly once. The uni-arm and the compact descriptions are combined but the equivalence relations ($\sim$) are stated explicitly for those $\mathbf{k}$ vectors which occur in more than one entry. Such tables are most informative and not too complicated for practical applications.

The authors wish to thank the editor of this volume, Uri Shmueli, for his patient support, for his encouragement and for his valuable help. They are grateful to the former Chairman of the Commission on *International Tables*, Theo Hahn, for his interest and advice. Part of the material in this chapter was first published as an article of the same title in *Z. Kristallogr.* (1995),

210, 243–254. We are indebted to R. Oldenbourg Verlag, Munich, Germany, for allowing us to reprint parts of this article.

APPENDIX A1.5.1
Reciprocal-space groups $(\mathcal{G})^*$

This table is based on Table 1 of Wintgen (1941).

In order to obtain the Hermann–Mauguin symbol of $(\mathcal{G})^*$ from that of $\mathcal{G}$, one replaces any screw rotations by rotations and any glide reflections by reflections. The result is the symmorphic space group $\mathcal{G}_0(\mathcal{G})$. For most space groups $\mathcal{G}$, the reciprocal-space group $(\mathcal{G})^*$ is isomorphic to $\mathcal{G}_0(\mathcal{G})$, *i.e.* $\mathcal{G}_0(\mathcal{G})$ and $(\mathcal{G})^*$ belong to the same arithmetic crystal class. In the following cases $(\mathcal{G})^*$ is isomorphic to a symmorphic space group $\mathcal{G}_0$ which is different from $\mathcal{G}_0(\mathcal{G})$. Thus the arithmetic crystal classes of $\mathcal{G}$ and $(\mathcal{G})^*$ are different, *i.e.* $(\mathcal{G})^*$ can not be obtained in this simple way:

(1) If the lattice symbol of $\mathcal{G}$ is F or I, it has to be replaced by I or F, *e.g.* $(\mathcal{G})^*$ is isomorphic to $Imm2$ for the arithmetic crystal class $\mathcal{G} = mm2F$. The tetragonal space groups form an exception to this rule; for these the symbol I persists.

(2) The other exceptions are listed in the following table (for the symbols of the arithmetic crystal classes see *IT* A, Section 8.2.3):

Arithmetic crystal class of $\mathcal{G}$	Reciprocal-space group $(\mathcal{G})^*$
$\bar{4}m2I$	$I\bar{4}2m$
$\bar{4}2mI$	$I\bar{4}m2$
$321P$	$P312$
$312P$	$P321$
$3m1P$	$P31m$
$31mP$	$P3m1$
$\bar{3}1mP$	$P\bar{3}m1$
$\bar{3}m1P$	$P\bar{3}1m$
$\bar{6}m2P$	$P\bar{6}2m$
$\bar{6}2mP$	$P\bar{6}m2$

2.1. Statistical properties of the weighted reciprocal lattice

By U. Shmueli and A. J. C. Wilson†

2.1.1. Introduction

The structure factor of the *hkl* reflection is given by

$$F(hkl) = \sum_{j=1}^{N} f_j \exp[2\pi i(hx_j + ky_j + lz_j)], \qquad (2.1.1.1)$$

where f_j is the atomic scattering factor [complex if there is appreciable dispersion; see Chapter 1.2 and *IT* C (2004, Section 4.2.6)], $x_j y_j z_j$ are the fractional coordinates of the jth atom and N is the number of atoms in the unit cell. The present chapter is concerned with the statistical properties of the structure factor F and the intensity $I = FF^*$, such as their average values, variances, higher moments and their probability density distributions.

Equation (2.1.1.1) expresses F as a function of two conceptually different sets of variables: *hkl* taking on integral values in reciprocal space and *xyz* in general having non-integral values in direct space, although the special positions tabulated for each space group in *IT* A (2005) may include the integers 0 and 1. In special positions, the non-integers often include rational fractions, but in general positions they are in principle irrational. Although *hkl* and *xyz* appear to be symmetrical variables in (2.1.1.1), these limitations on their values mean that one can consider two different sets of statistical properties. In the first we seek, for example, the average intensity of the *hkl* reflection (indices fixed) as the positional parameters of the N atoms are distributed with equal probability over the continuous range 0–1. In the second, we seek, for example, the average intensity of the observable reflections (or of a subgroup of them having about the same value of $\sin\theta$) with the values of *xyz* held constant at the values they have, or are postulated to have, in a crystal structure. Other examples are obtained by substituting the words 'probability density' for 'average intensity'. For brevity, we may call the statistics resulting from the first process *fixed-index* (continuously variable parameters being understood), and those resulting from the second process *fixed-parameter* (integral indices being understood). Theory based on the first process is (comparatively) easy; theory based on the second hardly exists, although there is a good deal of theory concerning the conditions under which the two processes will lead to the same result (Hauptman & Karle, 1953; Giacovazzo, 1977, 1980). Mathematically, of course, the condition is that the phase angle

$$\vartheta = 2\pi(hx + ky + lz) \qquad (2.1.1.2)$$

should be distributed with uniform probability over the range 0–2π, whichever set of variables is regarded as fixed, but it is not clear when this distribution can be expected in practice for fixed-parameter averaging. The usual conclusion is that the uniform distribution will be realized if there are enough atoms, if the atomic coordinates do not approximate to rational fractions, if there are enough reflections and if stereochemical effects are negligible (Shmueli *et al.*, 1984).

Obviously, the second process (fixed parameters, varying integral indices) corresponds to the observable reality, and various approximations to it have been attempted, in preference to assuming its equivalence with the first. For example, a third (approximate) method of averaging has been used (Wilson, 1949, 1981): *xyz* are held fixed and *hkl* are treated as continuous variables.

† Deceased.

2.1.2. The average intensity of general reflections

2.1.2.1. Mathematical background

The process may be illustrated by evaluating, or attempting to evaluate, the average intensity of reflection by the three processes. The intensity of reflection is given by multiplying equation (2.1.1.1) by its complex conjugate:

$$I = FF^* \qquad (2.1.2.1)$$

$$= \sum_{j,k} f_j f_k^* \exp\{2\pi i[h(x_j - x_k) + \ldots]\} \qquad (2.1.2.2)$$

$$= \Sigma + \sum_{j\neq k} f_j f_k^* \exp\{2\pi i[h(x_j - x_k) + \ldots]\}, \qquad (2.1.2.3)$$

where

$$\Sigma = \sum_j f_j f_j^* \qquad (2.1.2.4)$$

is the sum of the squares of the moduli of the atomic scattering factors. Wilson (1942) argued, without detailed calculation, that the average value of the exponential term would be zero and hence that

$$\langle I\rangle = \Sigma. \qquad (2.1.2.5)$$

Averaging equation (2.1.2.3) for *hkl* fixed, *xyz* ranging uniformly over the unit cell – the first process described above – gives this result identically, without complication or approximation. Ordinarily the second process cannot be carried out. We can, however, postulate a special case in which it is possible. We take a homoatomic structure and before averaging we correct the f's for temperature effects and the fall-off with $\sin\theta$, so that ff^* is the same for all the atoms and is independent of *hkl*. If the range of *hkl* over which the expression for I has to be averaged is taken as a parallelepiped in reciprocal space with h ranging from $-H$ to $+H$, k from $-K$ to $+K$, l from $-L$ to $+L$, equation (2.1.2.2) can be factorized into the product of the sums of three geometrical progressions. Algebraic manipulation then easily leads to

$$\langle I\rangle = ff^* \sum_j \sum_k \frac{\sin\pi N_H(x_j - x_k)}{N_H \sin\pi(x_j - x_k)} \times \frac{\sin\pi N_K(y_j - y_k)}{N_K \sin\pi(y_j - y_k)} \frac{\sin\pi N_L(z_j - z_k)}{N_L \sin\pi(z_j - z_k)}, \qquad (2.1.2.6)$$

where $N_H = 2H + 1$, $N_K = 2K + 1$ and $N_L = 2L + 1$. The terms with $j = k$ give Σ, but the remaining terms are not zero. Because of the periodic nature of the trigonometric terms, the effective coordinate differences are never greater than 0.5 and in a structure of any complexity there will be many much less than 0.5. For $HKL = 000$, in fact, $\langle I\rangle$ becomes the square of the modulus of the sum of the atomic scattering factors,

$$\langle I\rangle = \Phi\Phi^*, \qquad (2.1.2.7)$$

where

$$\Phi = \sum_{j=1}^{N} f_j, \qquad (2.1.2.8)$$

and not the sum of the squares of their moduli; for larger HKL, $\langle I\rangle$ rapidly decreases to Σ and then oscillates about that value.

Copyright © 2010 International Union of Crystallography

Wilson (1949, especially Section 2.1.1) suggested that the regions of averaging should be chosen so that at least one index of every reflection is ≥ 2 if $\langle I \rangle$ is to be identified with Σ, and this has proven to be a useful rule-of-thumb.

The third process of averaging replaces the sum over integral values of the indices by an integration over continuous values, the appropriate values of the limits in this example being $-(H + 1/2)$ to $+(H + 1/2)$. The effect is to replace the sines in the denominators, but not in the numerators, of equation (2.1.2.6) by their arguments, and this is equivalent to the approximation $\sin x \simeq x$ in the denominators only. This is a good approximation for atoms close together in the structure and thus giving the largest terms in the sums in equation (2.1.2.6), and gives the correct sign and order of magnitude even for x having its maximum value of $\pi/2$.

2.1.2.2. Physical background

The preceding section has used mathematical arguments. From a physical point of view, the radiation diffracted by atoms that are resolved will interfere destructively, so that the resulting intensity will be the sum of the intensities diffracted by individual atoms, whereas that from completely unresolved atoms will interfere constructively, so that *amplitudes* rather than intensities add. In intermediate cases there will be partial constructive interference. Resolution in accordance with the Rayleigh (1879) criterion requires that $s = (2 \sin \theta)/\lambda$ should be greater than half the reciprocal of the minimum interatomic distance in the crystal (Wilson, 1979); full resolution requires a substantial multiple of this. This criterion is essentially equivalent to that proposed from the study of a special case of the second process in the preceding section.

2.1.2.3. An approximation for organic compounds

In organic compounds there are very many interatomic distances of about 1.5 or 1.4 Å. Adoption of the preceding criterion would mean that the inner portion of the region of reciprocal space accessible by the use of copper $K\alpha$ radiation is not within the sphere of intensity statistics based on fixed-index (first process) averaging. No substantial results are available for fixed-parameter (second process) averaging, and very few from the approximation to it (third process).

To the extent to which the third process is acceptable, an approximation to the variation of $\langle I \rangle$ with $\sin \theta$ is obtainable. The exponent in equation (2.1.2.2) can be written as

$$2\pi i s r_{jk} \cos \psi, \tag{2.1.2.9}$$

where s is the radial distance in reciprocal space, r_{jk} is the distance from the jth to the kth atom and ψ is the angle between the vectors **s** and **r**. Averaging over a sphere of radius s, with ψ treated as the colatitude, gives

$$\langle I \rangle = \sum_j \sum_k f_j f_k \frac{\sin 2\pi s r_{jk}}{2\pi s r_{jk}}. \tag{2.1.2.10}$$

This is the familiar Debye expression. It has the correct limits for s zero and s large, and is in accord with the argument from resolution.

2.1.2.4. Effect of centring

In the preceding discussion there has been a tacit assumption that the lattice is primitive. A centred crystal can always be referred to a primitive lattice and if this is done no change is required. If the centred lattice is retained, many reflections are identically zero and the intensity of the nonzero reflections is enhanced by a factor of two (I and C lattices) or four (F lattice), so that the average intensity of all the reflections, zero and nonzero taken together, is unchanged.

Table 2.1.3.1. *Intensity-distribution effects of symmetry elements and centred lattices causing systematic absences*

Abbreviations and orientation of axes: A = acentric distribution, C = centric distribution, Z = systematically zero, S = distribution parameter, $\langle I \rangle$ = average intensity. Axes are parallel to **c**, planes are perpendicular to **c**.

Element	Reflections	Distribution	S/Σ	$\langle I \rangle/\Sigma$

C, I	All	$(Z + A)/2$	1	2
F	All	$(3Z + A)/2$	1	4

Other symmetry elements affect only zones and rows of reflections, and so do not affect the general average when the total number of reflections is large. Their effect on zones and rows is discussed in Section 2.1.3.

2.1.3. The average intensity of zones and rows

2.1.3.1. Symmetry elements producing systematic absences

Symmetry elements can be divided into two types: those that cause systematic absences and those that do not. Those producing systematic absences (glide planes and screw axes) produce at the same time groups of reflections (confined to zones and rows in reciprocal space, respectively) with an average intensity an integral[1] multiple of the general average. The effects for single symmetry elements of this type are given in Table 2.1.3.1 for the general reflections *hkl* and separately for any zones and rows that are affected. The 'average multipliers' are given in the column headed $\langle I \rangle/\Sigma$; 'distribution' and 'distribution parameters' are treated in Section 2.1.5. As for the centring, the fraction of reflections missing and the integer multiplying the average are related in such a way that the overall intensity is unchanged. The mechanism for compensation for the reflections with enhanced intensity is obvious.

2.1.3.2. Symmetry elements not producing systematic absences

Certain symmetry elements not producing absences (mirror planes and rotation axes) cause equivalent atoms to coincide in a

[1] The multiple is given as an exact integer for fixed-index averaging, an approximate integer for fixed-parameter averaging. Statements should be understood to refer to fixed-index averaging unless the contrary is explicitly stated.

Table 2.1.3.2. *Intensity-distribution effects of symmetry elements not causing systematic absences*

Abbreviations and orientation of axes: A = acentric distribution, C = centric distribution, S = distribution parameter, $\langle I\rangle$ = average intensity. Axes are parallel to **c**, planes are perpendicular to **c**.

plane or a line projection and hence produce a zone or row in reciprocal space for which the average intensity is an integral multiple of the general average (Wilson, 1950); the effects of single such symmetry elements are given in Table 2.1.3.2. There is, however, no obvious mechanism for compensation for this enhancement. When reflections are few this may be an important matter in assigning an approximate absolute scale by comparing observed and calculated intensities. Wilson (1964), Nigam (1972) and Nigam & Wilson (1980), noting that in such cases the finite size of atoms results in forbidden ranges of positional parameters, have shown that there is a diminution of the intensity of layers (rows) in the immediate neighbourhood of the enhanced zones (rows), just sufficient to compensate for the enhancement. In forming general averages, therefore, reflections from enhanced zones or rows should be included at their full intensity, not divided by the multiplier; the matter is discussed in more detail by Wilson (1987*a*). It should be noted, however, that organic structures containing molecules related by rotation axes are rare, and such structures related by mirror planes are even rarer (Wilson, 1993).

2.1.3.3. More than one symmetry element

Further alterations of the intensities occur if two or more such symmetry elements are present in the space group. The effects were treated in detail by Rogers (1950), who used them to construct a table for the determination of space groups by supplementing the usual knowledge of Laue group with statistical information. Only two pairs of space groups, the orthorhombic $I222$ and $I2_12_12_1$, and their cubic supergroups $I23$ and $I2_13_1$, remained unresolved. Examination of this table shows that what statistical information does is to resolve the Laue group into point groups; the further resolution into space groups is equivalent to the use of Table 3.1.4.1 in *IT* A (2005). The statistical consequences of each point group, as given by Rogers, are reproduced in Table 2.1.3.3.

Table 2.1.3.3. *Average multiples for the 32 point groups (modified from Rogers, 1950)*

The multiple gives S/Σ for the row and zone corresponding to the principal axis of the point-group symbol; those for the secondary and tertiary axes are given when the symbol contains such axes.

	Principal		Secondary		Tertiary

Note. The pairs of point groups, 1 and $\bar{1}$ and 3 and $\bar{3}$, not distinguished by average multiples, may be distinguished by their centric and acentric probability density functions. † The entry for the principal zone for the point group 422 was given incorrectly as 2 in the first edition of this volume.

2.1.4. Probability density distributions – mathematical preliminaries

For the purpose of this chapter, 'ideal' probability distributions or probability density functions are the asymptotic forms obtained by the use of the central-limit theorem when the number of atoms in the unit cell, N, is sufficiently large. In order to derive them it is necessary to outline the properties of characteristic functions and to state alternative conditions for the validity of the central-limit theorem; the distributions themselves are derived in Section 2.1.5.

2.1.4.1. Characteristic functions

The average value of $\exp(itx)$ is very important in probability theory; it is called the characteristic function of the distribution $f(x)$ and is denoted by $C_x(t)$ or, when no confusion can arise, by

$C(t)$. It exists for all legitimate distributions, whether discrete or continuous. In the continuous case it is given by

$$C(t) = \int_{-\infty}^{\infty} \exp(itx) f(x)\,\mathrm{d}x, \tag{2.1.4.1}$$

and is thus the Fourier transform of $f(x)$. In many cases it can be obtained from known integrals. For example, for the Cauchy distribution,

$$C(t) = \frac{a}{\pi} \int_{-\infty}^{\infty} \frac{\exp(itx)}{a^2 + x^2}\,\mathrm{d}x \tag{2.1.4.2}$$

$$= \exp(-a|t|), \tag{2.1.4.3}$$

and for the normal distribution,

$$C(t) = (2\pi\sigma^2)^{-1/2} \int_{-\infty}^{\infty} \exp\left(\frac{-(x-m)^2}{2\sigma^2}\right) \exp(itx)\,\mathrm{d}x \tag{2.1.4.4}$$

$$= \exp\left(imt - \frac{\sigma^2 t^2}{2}\right). \tag{2.1.4.5}$$

Since the characteristic function is the Fourier transform of the distribution function, the converse is true, and if the characteristic function is known the probability distribution function can be obtained by the use of Fourier inversion theorem,

$$f(x) = (1/2\pi) \int_{-\infty}^{\infty} \exp(-itx) C(t)\,\mathrm{d}t. \tag{2.1.4.6}$$

An alternative approach to the derivation of the distribution from a known characteristic function will be discussed below.

The most important property of characteristic functions in crystallography is the following: if x and y are independent random variables with characteristic functions $C_x(t)$ and $C_y(t)$, the characteristic function of their sum

$$z = x + y \tag{2.1.4.7}$$

is the product

$$C_z(t) = C_x(t) C_y(t). \tag{2.1.4.8}$$

Obviously this can be extended to any number of independent random variables.

When the moments exist, the characteristic function can be expanded in a power series in which the kth term is $m_k(it)^k/k!$. If the power series

$$\exp(itx) = 1 + itx + \frac{(it)^2 x^2}{2!} + \frac{(it)^3 x^3}{3!} + \ldots \tag{2.1.4.9}$$

is substituted in equation (2.1.4.1), one obtains

$$C(t) = 1 + itm_1' + \frac{(it)^2 m_2'}{2!} + \frac{(it)^3 m_3'}{3!} + \ldots. \tag{2.1.4.10}$$

The moments are written with primes in order to indicate that equation (2.1.4.10) is valid for moments about an arbitrary origin as well as for moments about the mean. If the random variable is transformed by a change of origin and scale, say

$$y = \frac{x - a}{b}, \tag{2.1.4.11}$$

the characteristic function for y becomes

$$C_y(t) = b \exp(-iat/b) C_x(t). \tag{2.1.4.12}$$

2.1.4.2. The cumulant-generating function

A function that is often more useful than the characteristic function is its logarithm, the cumulant-generating function:

$$K(t) = \log C(t) = k_1 + \frac{k_2(it)^2}{2!} + \frac{k_3(it)^3}{3!} + \ldots, \tag{2.1.4.13}$$

where the k's are called the *cumulants* and may be regarded as being defined by the equation. They can be evaluated in terms of the moments by combining the series (2.1.4.10) for $C(t)$ with the ordinary series for the logarithm and equating the coefficients of t^r. In most cases the process as described is tedious, but it can be shortened by use of a general method [Stuart & Ord (1994), Section 3.14, pp. 87–88; Exercise 3.19, p. 119]. Obviously, the cumulants exist only if the moments exist. The first few relations are

$$\begin{aligned} k_0 &= 0 \\ k_1 &= m_1' \\ k_2 &= m_2 = m_2' - (m_1')^2 \\ k_3 &= m_3 = m_3' - 3m_2'm_1' + 2(m_1')^2 \\ k_4 &= m_4 - 3(m_2)^2 \\ &= m_4' - m_3'm_1' - 3(m_2')^2 + 12m_2'(m_1)^2 - 6(m_1')^4. \end{aligned} \tag{2.1.4.14}$$

Such expressions and their converses up to k_{10} are given by Stuart & Ord (1994, pp. 88–91). Since all the cumulants except k_1 can be expressed in terms of the central moments only (*i.e.*, those unprimed), only k_1 is changed by a change of the origin. Because of this property, they are sometimes called the semi-invariants (or seminvariants) of the distribution. Since addition of random variables is equivalent to the multiplication of their characteristic functions [equation (2.1.4.8)] and multiplication of functions is equivalent to the addition of their logarithms, each cumulant of the distribution of the sum of a number of random variables is equal to the sum of the cumulants of the distribution functions of the individual variables – hence the name cumulants. Although the cumulants (except k_1) are independent of a change of origin, they are not independent of a change of scale. As for the moments, a change of scale simply multiplies them by a power of the scale factor; if $y = x/b$

$$(k_y)_r = (k_x)_r / b^r. \tag{2.1.4.15}$$

The cumulants of the normal distribution are particularly simple. From equation (2.1.4.5), the cumulant-generating function of a normal distribution is

$$K(t) = imt - \sigma^2 t^2/2 \tag{2.1.4.16}$$

$$k_1 = m \tag{2.1.4.17}$$

$$k_2 = \sigma^2, \tag{2.1.4.18}$$

all cumulants with $r > 2$ are identically zero.

2.1.4.3. The central-limit theorem

A simple form of this important theorem can be stated as follows:

If $x_1, x_2, \ldots, x_n$ are independent and identically distributed random variables, each of them having the same mean m and variance σ^2, then the sum

$$S_n = \sum_{j=1}^{n} x_j \tag{2.1.4.19}$$

tends to be normally distributed – independently of the distribution(s) of the individual random variables – with mean nm and variance $n\sigma^2$, provided n is sufficiently large.

In order to prove this theorem, let us define a standardized random variable corresponding to the sum S_n, *i.e.*, such that its mean is zero and its variance is unity:

$$\hat{S}_n = \frac{S_n - nm}{\sigma\sqrt{n}} = \frac{\sum_{j=1}^{n}(x_j - m)}{\sigma\sqrt{n}} \equiv \sum_{j=1}^{n}\frac{W_j}{\sqrt{n}}, \qquad (2.1.4.20)$$

where $W_j = (x_j - m)/\sigma$ is a standardized single random variable. The characteristic function of $\hat{S}_n$ is therefore given by

$$\begin{aligned} C_n(\hat{S}_n, t) &= \langle \exp(it\hat{S}_n)\rangle \\ &= \left\langle \exp\left[it\sum_{j=1}^{n}\frac{W_j}{\sqrt{n}}\right]\right\rangle \qquad (2.1.4.21)\\ &= \prod_{j=1}^{n}\left\langle \exp\left[it\frac{W_j}{\sqrt{n}}\right]\right\rangle \qquad (2.1.4.22)\\ &= \left\{\left\langle \exp\left[it\frac{W_1}{\sqrt{n}}\right]\right\rangle\right\}^n, \qquad (2.1.4.23)\end{aligned}$$

where the brackets $\langle\ \rangle$ denote the operation of averaging with respect to the appropriate probability density function (p.d.f.) [*cf.* equation (2.1.4.1)]. Equation (2.1.4.22) follows from equation (2.1.4.21) by the assumption of independence, while the assumption of identically distributed variables leads to the identity of the characteristic functions of the individual variables – as seen in equation (2.1.4.23).

On the assumption that moments of all the orders exist – a most plausible assumption in situations usually encountered in structure-factor statistics – we can now expand the characteristic function of a single variable in a power series [*cf.* equation (2.1.4.10)]:

$$\begin{aligned}\left\langle \exp\left[it\frac{W_1}{\sqrt{n}}\right]\right\rangle &= \left\langle \sum_{r=0}^{\infty}\frac{(it)^r}{r!}\frac{W_1^r}{n^{r/2}}\right\rangle \\ &= \sum_{r=0}^{\infty}\frac{(it)^r}{r!}\frac{\langle W_1^r\rangle}{n^{r/2}} \\ &\equiv 1 - \frac{t^2}{2n} + \frac{\zeta(t,n)}{n}, \qquad (2.1.4.24)\end{aligned}$$

since $\langle W_1\rangle = 0$, $\langle W_1^2\rangle = 1$, and the quantity denoted by $\zeta(t, n)$ in (2.1.4.24) is given by

$$\zeta(t,n) = \sum_{r=3}^{\infty}\frac{(it)^r}{r!}\frac{\langle W_1^r\rangle}{n^{(r/2)-1}}. \qquad (2.1.4.25)$$

The characteristic function of $\hat{S}_n$ is therefore

$$\langle \exp(it\hat{S}_n)\rangle = \left[1 - \frac{t^2}{2n} + \frac{\zeta(t,n)}{n}\right]^n. \qquad (2.1.4.26)$$

Now, as is seen from (2.1.4.25), for every fixed t the quantity $\zeta(t, n)$ tends to zero as n tends to infinity. The cumulant-generating function of the standardized sum then becomes

$$\log C_n(\hat{S}_n, t) = n\log\left[1 - \frac{1}{n}\left(\frac{t^2}{2} - \zeta(t,n)\right)\right] \qquad (2.1.4.27)$$

and the logarithm on the right-hand side of equation (2.1.4.27) has the form $\log(1 - z)$ with $|z| \to 0$ as $n \to \infty$. We may therefore use the expansion

$$\log(1-z) = -\left(z + \frac{z^2}{2} + \frac{z^3}{3} + \cdots\right),$$

which is valid for $|z| < 1$. We then obtain

$$\begin{aligned}\log C_n(\hat{S}_n, t) &= -n\left[\frac{1}{n}\left(\frac{t^2}{2} - \zeta(t,n)\right) + \frac{1}{2n^2}\left(\frac{t^2}{2} - \zeta(t,n)\right)^2\right. \\ &\quad \left. + \frac{1}{3n^3}\left(\frac{t^2}{2} - \zeta(t,n)\right)^3 + \cdots\right] \\ &= -\frac{t^2}{2} + \zeta(t,n) - \frac{1}{2n}\left(\frac{t^2}{2} - \zeta(t,n)\right)^2 \\ &\quad - \frac{1}{3n^2}\left(\frac{t^2}{2} - \zeta(t,n)\right)^3 - \cdots\end{aligned}$$

and finally, for every fixed t,

$$\lim_{n\to\infty}\log C_n(\hat{S}_n, t) = -\frac{t^2}{2}. \qquad (2.1.4.28)$$

Since the logarithm is a continuous function of t, it follows directly that

$$\lim_{n\to\infty} C_n(\hat{S}_n, t) = \exp\left(-\frac{t^2}{2}\right). \qquad (2.1.4.29)$$

The right-hand side of (2.1.4.29) is just the characteristic function of a standardized normal p.d.f., *i.e.*, a normal p.d.f. with zero mean and unit variance [*cf.* equation (2.1.4.5)]. The asymptotic expression for the p.d.f. of the standardized sum is therefore obtained as

$$p(\hat{S}) = \frac{1}{\sqrt{2\pi}}\exp\left(-\frac{\hat{S}^2}{2}\right),$$

which proves the above version of the central-limit theorem.

Surprisingly, this theorem has a very wide applicability and values of n as low as 30 are often large enough for the theorem to be useful. Situations in which the normal p.d.f. must be modified or replaced by an altogether different one are dealt with in Sections 2.1.7 and 2.1.8 of this chapter.

2.1.4.4. Conditions of validity

The above outline of a proof of the central-limit theorem depended on the existence of moments of all orders. The components of structure factors always possess finite moments of all orders, but the existence of moments beyond the second is not necessary for the validity of the theorem and it can be proved under much less stringent conditions. In fact, if all the random variables in equation (2.1.4.19) have the *same* distribution – as in a homoatomic structure – the only requirement is that the second moments of the distributions should exist [the Lindeberg–Lévy theorem (*e.g.* Cramér, 1951)]. If the distributions are not the same – as in a heteroatomic structure – some further condition is necessary to ensure that no individual random variable dominates the sum. The Liapounoff proof requires the existence of third absolute moments, but this is regarded as aesthetically displeasing; a theorem that ultimately involves only means and variances should require only means and variances in the proof. The Lindeberg–Cramér conditions meet this aesthetic criterion. Roughly, the conditions are that S^2, the variance of the sum, should tend to infinity and σ_j^2/S^2, where σ_j^2 is the variance of the jth random variable, should tend to zero for all j as n tends to infinity. The precise formulation is quoted by Kendall & Stuart (1977, p. 207).

2.1.4.5. Non-independent variables

The central-limit theorem, under certain conditions, remains valid even when the variables summed in equation (2.1.4.19) are not independent. The conditions have been investigated by Bernstein (1922, 1927); roughly they amount to requiring that the

variables should not be too closely correlated. The theorem applies, in particular, when each x_r is related to a finite number, $f(n)$, of its neighbours, when the x's are said to be $f(n)$ dependent. The $f(n)$ dependence seems plausible for crystallographic applications, since the positions of atoms close together in a structure are closely correlated by interatomic forces, whereas those far apart will show little correlation if there is any flexibility in the asymmetric unit when unconstrained. Harker's (1953) idea of 'globs' seems equivalent to $f(n)$ dependence. Long-range stereochemical effects, as in pseudo-graphitic aromatic hydrocarbons, would presumably produce long-range correlations and make $f(n)$ dependence less plausible. If Bernstein's conditions are satisfied, the central-limit theorem would apply, but the actual value of $\langle x^2\rangle - \langle x\rangle^2$ would have to be used for the variance, instead of the sum of the variances of the random variables in (2.1.4.19). Because of the correlations the two values are no longer equal.

French & Wilson (1978) seem to have been the first to appeal explicitly to the central-limit theorem extended to non-independent variables, but many previous workers [for typical references, see Wilson (1981)] tacitly made the replacement – in the X-ray case substituting the local mean intensity for the sum of the squares of the atomic scattering factors.

2.1.5. Ideal probability density distributions

In applications of the central-limit theorem, and its extensions, to intensity statistics the x_j's of equation (2.1.4.19) have the form (atomic scattering factor of the jth atom) times (a trigonometric expression characteristic of the space group and Wyckoff position; also known as the trigonometric structure factor). These trigonometric expressions for all the space groups, and general Wyckoff positions, are given in Tables A1.4.3.1 through A1.4.3.7, and their first few even moments (fixed-index averaging) are given in Table 2.1.7.1. One cannot, of course, conclude that the magnitudes of the structure factor always have a normal distribution – even if the structure is homoatomic; one must look at each problem and see what components of the structure factor can be put in the form (2.1.4.19), deduce the m and σ^2 to be used for each, and combine the components to obtain the asymptotic (large N, not large x) expression for the problem in question. Ordinarily the components are the real and the imaginary parts of the structure factor; the structure factor is purely real only if the structure is centrosymmetric, the space-group origin is chosen at a crystallographic centre and the atoms are nondispersive.

2.1.5.1. Ideal acentric distributions

The ideal acentric distributions are obtained by applying the central-limit theorem to the real and the imaginary parts of the structure factor, as given by equation (2.1.1.1). Consider first a crystal with no rotational symmetry (space group $P1$). The real part, A, of the structure factor is then given by

$$A = \sum_{j=1}^{N} f_j \cos\vartheta_j, \tag{2.1.5.1}$$

where N is the number of atoms in the unit cell and ϑ_j is the phase angle of the jth atom. The central-limit theorem then states that A tends to be normally distributed about its mean value with variance equal to its mean-square deviation from its mean. Under the assumption that the phase angles ϑ_j are uniformly distributed on the 0–2π range, the mean value of each cosine is zero, so that its variance is

$$\sigma^2 = \sum_{j=1}^{N} f_j^2 \langle\cos^2\vartheta_j\rangle. \tag{2.1.5.2}$$

Under the same assumption, the mean value of each $\cos^2\vartheta$ is one-half, so that the variance becomes

$$\sigma^2 = (1/2)\sum_{j=1}^{N} f_j^2 = (1/2)\Sigma, \tag{2.1.5.3}$$

where Σ is the sum of the squares of the atomic scattering factors [*cf.* equation (2.1.2.4)]. The asymptotic form of the distribution of A is therefore given by

$$p(A)\,\mathrm{d}A = (\pi\Sigma)^{-1/2}\exp(-A^2/\Sigma)\,\mathrm{d}A. \tag{2.1.5.4}$$

A similar calculation, with sines instead of cosines, gives an analogous distribution for the imaginary part B, so that the joint probability of the real and imaginary parts of F is

$$p(A, B)\,\mathrm{d}A\,\mathrm{d}B = (\pi\Sigma)^{-1}\exp[-(A^2 + B^2)/\Sigma]\,\mathrm{d}A\,\mathrm{d}B. \tag{2.1.5.5}$$

Ordinarily, however, we are more interested in the distribution of the magnitude, $|F|$, of the structure factor than in the distribution of A and B. Using polar coordinates in equation (2.1.5.5) [$A = |F|\cos\phi$, $B = |F|\sin\phi$] and integrating over the angle ϕ gives

$$p(|F|)\,\mathrm{d}|F| = (2|F|/\Sigma)\exp(-|F|^2/\Sigma)\,\mathrm{d}|F|. \tag{2.1.5.6}$$

It is usually convenient, in structure-factor and intensity statistics, to express the results in terms of the normalized structure factor E and its magnitude $|E|$. If $|F|$ has been put on an absolute scale (see Section 2.2.4.3), we have

$$E = \frac{F}{\sqrt{\Sigma}} \quad \text{and} \quad |E| = \frac{|F|}{\sqrt{\Sigma}}, \tag{2.1.5.7}$$

so that

$$p(|E|)\,\mathrm{d}|E| = 2|E|\exp(-|E|^2)\,\mathrm{d}|E| \tag{2.1.5.8}$$

is the normalized-structure-factor version of (2.1.5.6).

Distributions resulting from noncentrosymmetric crystals are known as *acentric* distributions; those arising from centrosymmetric crystals are known as *centric*. These adjectives are used to describe *distributions*, not crystal symmetry.

2.1.5.2. Ideal centric distributions

When a nondispersive crystal is centrosymmetric, and the space-group origin is chosen at a crystallographic centre of symmetry, the imaginary part B of its structure amplitude is zero. In the simplest case, space group $P\bar{1}$, the contribution of the jth atom plus its centrosymmetric counterpart is $2f_j\cos\vartheta_j$. The calculation of $p(A)$ goes through as before, with allowance for the fact that there are $N/2$ pairs instead of N independent atoms, giving

$$p(A)\,\mathrm{d}A = (2\pi\Sigma)^{-1/2}\exp[-A^2/(2\Sigma)]\,\mathrm{d}A \tag{2.1.5.9}$$

or equivalently

$$p(|F|)\,\mathrm{d}|F| = [2/(\pi\Sigma)]^{1/2}\exp[-|F|^2/(2\Sigma)]\,\mathrm{d}|F| \tag{2.1.5.10}$$

or

$$p(|E|)\,\mathrm{d}|E| = (2/\pi)^{1/2}\exp(-|E|^2/2)\,\mathrm{d}|E|. \tag{2.1.5.11}$$

2.1.5.3. Effect of other symmetry elements on the ideal acentric and centric distributions

Additional crystallographic symmetry elements do not produce any essential alterations in the ideal centric or acentric distribution; their main effect is to replace the parameter Σ by a 'distribution parameter', called S by Wilson (1950) and Rogers

Table 2.1.5.1. *Some properties of gamma and beta distributions*

If $x_1, x_2, \ldots, x_n$ are independent gamma-distributed variables with parameters $p_1, p_2, \ldots, p_n$, their sum is a gamma-distributed variable with $p = p_1 + p_2 + \ldots + p_n$.

If x and y are independent gamma-distributed variables with parameters p and q, then the ratio $u = x/y$ has the distribution $\beta_2(u;\ p, q)$.

With the same notation, the ratio $v = x/(x + y)$ has the distribution $\beta_1(v;\ p, q)$.

Differences and products of gamma-distributed variables do not lead to simple results. For proofs, details and references see Kendall & Stuart (1977).

Name of the distribution, its functional form, mean and variance
Gamma distribution with parameter p: $\gamma_p(x) = [\Gamma(x)]^{-1} x^{p-1} \exp(-x); \quad p \le x \le \infty, \quad p > 0$ mean: $\langle x \rangle = p$; variance: $\langle (x - \langle x \rangle)^2 \rangle = p$.
Beta distribution of first kind with parameters p and q: $\beta_1(x;\ p, q) = \dfrac{\Gamma(p+q)}{\Gamma(p)\Gamma(q)} x^{p-1}(1-x)^{q-1}; \quad 0 \le x \le \infty, \quad p, q > 0$ mean: $\langle x \rangle = p/(p+q)$; variance: $\langle (x - \langle x \rangle)^2 \rangle = pq/[(p+q)^2(p+q+1)]$.
Beta distribution of second kind with parameters p and q: $\beta_2(x;\ p, q) = \dfrac{\Gamma(p+q)}{\Gamma(p)\Gamma(q)} x^{p-1}(1+x)^{-p-q}; \quad 0 \le x \le \infty, \quad p, q > 0$ mean: $\langle x \rangle = p/(q-1)$; variance: $\langle (x - \langle x \rangle)^2 \rangle = p(p+q-1)/[(q-1)(q-2)]$.

(1950), in certain groups of reflections. In addition, in noncentrosymmetric space groups, the distribution of certain groups of reflections becomes centric, though the general reflections remain acentric. The changes are summarized in Tables 2.1.3.1 and 2.1.3.2. The values of S are integers for lattice centring, glide planes and those screw axes that produce absences, and approximate integers for rotation axes and mirror planes; the modulations of the average intensity in reciprocal space outlined in Section 2.1.3.2 apply.

It should be noted that if intensities are normalized to the average of the group to which they belong, rather than to the general average, the distributions given in equations (2.1.5.8) and (2.1.5.11) are not affected.

2.1.5.4. Other ideal distributions

The distributions just derived are asymptotic, as they are limiting values for large N. They are the only ideal distributions, in this sense, when there is only strict crystallographic symmetry and no dispersion. However, other ideal (asymptotic) distributions arise when there is noncrystallographic symmetry, or if there is dispersion. The *subcentric* distribution,

$$p(|E|)\,\mathrm{d}|E| = \frac{2|E|}{(1-k^2)^{1/2}} \exp[-|E|^2/(1-k^2)] \times I_0\left(\frac{k|E|^2}{1-k^2}\right) \mathrm{d}|E|, \qquad (2.1.5.12)$$

where $I_0(x)$ is a modified Bessel function of the first kind and k is the ratio of the scattering from the centrosymmetric part to the total scattering, arises when a noncentrosymmetric crystal contains centrosymmetric parts or when dispersion introduces effective noncentrosymmetry into the scattering from a centrosymmetric crystal (Srinivasan & Parthasarathy, 1976, ch. III; Wilson, 1980*a*,*b*; Shmueli & Wilson, 1983). The *bicentric* distribution

$$p(|E|)\,\mathrm{d}|E| = \pi^{-3/2} \exp(-|E|^2/8) K_0(|E|^2/8)\,\mathrm{d}|E| \qquad (2.1.5.13)$$

arises, for example, when the 'asymmetric unit in a centrosymmetric crystal is a centrosymmetric molecule' (Lipson & Woolfson, 1952); $K_0(x)$ is a modified Bessel function of the second kind. There are higher hypercentric, hyperparallel and sesquicentric analogues (Wilson, 1952; Rogers & Wilson, 1953; Wilson, 1956). The ideal subcentric and bicentric distributions are expressed in terms of known functions, but the higher hypercentric and the sesquicentric distributions have so far been studied only through their moments and integral representations. Certain hypersymmetric distributions can be expressed in terms of Meijer's G functions (Wilson, 1987*b*).

2.1.5.5. Relation to distributions of I

When only the intrinsic probability distributions are being considered, it does not greatly matter whether the variable chosen is the intensity of reflection (I), or its positive square root, the modulus of the structure factor ($|F|$), since both are necessarily real and non-negative. In an obvious notation, the relation between the intensity distribution and the structure-factor distribution is

$$p_I(I) = (1/2) I^{-1/2} p_{|F|}(I^{1/2}) \qquad (2.1.5.14)$$

or

$$p_{|F|}(|F|) = 2|F| p_I(|F|^2). \qquad (2.1.5.15)$$

Statistical fluctuations in counting rates, however, introduce a small but finite probability of negative observed intensities (Wilson, 1978*a*, 1980*a*) and thus of imaginary structure factors. This practical complication is treated in *IT* C (2004, Parts 7 and 8).

Both the ideal centric and acentric distributions are simple members of the family of gamma distributions, defined by

$$\gamma_n(x)\,\mathrm{d}x = [\Gamma(n)]^{-1} x^{n-1} \exp(-x)\,\mathrm{d}x, \qquad (2.1.5.16)$$

where n is a parameter, not necessarily integral, and $\Gamma(n)$ is the gamma function. Thus the ideal acentric intensity distribution is

$$p(I)\,\mathrm{d}I = \exp(-I/\Sigma)\,\mathrm{d}(I/\Sigma) \qquad (2.1.5.17)$$

$$= \gamma_1(I/\Sigma)\,\mathrm{d}(I/\Sigma) \qquad (2.1.5.18)$$

and the ideal centric intensity distribution is

$$p(I)\,\mathrm{d}I = (2\Sigma/\pi)^{1/2} \exp[-I/(2\Sigma)]\,\mathrm{d}[I/(2\Sigma)] \qquad (2.1.5.19)$$

$$= \gamma_{1/2}[I/(2\Sigma)]\,\mathrm{d}[I/(2\Sigma)]. \qquad (2.1.5.20)$$

The properties of gamma distributions and of the related beta distributions, summarized in Table 2.1.5.1, are used in Section 2.1.6 to derive the probability density functions of sums and of ratios of intensities drawn from one of the ideal distributions.

2.1.5.6. Cumulative distribution functions

The integral of the probability density function $f(x)$ from the lower end of its range up to an arbitrary value x is called the cumulative probability distribution, or simply the distribution function, $F(x)$, of x. It can always be written

$$F(x) = \int_{-\infty}^{x} f(u)\,\mathrm{d}u; \qquad (2.1.5.21)$$

if the lower end of its range is not actually $-\infty$ one takes $f(x)$ as identically zero between $-\infty$ and the lower end of its range. For the distribution of A [equation (2.1.5.4) or (2.1.5.9)] the lower

limit is in fact $-\infty$; for the distribution of $|F|$, $|E|$, I and I/Σ the lower end of the range is zero. In such cases, equation (2.1.5.21) becomes

$$F(x) = \int_0^x f(x)\,\mathrm{d}x. \qquad (2.1.5.22)$$

In crystallographic applications the cumulative distribution is usually denoted by $N(x)$, rather than by the capital letter corresponding to the probability density function designation. The cumulative forms of the ideal acentric and centric distributions (Howells *et al.*, 1950) have found many applications. For the acentric distribution of $|E|$ [equation (2.1.5.8)] the integration is readily carried out:

$$N(|E|) = 2\int_0^{|E|} y\exp(-y^2)\,\mathrm{d}y = 1 - \exp(-|E|^2). \qquad (2.1.5.23)$$

The integral for the centric distribution of $|E|$ [equation (2.1.5.11)] cannot be expressed in terms of elementary functions, but the integral required has so many important applications in statistics that it has been given a special name and symbol, the error function $\mathrm{erf}(x)$, defined by

$$\mathrm{erf}(x) = (2/\pi^{1/2})\int_0^x \exp(-t^2)\,\mathrm{d}t. \qquad (2.1.5.24)$$

For the centric distribution, then

$$N(|E|) = (2/\pi)^{1/2}\int_0^{|E|} y\exp(-y^2/2)\,\mathrm{d}y \qquad (2.1.5.25)$$

$$= \mathrm{erf}(|E|/2^{1/2}). \qquad (2.1.5.26)$$

The error function is extensively tabulated [see *e.g.* Abramowitz & Stegun (1972), pp. 310–311, and a closely related function on pp. 966–973].

The foregoing and following structure-factor and intensity statistics, presented in this chapter, are centred around the unambiguous determination of crystal symmetry. These statistics, especially the ideal ones, are routinely applied to X-ray diffraction data for completing the symmetry information where needed. On the other hand, the symmetry of very fine grained, imperfectly crystalline material or individual nanostructures can be experimentally determined by the convergent-beam electron diffraction technique using an electron microscope with a nanoscale probe, as described and illustrated in Section 2.5.3 of this volume.

2.1.6. Distributions of sums, averages and ratios

2.1.6.1. Distributions of sums and averages

In Section 2.1.2.1, it was shown that the average intensity of a sufficient number of reflections is Σ [equation (2.1.2.4)]. When the number of reflections is not 'sufficient', their mean value will show statistical fluctuations about Σ; such statistical fluctuations are in addition to any systematic variation resulting from non-independence of atomic positions, as discussed in Sections 2.1.2.1–2.1.2.3. We thus need to consider the probability density functions of sums like

$$J_n = \sum_{i=1}^{n} G_i, \qquad (2.1.6.1)$$

and averages like

$$Y = J_n/n, \qquad (2.1.6.2)$$

where G_i is the intensity of the ith reflection. The probability density distributions are easily obtained from a property of gamma distributions: If $x_1, x_2, \ldots, x_n$ are independent gamma-distributed variables with parameters $p_1, p_2, \ldots, p_n$, their sum is a gamma-distributed variable with parameter p equal to the sum of the parameters. The sum of n intensities drawn from an acentric distribution thus has the distribution

$$p(J_n)\,\mathrm{d}J_n = \gamma_n(J_n/\Sigma)\,\mathrm{d}(J_n/\Sigma); \qquad (2.1.6.3)$$

the parameters of the variables added are all equal to unity, so that their sum is p. Similarly, the sum of n intensities drawn from a centric distribution has the distribution

$$p(J_n)\,\mathrm{d}J_n = \gamma_{n/2}[J_n/(2\Sigma)]\,\mathrm{d}[J_n/(2\Sigma)]; \qquad (2.1.6.4)$$

each parameter has the value of one-half. The corresponding distributions of the averages of n intensities are then

$$p(Y)\,\mathrm{d}Y = \gamma_n(nY/\Sigma)\,\mathrm{d}(nY/\Sigma) \qquad (2.1.6.5)$$

for the acentric case, and

$$p(Y)\,\mathrm{d}Y = \gamma_{n/2}[nY/(2\Sigma)]\,\mathrm{d}[nY/(2\Sigma)] \qquad (2.1.6.6)$$

for the centric. In both cases the expected value of Y is Σ and the variances are Σ^2/n and $2\Sigma^2/n$, respectively, just as would be expected.

2.1.6.2. Distribution of ratios

Ratios like

$$S_{n,m} = J_n/K_m, \qquad (2.1.6.7)$$

where J_n is given by equation (2.1.6.1),

$$K_m = \sum_{j=1}^{m} H_j, \qquad (2.1.6.8)$$

and the H_j's are the intensities of a set of reflections (which may or may not overlap with those included in J_n), are used in correlating intensities measured under different conditions. They arise in correlating reflections on different layer lines from the same or different specimens, in correlating the same reflections from different crystals, in normalizing intensities to the local average or to Σ, and in certain systematic trial-and-error methods of structure determination (see Rabinovich & Shakked, 1984, and references therein). There are three main cases:

(i) G_i and H_i refer to the *same* reflection; for example, they might be the observed and calculated quantities for the *hkl* reflection measured under different conditions or for different crystals of the same substance; or

(ii) G_i and H_i are *unrelated*; for example, the observed and calculated values for the *hkl* reflection for a completely wrong trial structure, of values for entirely different reflections, as in reducing photographic measurements on different layer lines to the same scale; or

(iii) the G_i's are a subset of the H_i's, so that $G_i = H_i$ for $i < n$ and $m > n$.

Aside from the scale factor, in case (i) G_i and H_i will differ chiefly through relatively small statistical fluctuations and uncorrected systematic errors, whereas in case (ii) the differences will be relatively large because of the inherent differences in the intensities. Here we are concerned only with cases (ii) and (iii); the practical problems of case (i) are postponed to *IT* C (2004), Chapter 7.5.

There is little in the crystallographic literature concerning the probability distribution of sums like (2.1.6.1) or ratios like (2.1.6.7); certain results are reviewed by Srinivasan & Parthasarathy (1976, ch. 5), but with a bias toward partially related structures that makes it difficult to apply them to the immediate problem.

In case (ii) (G_i and H_i independent), acentric distribution, Table 2.1.5.1 gives the distribution of the ratio

$$u = nY/(mZ) \tag{2.1.6.9}$$

$$p(u)\,\mathrm{d}u = \beta_2[nY/(mZ);\, n, m]\,\mathrm{d}[nY/(mZ)], \tag{2.1.6.10}$$

where β_2 is a beta distribution of the second kind, Y is given by equation (2.1.6.2) and Z by

$$Z = K_m/m, \tag{2.1.6.11}$$

where n is the number of intensities included in the numerator and m is the number in the denominator. The expected value of Y/Z is then

$$\langle Y/Z\rangle = \frac{m}{m-1} = 1 + \frac{1}{m} + \ldots \tag{2.1.6.12}$$

with variance

$$\sigma^2 = \frac{(n+m-1)m^2}{(m-1)^2(m-2)n}. \tag{2.1.6.13}$$

One sees that Y/Z is a biased estimate of the scaling factor between two sets of intensities and the bias, of the order of m^{-1}, depends only on the number of intensities averaged in the denominator. This may seem odd at first sight, but it becomes plausible when one remembers that the mean of a quantity is an unbiased estimator of itself, but the reciprocal of a mean is not an unbiased estimator of the mean of a reciprocal. The mean exists only if $m > 1$ and the variance only for $m > 2$.

In the centric case, the expression for the distribution of the ratio of the two means Y and Z becomes

$$p(u)\,\mathrm{d}u = \beta_2[nY/(mZ);\ n/2, m/2]\,\mathrm{d}[nY/(mZ)] \tag{2.1.6.14}$$

with the expected value of Y/Z equal to

$$\langle Y/Z\rangle = \frac{m}{m-2} = 1 + \frac{2}{m} + \ldots \tag{2.1.6.15}$$

and with its variance equal to

$$\sigma^2 = \frac{2(n+m-2)m^2}{(m-2)^2(m-4)n}. \tag{2.1.6.16}$$

For the same number of reflections, the bias in $\langle Y/Z\rangle$ and the variance for the centric distribution are considerably larger than for the acentric. For both distributions the variance of the scaling factor approaches zero when n and m become large. The variances are large for m small, in fact 'infinite' if the number of terms averaged in the denominator is sufficiently small. These biases are readily removed by multiplying Y/Z by $(m-1)/m$ or $(m-2)/m$. Many methods of estimating scaling factors – perhaps most – also introduce bias (Wilson, 1975; Lomer & Wilson, 1975; Wilson, 1976, 1978*c*) that is not so easily removed. Wilson (1986*a*) has given reasons for supposing that the bias of the ratio (2.1.6.7) approximates to

$$1 + \frac{\sigma^2(I)}{m\langle I\rangle^2}, \tag{2.1.6.17}$$

whatever the intensity distribution. Equations (2.1.6.12) and (2.1.6.15) are consistent with this.

2.1.6.3. Intensities scaled to the local average

When the G_i's are a subset of the H_i's, the beta distributions of the second kind are replaced by beta distributions of the first kind, with means and variances readily found from Table 2.1.5.1. The distribution of such a ratio is chiefly of interest when Y relates to a single reflection and Z relates to a group of m intensities including Y. This corresponds to normalizing intensities to the local average. Its distribution is

$$p(I/\langle I\rangle)\,\mathrm{d}(I/\langle I\rangle) = \beta_1(I/n\langle I\rangle;\ 1, n-1)\,\mathrm{d}(I/n\langle I\rangle) \tag{2.1.6.18}$$

in the acentric case, with an expected value of $I/\langle I\rangle$ of unity; there is no bias, as is obvious *a priori*. The variance of $I/\langle I\rangle$ is

$$\sigma^2 = \frac{n-1}{n+1}, \tag{2.1.6.19}$$

which is less than the variance of the intensities normalized to an 'infinite' population by a fraction of the order of $2/n$. Unlike the variance of the scaling factor, the variance of the normalized intensity approaches unity as n becomes large. For intensities having a centric distribution, the distribution normalized to the local average is given by

$$p(I/\langle I\rangle)\,\mathrm{d}(I/\langle I\rangle) = \beta_1[I/n\langle I\rangle;\ 1/2, (n-1)/2]\,\mathrm{d}(I/n\langle I\rangle), \tag{2.1.6.20}$$

with an expected value of $I/\langle I\rangle$ of unity and with variance

$$\sigma^2 = \frac{2(n-1)}{n+2}, \tag{2.1.6.21}$$

less than that for an 'infinite' population by a fraction of about $3/n$.

Similar considerations apply to intensities normalized to Σ in the usual way, since they are equal to those normalized to $\langle I\rangle$ multiplied by $\langle I\rangle/\Sigma$.

2.1.6.4. The use of normal approximations

Since J_n and K_m [equations (2.1.6.1) and (2.1.6.8)] are sums of identically distributed variables conforming to the conditions of the central-limit theorem, it is tempting to approximate their distributions by normal distributions with the correct mean and variance. This would be reasonably satisfactory for the distributions of J_n and K_m themselves for quite small values of n and m, but unsatisfactory for the distribution of their ratio for any values of n and m, even large. The ratio of two variables with normal distributions is notorious for its rather indeterminate mean and 'infinite' variance, resulting from the 'tail' of the denominator distributions extending through zero to negative values. The leading terms of the ratio distribution are given by Kendall & Stuart (1977, p. 288).

2.1.7. Non-ideal distributions: the correction-factor approach

2.1.7.1. Introduction

The probability density functions (p.d.f.'s) of the magnitude of the structure factor, presented in Section 2.1.5, are based on the central-limit theorem discussed above. In particular, the centric and acentric p.d.f.'s given by equations (2.1.5.11) and (2.1.5.8), respectively, are expected to account for the statistical properties of diffraction patterns obtained from crystals consisting of nearly equal atoms, which obey the fundamental assumptions of uniformity and independence of the atomic contributions and are not affected by noncrystallographic symmetry and dispersion. It is also assumed there that the number of atoms in the asymmetric unit is large. Distributions of structure-factor magnitudes which are based on the central-limit theorem, and thus obey the above assumptions, have been termed 'ideal', and the subjects of the following sections are those distributions for which some of the above assumptions/restrictions are not fulfilled; the latter distributions will be called 'non-ideal'.

We recall that the assumption of uniformity consists of the requirement that the fractional part of the scalar product $hx + ky + lz$ be uniformly distributed over the [0, 1] interval, which holds well if x, y, z are rationally independent (Hauptman & Karle, 1953), and permits one to regard the atomic contribu-

tion to the structure factor as a random variable. This is of course a necessary requirement for any statistical treatment. If, however, the atomic composition of the asymmetric unit is widely heterogeneous, the structure factor is then a sum of unequally distributed random variables and the Lindeberg–Lévy version of the central-limit theorem (*cf.* Section 2.1.4.4) cannot be expected to apply. Other versions of this theorem might still predict a normal p.d.f. of the sum, but at the expense of a correspondingly large number of terms/atoms. It is well known that atomic heterogeneity gives rise to severe deviations from ideal behaviour (*e.g.* Howells *et al.*, 1950) and one of the aims of crystallographic statistics has been the introduction of a correct dependence on the atomic composition into the non-ideal p.d.f.'s [for a review of the early work on non-ideal distributions see Srinivasan & Parthasarathy (1976)]. A somewhat less well known fact is that the dependence of the p.d.f.'s of $|E|$ on space-group symmetry becomes more conspicuous as the composition becomes more heterogeneous (*e.g.* Shmueli, 1979; Shmueli & Wilson, 1981). Hence both the composition and the symmetry dependence of the intensity statistics are of interest. Other problems, which likewise give rise to non-ideal p.d.f.'s, are the presence of heavy atoms in (variable) special positions, heterogeneous structures with complete or partial noncrystallographic symmetry, and the presence of outstandingly heavy dispersive scatterers.

The need for theoretical representations of non-ideal p.d.f.'s is exemplified in Fig. 2.1.7.1, which shows the ideal centric and acentric p.d.f.'s together with a frequency histogram of $|E|$ values, recalculated for a centrosymmetric structure containing a platinum atom in the asymmetric unit of $P\bar{1}$ (Faggiani *et al.*, 1980). Clearly, the deviation from the Gaussian p.d.f., predicted by the central-limit theorem, is here very large and a comparison with the possible ideal distributions can (in this case) lead to wrong conclusions.

Two general approaches have so far been employed in derivations of non-ideal p.d.f.'s which account for the above-mentioned problems: the correction-factor approach, to be dealt with in the following sections, and the more recently introduced Fourier method, to which Section 2.1.8 is dedicated. In what follows, we introduce briefly the mathematical background of the correction-factor approach, apply this formalism to centric and acentric non-ideal p.d.f.'s, and present the numerical values of the moments of the trigonometric structure factor which permit an approximate evaluation of such p.d.f.'s for all the three-dimensional space groups.

2.1.7.2. Mathematical background

Suppose that $p(x)$ is a p.d.f. which accurately describes the experimental distribution of the random variable x, where x is related to a sum of random variables and can be assumed to obey (to some approximation) an ideal p.d.f., say $p^{(0)}(x)$, based on the central-limit theorem. In the correction-factor approach we seek to represent $p(x)$ as

$$p(x) = p^{(0)}(x) \sum_k d_k f_k(x), \qquad (2.1.7.1)$$

where d_k are coefficients which depend on the cause of the deviation of $p(x)$ from the central-limit theorem approximation and $f_k(x)$ are suitably chosen functions of x. A choice of the set $\{f_k\}$ is deemed suitable, if only from a practical point of view, if it allows the convenient introduction of the cause of the above deviation of $p(x)$ into the expansion coefficients d_k. This requirement is satisfied – also from a theoretical point of view – by taking $f_k(x)$ as a set of polynomials which are orthogonal with respect to the ideal p.d.f., taken as their weight function (*e.g.* Cramér, 1951). That is, the functions $f_k(x)$ so chosen have to obey the relationship

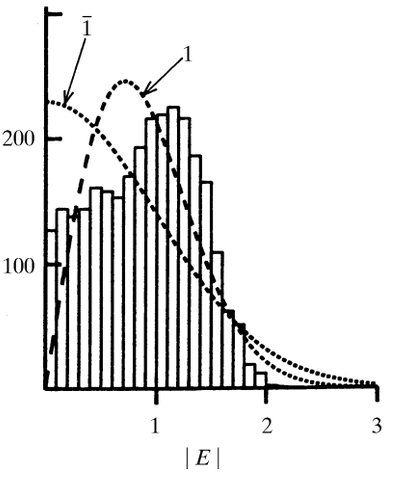

Fig. 2.1.7.1. Atomic heterogeneity and intensity statistics. The histogram appearing in this figure was constructed from $|E|$ values which were recalculated from atomic parameters published for the centrosymmetric structure of $C_6H_{18}Cl_2N_4O_4Pt$ (Faggiani *et al.*, 1980). The space group of the crystal is $P\bar{1}$, $Z = 2$, *i.e.* all the atoms are located in general positions. The figure shows a comparison of the recalculated distribution of $|E|$ with the ideal centric [equation (2.1.5.11)] and acentric [equation (2.1.5.8)] p.d.f.'s, denoted by $\bar{1}$ and 1, respectively.

$$\int_a^b f_k(x) f_m(x) p^{(0)}(x)\,\mathrm{d}x = \delta_{km} = \begin{cases} 1, & \text{if} \quad k = m \\ 0, & \text{if} \quad k \neq m \end{cases}, \qquad (2.1.7.2)$$

where $[a, b]$ is the range of existence of all the functions involved. It can be readily shown that the coefficients d_k are given by

$$d_k = \int_a^b f_k(x) p(x)\,\mathrm{d}x = \langle f_k(x) \rangle = \sum_{n=0}^{k} c_n^{(k)} \langle x^n \rangle, \qquad (2.1.7.3)$$

where the brackets $\langle\ \rangle$ in equation (2.1.7.3) denote averaging with respect to the *unknown* p.d.f. $p(x)$ and $c_n^{(k)}$ is the coefficient of the nth power of x in the polynomial $f_k(x)$. The coefficients d_k are thus directly related to the moments of the non-ideal distribution and the coefficients of the powers of x in the orthogonal polynomials. The latter coefficients can be obtained by the Gram–Schmidt procedure (*e.g.* Spiegel, 1974), or by direct use of the Szegö determinants (*e.g.* Cramér, 1951), for any weight function that has finite moments. However, the feasibility of the present approach depends on our ability to obtain the moments $\langle x^n \rangle$ *without* the knowledge of the non-ideal p.d.f., $p(x)$.

2.1.7.3. Application to centric and acentric distributions

We shall summarize here the non-ideal centric and acentric distributions of the magnitude of the normalized structure factor E (*e.g.* Shmueli & Wilson, 1981; Shmueli, 1982). We assume that (i) all the atoms are located in general positions and have rationally independent coordinates, (ii) all the scatterers are dispersionless, and (iii) there is no noncrystallographic symmetry. Arbitrary atomic composition and space-group symmetry are admitted. The appropriate weight functions and the corresponding orthogonal polynomials are

$p^{(0)}(\|E\|)$	$f_k(x)$	Non-ideal distribution
$(2/\pi)^{1/2} \exp(-\|E\|^2/2)$	$He_{2k}(\|E\|)/[(2k)!]^{1/2}$	Centric
$2\|E\| \exp(-\|E\|^2)$	$L_k(\|E\|^2)$	Acentric

(2.1.7.4)

where He_k and L_k are Hermite and Laguerre polynomials, respectively, as defined, for example, by Abramowitz & Stegun (1972). Equations (2.1.7.2), (2.1.7.3) and (2.1.7.4) suffice for the general formulation of the above non-ideal p.d.f.'s of $|E|$. Their full derivation entails (i) the expression of a sufficient number of moments of $|E|$ in terms of absolute moments of the trigonometric structure factor (*e.g.* Shmueli & Wilson, 1981; Shmueli, 1982) and (ii) calculation of the latter moments for the various symmetries (Wilson, 1978*b*; Shmueli & Kaldor, 1981, 1983). The notation below is similar to that employed by Shmueli (1982).

These non-ideal p.d.f.'s of $|E|$, for which the first five expansion terms are available, are given by

$$p_{\rm c}(|E|) = p_{\rm c}^{(0)}(|E|)\left[1 + \sum_{k=2}^{\infty} \frac{A_{2k}}{(2k)!} He_{2k}(|E|)\right] \qquad (2.1.7.5)$$

and

$$p_{\rm a}(|E|) = p_{\rm a}^{(0)}(|E|)\left[1 + \sum_{k=2}^{\infty} \frac{(-1)^k B_{2k}}{k!} L_k(|E|^2)\right] \qquad (2.1.7.6)$$

for centrosymmetric and noncentrosymmetric space groups, respectively, where $p_{\rm c}^{(0)}(|E|)$ and $p_{\rm a}^{(0)}(|E|)$ are the ideal centric and acentric p.d.f.'s [see (2.1.7.4)] and the unified form of the coefficients A_{2k} and B_{2k}, for k = 2, 3, 4 and 5, is

$$\begin{aligned}
&A_4 \quad \text{or} \quad B_4 = a_4 Q_4 \\
&A_6 \quad \text{or} \quad B_6 = a_6 Q_6 \\
&A_8 \quad \text{or} \quad B_8 = a_8 Q_8 + U(a_4^2 Q_4^2 - \gamma_4^2) \\
&A_{10} \quad \text{or} \quad B_{10} = a_{10} Q_{10} + V(a_4 a_6 Q_4 Q_6 - \gamma_4 \gamma_6 Q_{10}) \\
&\qquad\qquad + W\gamma_4^2 Q_{10}
\end{aligned} \qquad (2.1.7.7)$$

(Shmueli, 1982), where U = 35 or 18, V = 210 or 100 and W = 3150 or 900 according as A_{2k} or B_{2k} is required, respectively, and the other quantities in equation (2.1.7.7) are given below. The *composition-dependent* terms in equations (2.1.7.7) are

$$Q_{2k} = \frac{\sum_{j=1}^{m} f_j^{2k}}{\left(\sum_{n=1}^{m} f_n^2\right)^k}, \qquad (2.1.7.8)$$

where m is the number of atoms in the asymmetric unit, f_j, $j = 1, \ldots, m$ are their scattering factors, and the *symmetry* dependence is expressed by the coefficients a_{2k} in equation (2.1.7.7), as follows:

$$a_{2k} = (-1)^{k-1}(k-1)!\alpha_{k0} + \sum_{p=2}^{k}(-1)^{k-p}(k-p)!\alpha_{kp}\gamma_{2p}, \quad (2.1.7.9)$$

where

$$\alpha_{kp} = \binom{k}{p}\frac{(2k-1)!!}{(2p-1)!!} \quad \text{or} \quad \binom{k}{p}\frac{k!}{p!} \qquad (2.1.7.10)$$

according as the space group is centrosymmetric or noncentrosymmetric, respectively, and γ_{2p} in equation (2.1.7.9) is given by

$$\gamma_{2p} = \frac{\langle |T|^{2p}\rangle}{\langle |T|^2\rangle^p}, \qquad (2.1.7.11)$$

where $\langle |T|^k\rangle$ is the kth absolute moment of the trigonometric structure factor

$$T(\mathbf{h}) = \sum_{s=1}^{g} \exp[2\pi i \mathbf{h}^T(\mathbf{P}_s\mathbf{r} + \mathbf{t}_s)] \equiv \xi(\mathbf{h}) + i\eta(\mathbf{h}). \qquad (2.1.7.12)$$

In equation (2.1.7.12), g is the number of general equivalent positions listed in *IT* A (2005) for the space group in question, times the multiplicity of the Bravais lattice, $(\mathbf{P}_s, \mathbf{t}_s)$ is the sth space-group operator and $\mathbf{r}$ is an atomic position vector.

The cumulative distribution functions, obtained by integrating equations (2.1.7.5) and (2.1.7.6), are given by

$$N_{\rm c}(|E|) = \mathrm{erf}\left(\frac{|E|}{\sqrt{2}}\right) - \frac{2}{\sqrt{\pi}}\exp\left(-\frac{|E|^2}{2}\right) \times \left[\sum_{k=2}^{\infty} \frac{A_{2k}}{(2k)!} He_{2k-1}(|E|)\right] \qquad (2.1.7.13)$$

and

$$N_{\rm a}(|E|) = 1 - \exp(-|E|^2) + \exp(-|E|^2) \times \left\{\sum_{k=2}^{\infty} \frac{(-1)^k B_{2k}}{k!}[L_{k-1}(|E|^2) - L_k(|E|^2)]\right\} \qquad (2.1.7.14)$$

for centrosymmetric and noncentrosymmetric space groups, respectively, where the coefficients are defined in equations (2.1.7.7)–(2.1.7.12). Note that the first term on the right-hand side of equation (2.1.7.13) and the first two terms on the right-hand side of equation (2.1.7.14) are just the cumulative distributions derived from the ideal centric and acentric p.d.f.'s in Section 2.1.5.6.

The moments $\langle |T|^{2k}\rangle$ were compiled for all the space groups by Wilson (1978*b*) for $k = 1$ and 2, and by Shmueli & Kaldor (1981, 1983) for k = 1, 2, 3 and 4. These results are presented in Table 2.1.7.1. Closed expressions for the normalized moments γ_{2p} were obtained by Shmueli (1982) for the triclinic, monoclinic and orthorhombic space groups except *Fdd*2 and *Fddd* (see Table 2.1.7.2). The composition-dependent terms, Q_{2k}, are most conveniently computed as weighted averages over the ranges of $(\sin\theta)/\lambda$ which were used in the construction of the Wilson plot for the computation of the $|E|$ values.

2.1.7.4. Fourier versus Hermite approximations

As noted in Section 2.1.8.7 below, the Fourier representation of the probability distribution of $|F|$ is usually much better than the particular orthogonal-function representation discussed in Section 2.1.7.3. Many, perhaps most, non-ideal centric distributions look like slight distortions of the ideal (Gaussian) distribution and have no resemblance to a cosine function. The empirical observation thus seems paradoxical. The probable explanation has been pointed out by Wilson (1986*b*). A truncated Fourier series is a best approximation, in the least-squares sense, to the function represented. The particular orthogonal-function approach used in equation (2.1.7.5), on the other hand, is not a least-squares approximation to $p_{\rm c}(|E|)$, but is a least-squares approximation to

$$p_{\rm c}(|E|)\exp(|E|^2/4). \qquad (2.1.7.15)$$

The usual expansions (often known as Gram–Charlier or Edgeworth) thus give great weight to fitting the distribution of the (compararively few) strong reflections, at the expense of a poor fit for the (much more numerous) weak-to-medium ones. Presumably, a similar situation exists for the representation of acentric distributions, but this has not been investigated in detail. Since the centric distributions $p_{\rm c}(|E|)$ often look nearly Gaussian, one is led to ask if there is an expansion in orthogonal functions that (i) has the leading term $p_{\rm c}(|E|)$ and (ii) is a least-squares (as well as an orthogonal-function)[2] fit to $p_{\rm c}(|E|)$. One does exist, based on the orthogonal functions

[2] The condition for this desirable property seems to be that the weight function in equation (2.1.7.2) should be unity.

Table 2.1.7.1. *Some even absolute moments of the trigonometric structure factor*

The symbols p, q, r and s denote the second, fourth, sixth and eighth absolute moments of the trigonometric structure factor T [equation (2.1.7.12)], respectively, and the columns of the table contain (for some conciseness) p, q, r/p and s/p^2. The numbers in parentheses, appearing beside some space-group entries, refer to *hkl* subsets which are defined in the note at the end of the table. These subset references are identical with those given by Shmueli & Kaldor (1981, 1983). The symbols q, r and s are also equivalent to $\gamma_4 P^2$, $\gamma_6 P^3$ and $\gamma_8 P^4$, respectively, where γ_{2n} are the normalized absolute moments given by equation (2.1.7.11).

Table 2.1.7.2. *Closed expressions for γ_{2k} [equation (2.1.7.11)] for space groups of low symmetry*

The normalized moments γ_{2k} are expressed in terms of M_k, where

$$M_k = \frac{(2k)!}{2^k(k!)^2} = \frac{(2k-1)!!}{k!},$$

and l', which takes on the values 1, 2 or 4 according as the Bravais lattice is of type P, one of the types A, B, C or I, or type F, respectively. The expressions for γ_{2k} are identical for all the space groups based on a given point group, except *Fdd*2 and *Fddd*. The expressions are valid for general reflections and under the restrictions given in the text.

Point group(s)	Expression for γ_{2k}
1	1
$\bar{1}$, 2, m	$l'^{k-1}M_k$
$2/m$, $mm2$	$l'^{k-1}M_k^2$
mmm	$l'^{k-1}M_k^3$
222	$\dfrac{l'^{k-1}}{2^k(k!)^2}\displaystyle\sum_{p=0}^{k}(M_pM_{k-p})^3[p!(k-p)!]^2$

$$f_k = n(x)He_k(2^{1/2}x), \qquad (2.1.7.16)$$

where $n(x)$ is the Gaussian distribution (Myller-Lebedeff, 1907). Unfortunately, no reasonably simple relationship between the coefficients d_k and readily evaluated properties of $p_c(|E|)$ has been found, and the Myller-Lebedeff expansion has not, as yet, been applied in crystallography. Although Stuart & Ord (1994, p. 112) dismiss it in a three-line footnote, it does have important applications in astronomy (van der Marel & Franx, 1993; Gerhard, 1993).

2.1.8. Non-ideal distributions: the Fourier method

The starting point of the method described in the previous section is the central-limit theorem approximation, and the method consists of finding correction factors which result in better approximations to the actual p.d.f. Conceptually, this is equivalent to improving the approximation of the characteristic function [*cf.* equation (2.1.4.10)] over that which led to the central-limit theorem result.

The method to be described in this section does not depend on any initial approximation and will be shown to utilize the dependence of the exact value of the characteristic function on the space-group symmetry, atomic composition and other factors. This approach has its origin in a simple but ingenious observation by Barakat (1974), who noted that if a random variable has lower and upper bounds then the corresponding p.d.f. can be nonzero only within these bounds and can therefore be expanded in an ordinary Fourier series and set to zero (identically) outside the bounded interval. Barakat's (1974) work dealt with intensity statistics of laser speckle, where sinusoidal waves are involved, as in the present problem. This method was applied by Weiss & Kiefer (1983) to testing the accuracy of a steepest-descents approximation to the exact solution of the problem of random walk, and its first application to crystallographic intensity statistics soon followed (Shmueli *et al.*, 1984). Crystallographic (*e.g.* Shmueli & Weiss, 1987; Rabinovich *et al.*, 1991*a*,*b*) and noncrystallographic (Shmueli *et al.*, 1985; Shmueli & Weiss, 1985*a*; Shmueli, Weiss & Wilson, 1989; Shmueli *et al.*, 1990) symmetry was found to be tractable by this approach, as well as joint conditional p.d.f.'s of several structure factors (Shmueli & Weiss, 1985*b*, 1986; Shmueli, Rabinovich & Weiss, 1989). The Fourier method is illustrated below by deriving the exact counterparts of equations (2.1.7.5) and (2.1.7.6) and specifying them for some simple symmetries. We shall then indicate a method of treating higher symmetries and present results which will suffice

for evaluation of Fourier p.d.f.'s of $|E|$ for a wide range of space groups.

2.1.8.1. General representations of p.d.f.'s of $|E|$ by Fourier series

We assume, as before, that (i) the atomic phase factors $\vartheta_j = 2\pi \mathbf{h}^T \mathbf{r}_j$ [*cf.* equation (2.1.1.2)] are uniformly distributed on (0–2π) and (ii) the atomic contributions to the structure factor are independent. For a centrosymmetric space group, with the origin chosen at a centre of symmetry, the random variable is the (real) normalized structure factor E and its bounds are $-E_{\rm M}$ and $E_{\rm M}$, where

$$E_{\rm M} = \sum_{j=1}^{N} n_j, \text{ with } n_j = \frac{f_j}{\left(\sum_{k=1}^{N} f_k^2\right)^{1/2}}. \tag{2.1.8.1}$$

Here, $E_{\rm M}$ is the maximum possible value of E and f_j is the conventional scattering factor of the jth atom, including its temperature factor. The p.d.f., $p(E)$, can be nonzero in the range $(-E_{\rm M}, E_{\rm M})$ only and can thus be expanded in the Fourier series

$$p(E) = (\alpha/2) \sum_{k=-\infty}^{\infty} C_k \exp(-\pi i k \alpha E), \tag{2.1.8.2}$$

where $\alpha = 1/E_{\rm M}$. Only the real part of $p(E)$ is relevant. The Fourier coefficients can be obtained in the conventional manner by integrating over the range $(-E_{\rm M}, E_{\rm M})$,

$$C_k = \int_{-E_{\rm M}}^{E_{\rm M}} p(E) \exp(\pi i k \alpha E)\, {\rm d}E. \tag{2.1.8.3}$$

Since, however, $p(E) = 0$ for $E < -E_{\rm M}$ and $E > E_{\rm M}$, it is possible and convenient to replace the limits of integration in equation (2.1.8.3) by infinity. Thus

$$C_k = \int_{-\infty}^{\infty} p(E) \exp(\pi i k \alpha E)\, {\rm d}E = \langle \exp(\pi i k \alpha E) \rangle. \tag{2.1.8.4}$$

Equation (2.1.8.4) shows that C_k is a Fourier transform of the p.d.f. $p(E)$ and, as such, it is the value of the corresponding characteristic function at the point $t_k = \pi \alpha k$ [*i.e.*, $C_k = C(\pi \alpha k$, where the characteristic function $C(t)$ is defined by equation (2.1.4.1)]. It is also seen that C_k is the expected value of the exponential $\exp(\pi i k \alpha E)$. It follows that the feasibility of the present approach depends on one's ability to evaluate the characteristic function in closed form *without* the knowledge of the p.d.f.; this is analogous to the problem of evaluating absolute moments of the structure factor for the correction-factor approach, discussed in Section 2.1.7. Fortunately, in crystallographic applications these calculations are feasible, provided individual isotropic motion is assumed. The formal expression for the p.d.f. of $|E|$, for any centrosymmetric space group, is therefore

$$p(|E|) = \alpha \left[1 + 2 \sum_{k=1}^{\infty} C_k \cos(\pi k \alpha |E|) \right], \tag{2.1.8.5}$$

where use is made of the assumption that $p(E) = p(-E)$, and the Fourier coefficients are evaluated from equation (2.1.8.4).

The p.d.f. of $|E|$ for a noncentrosymmetric space group is obtained by first deriving the joint p.d.f. of the real and imaginary parts of E and then integrating out its phase. The general expression for E is

$$E = A + iB = |E| \cos\varphi + i|E| \sin\varphi, \tag{2.1.8.6}$$

where φ is the phase of E. The required joint p.d.f. is

$$p(A, B) = (\alpha^2/4) \sum_m \sum_n C_{mn} \exp[-\pi i \alpha (mA + nB)], \tag{2.1.8.7}$$

and introducing polar coordinates $m = r \sin\Delta$ and $n = r \cos\Delta$, where $r = \sqrt{m^2 + n^2}$ and $\Delta = \tan^{-1}(m/n)$, we have

$$p(|E|, \varphi) = (\alpha^2/4)|E| \sum_m \sum_n C_{mn} \exp[-\pi i \alpha |E| \times \sqrt{m^2 + n^2} \sin(\varphi + \Delta)]. \tag{2.1.8.8}$$

Integrating out the phase φ, we obtain

$$p(|E|) = (\pi \alpha^2 |E|/2) \sum_m \sum_n C_{mn} J_0(\pi \alpha |E| \sqrt{m^2 + n^2}), \tag{2.1.8.9}$$

where $J_0(x)$ is the Bessel function of the first kind (*e.g.* Abramowitz & Stegun, 1972). This is a general form of the p.d.f. of $|E|$ for a noncentrosymmetric space group. The Fourier coefficients are obtained, similarly to the above, as

$$C_{mn} = \langle \exp[\pi i \alpha (mA + nB)] \rangle \tag{2.1.8.10}$$

and the average in equation (2.1.8.10), just as that in equation (2.1.8.4), is evaluated in terms of integrals over the appropriate trigonometric structure factors. In terms of the characteristic function for a joint p.d.f. of A and B, the Fourier coefficient in equation (2.1.8.10) is given by $C_{mn} = C(\pi \alpha m, \pi \alpha n)$.

We shall denote the characteristic function by $C(t_1)$ if it corresponds to a Fourier coefficient of a Fourier series for a centrosymmetric space group and by $C(t_1, t_2)$ or by $C(t, \Delta)$, where $t = (t_1^2 + t_2^2)^{1/2}$ and $\Delta = \tan^{-1}(t_1/t_2)$, if it corresponds to a Fourier series for a noncentrosymmetric space group.

2.1.8.2. Fourier–Bessel series

Equations (2.1.8.5) and (2.1.8.9) are the exact counterparts of equations (2.1.7.5) and (2.1.7.6), respectively. The computational effort required to evaluate equation (2.1.8.9) is somewhat greater than that for (2.1.8.5), because a double Fourier series has to be summed. The p.d.f. for *any* noncentrosymmetric space group can be expressed by a double Fourier series, but this can be simplified if the characteristic function depends on $t = (t_1^2 + t_2^2)^{1/2}$ alone, rather than on t_1 and t_2 separately. In such cases the p.d.f. of $|E|$ for a noncentrosymmetric space group can be expanded in a *single* Fourier–Bessel series (Barakat, 1974; Weiss & Kiefer, 1983; Shmueli *et al.*, 1984). The general form of this expansion is

$$p(|E|) = 2\alpha^2 |E| \sum_{u=1}^{\infty} D_u J_0(\alpha \lambda_u |E|), \tag{2.1.8.11}$$

where

$$D_u = \frac{C(\alpha \lambda_u)}{J_1^2(\lambda_u)} \tag{2.1.8.12}$$

and

$$C(\alpha \lambda_u) = \prod_{j=1}^{N/g} C_{ju}, \tag{2.1.8.13}$$

where $J_1(x)$ is the Bessel function of the first kind, and λ_u is the uth root of the equation $J_0(x) = 0$; the atomic contribution C_{ju} to equation (2.1.8.13) is computed as

$$C_{ju} = C(\alpha n_j \lambda_u). \tag{2.1.8.14}$$

The roots λ_u are tabulated in the literature (*e.g.* Abramowitz & Stegun, 1972), but can be most conveniently computed as follows. The first five roots are given by

$$\lambda_1 = 2.4048255577$$
$$\lambda_2 = 5.5200781103$$
$$\lambda_3 = 8.6537279129$$
$$\lambda_4 = 11.7915344390$$
$$\lambda_5 = 14.9309177085$$

and the higher ones can be obtained from McMahon's approximation (*cf.* Abramowitz & Stegun, 1972)

$$\lambda_u = \beta + \frac{1}{8\beta} - \frac{124}{3(8\beta)^3} + \frac{120928}{15(8\lambda)^5} - \frac{401743168}{105(8\lambda)^7} + \ldots, \quad (2.1.8.15)$$

where $\beta = (u - \frac{1}{4})\pi$. For $u > 5$ the values given by equation (2.1.8.15) have a relative error less than 10^{-11} so that no refinement of roots of higher orders is needed (Shmueli *et al.*, 1984). Numerical computations of single Fourier–Bessel series are of course faster than those of the double Fourier series, but both representations converge fairly rapidly.

2.1.8.3. Simple examples

Consider the Fourier coefficient of the p.d.f. of $|E|$ for the centrosymmetric space group $P\bar{1}$. The normalized structure factor is given by

$$E = 2\sum_{j=1}^{N/2} n_j \cos\vartheta_j, \quad \text{with} \quad \vartheta_j = 2\pi \mathbf{h}^T \cdot \mathbf{r}_j, \quad (2.1.8.16)$$

and the Fourier coefficient is

$$\begin{aligned} C_k &= \langle \exp(\pi i k \alpha E)\rangle & (2.1.8.17)\\ &= \left\langle \exp\left[2\pi i k\alpha \sum_{j=1}^{N/2} n_j \cos\vartheta_j\right]\right\rangle & (2.1.8.18)\\ &= \left\langle \prod_{j=1}^{N/2} \exp(2\pi i k\alpha n_j \cos\vartheta_j)\right\rangle & (2.1.8.19)\\ &= \prod_{j=1}^{N/2} \langle \exp(2\pi i k\alpha n_j \cos\vartheta_j)\rangle & (2.1.8.20)\\ &= \prod_{j=1}^{N/2} \left\{(1/2\pi)\int_{-\pi}^{\pi} \exp(2\pi i k\alpha n_j \cos\vartheta)\,\mathrm{d}\vartheta\right\} & (2.1.8.21)\\ &= \prod_{j=1}^{N/2} J_0(2\pi k\alpha n_j). & (2.1.8.22) \end{aligned}$$

Equation (2.1.8.20) is obtained from equation (2.1.8.19) if we make use of the assumption of independence, the assumption of uniformity allows us to rewrite equation (2.1.8.20) as (2.1.8.21), and the expression in the braces in the latter equation is just a definition of the Bessel function $J_0(2\pi k\alpha n_j)$ (*e.g.* Abramowitz & Stegun, 1972).

Let us now consider the Fourier coefficient of the p.d.f. of $|E|$ for the noncentrosymmetric space group $P1$. We have

$$A = \sum_{j=1}^{N} n_j \cos\vartheta_j \quad \text{and} \quad B = \sum_{j=1}^{N} n_j \sin\vartheta_j. \quad (2.1.8.23)$$

These expressions for A and B are substituted in equation (2.1.8.10), resulting in

$$\begin{aligned} C_{mn} &= \left\langle \prod_{j=1}^{N} \exp[\pi i\alpha n_j (m\cos\vartheta_j + n\sin\vartheta_j)]\right\rangle & (2.1.8.24)\\ &= \left\langle \prod_{j=1}^{N} \exp[\pi i\alpha n_j \sqrt{m^2+n^2}\sin(\vartheta_j + \Delta)]\right\rangle & (2.1.8.25)\\ &= \prod_{j=1}^{N} J_0(\pi\alpha n_j \sqrt{m^2+n^2}). & (2.1.8.26) \end{aligned}$$

Equation (2.1.8.24) leads to (2.1.8.25) by introducing polar coordinates analogous to those leading to equation (2.1.8.8), and equation (2.1.8.26) is then obtained by making use of the assumptions of independence and uniformity in an analogous manner to that detailed in equations (2.1.8.12)–(2.1.8.22) above.

The right-hand side of equation (2.1.8.26) is to be used as a Fourier coefficient of the double Fourier series given by (2.1.8.9). Since, however, this coefficient depends on $(m^2+n^2)^{1/2}$ alone rather than on m and n separately, the p.d.f. of $|E|$ for $P1$ can also be represented by a Fourier–Bessel series [*cf.* equation (2.1.8.11)] with coefficient

$$D_u = \frac{1}{J_1^2(\lambda_u)} \prod_{j=1}^{N} J_0(\alpha n_j \lambda_u), \quad (2.1.8.27)$$

where λ_u is the uth root of the equation $J_0(x) = 0$.

2.1.8.4. A more complicated example

We now illustrate the methodology of deriving characteristic functions for space groups of higher symmetries, following the method of Rabinovich *et al.* (1991*a*,*b*). The derivation is performed for the space group $P\bar{6}$ (No. 174). According to Table A1.4.3.6, the real and imaginary parts of the normalized structure factor are given by

$$\begin{aligned} A &= 2\sum_{j=1}^{N/6} n_j [C(hki)c(lz)]_j \\ &= 2\sum_{j=1}^{N/6} n_j \cos\tau_j \sum_{k=1}^{3} \cos\alpha_{jk} & (2.1.8.28) \end{aligned}$$

and

$$\begin{aligned} B &= 2\sum_{j=1}^{N/6} n_j [S(hki)c(lz)]_j \\ &= 2\sum_{j=1}^{N/6} n_j \cos\tau_j \sum_{k=1}^{3} \sin\alpha_{jk}, & (2.1.8.29) \end{aligned}$$

where

$$\begin{aligned} \alpha_{j1} &= 2\pi(hx_j + ky_j),\\ \alpha_{j2} &= 2\pi(kx_j + iy_j),\\ \alpha_{j3} &= 2\pi(ix_j + hy_j),\\ \tau_j &= 2\pi l z_j. \end{aligned}$$

Note that $\alpha_{j1} + \alpha_{j2} + \alpha_{j3} = 0$, *i.e.*, one of these contributions depends on the other two; this is a recurring problem in calculations pertaining to trigonal and hexagonal systems. For brevity, we write directly the general form of the characteristic function from which the functional form of the Fourier coefficient can be readily obtained. The characteristic function is given by

$$\begin{aligned} C(t_1, t_2) &= \langle \exp[i(t_1 A + t_2 B)]\rangle & (2.1.8.30)\\ &= \prod_{j=1}^{N/6} \left\langle \exp\left[2in_j \cos\tau_j \sum_{k=1}^{3} (t_1\cos\alpha_{jk} + t_2 \sin\alpha_{jk})\right]\right\rangle & (2.1.8.31)\\ &= \prod_{j=1}^{N/6} \left\langle \exp\left[2in_j t\cos\tau_j \sum_{k=1}^{3} (\sin\Delta\cos\alpha_{jk} \right.\right.\\ &\quad \left.\left. + \cos\Delta\sin\alpha_{jk})\right]\right\rangle & (2.1.8.32)\\ &= \prod_{j=1}^{N/6} \left\langle \exp\left[2in_j t\cos\tau_j \sum_{k=1}^{3} \sin(\alpha_{jk} + \Delta)\right]\right\rangle, & (2.1.8.33) \end{aligned}$$

where $\Delta = \tan^{-1}(t_1/t_2)$, $t = (t_1^2 + t_2^2)^{1/2}$ and the assumption of independence was used. If we further employ the assumption of

Table 2.1.8.1. *Atomic contributions to characteristic functions for $p(|E|)$*

The table lists symbolic expressions for the atomic contributions to exact characteristic functions (abbreviated as c.f.) for $p(|E|)$, to be computed as single Fourier series (centric), double Fourier series (acentric) and single Fourier–Bessel series (acentric), as defined in Sections 2.1.8.1 and 2.1.8.2. The symbolic expressions are defined in Section 2.1.8.5. The table is arranged by point groups, space groups and parities of the reflection indices analogously to the table of moments, Table 2.1.7.1, and covers all the space groups and statistically different parities of *hkl* up to and including space group $Fd\bar{3}$. The expressions are valid for atoms in general positions, for general reflections and presume the absence of noncrystallographic symmetry and of dispersive scatterers. The p.d.f.'s of $|E|$ for any centrosymmetric space group are computed from a single Fourier series [*cf.* (2.1.8.5)]. For a noncentrosymmetric space group the p.d.f. of $|E|$ *must* be computed from a double Fourier series [*cf.* (2.1.8.9)] – if the characteristic function in the table depends on Δ – and *may* be computed from a single Fourier–Bessel series [*cf.* (2.1.8.11)] if it does not depend on Δ. However, the p.d.f. of $|E|$ for any noncentrosymmetric space group may also be computed from a double Fourier series (*cf.* Section 2.1.8.1).

† And the enantiomorphous space group.

uniformity, while remembering that the angular variables α_{jk} are not independent, the characteristic function can be written as

$$C(t_1, t_2) = \prod_{j=1}^{N/6}\left\{(1/2\pi)\int_{-\pi}^{\pi} \mathrm{d}\tau\left([1/(2\pi)^2]\right.\right. \times \int_{-\pi}^{\pi}\int_{-\pi}^{\pi}\int_{-\pi}^{\pi} \mathrm{d}\alpha_1\,\mathrm{d}\alpha_2\,\mathrm{d}\alpha_3\,\delta_{2\pi}(\alpha_1+\alpha_2+\alpha_3) \left.\left. \times \exp\left[2in_jt\cos\tau\sum_{k=1}^{3}\sin(\alpha_k+\Delta)\right]\right)\right\}, \tag{2.1.8.34}$$

where

$$\delta_{2\pi}(\alpha) = \frac{1}{2\pi}\sum_{k=-\infty}^{\infty}\exp(-ik\alpha) \tag{2.1.8.35}$$

is the Fourier representation of the periodic delta function. Equation (2.1.8.34) then becomes

$$C(t_1, t_2) = \prod_{j=1}^{N/6}\left\{(1/2\pi)\int_{-\pi}^{\pi}\mathrm{d}\tau\sum_{k=-\infty}^{\infty}\left[(1/2\pi) \times \int_{-\pi}^{\pi}\exp\bigl(-ik\alpha+2in_jt\cos\tau\sin(\alpha+\Delta)\bigr)\,\mathrm{d}\alpha\right]^3\right\}. \tag{2.1.8.36}$$

If we change the variable α to $\alpha'-\Delta$, $\sin(\alpha+\Delta)$ becomes $\sin\alpha'$ and $-ik\alpha = -ik\alpha' + ik\Delta$. Hence

$$C(t_1, t_2) = \prod_{j=1}^{N/6}\left\{(1/2\pi)\int_{-\pi}^{\pi}\mathrm{d}\tau\sum_{k=-\infty}^{\infty}\exp(3ik\Delta)J_k^3(2n_jt\cos\tau)\right\}. \tag{2.1.8.37}$$

The imaginary part of the summation, involving Bessel functions of odd orders, vanishes upon integration and the latter is restricted to the positive quadrant in τ. Thus, upon replacing cosines by sines (this is permissible at this stage) the atomic contribution to the characteristic function becomes

$$C_j(t, \Delta) = (2/\pi)\int_0^{\pi/2}\left[J_0^3(2n_jt\sin\tau) + 2\sum_{k=1}^{\infty}\cos(6k\Delta)J_k^3(2n_jt\sin\tau)\right]\mathrm{d}\tau \tag{2.1.8.38}$$

and a double Fourier series must be used for the p.d.f.

2.1.8.5. Atomic characteristic functions

Expressions for the atomic contributions to the characteristic functions were obtained by Rabinovich *et al.* (1991*a*) for a wide range of space groups, by methods similar to those described above. These expressions are collected in Table 2.1.8.1 in terms of symbols which are defined below. The following abbreviations are used in the subsequent definitions of the symbols:

$$s_\pm = 2an_j\sin(\tau\pm\rho),$$
$$c_\pm = 2an_j\cos(\tau\pm\rho) \quad \text{and}$$
$$\sigma_\pm = 2an_j\sin(\tau\pm 2\pi/3+\rho),$$

and the symbols appearing in Table 2.1.8.1 are given below:

$$\begin{aligned}
{}^{(a)}L_j(a,\rho) &= \langle J_0(s_+)J_0(s_-)\rangle_\tau \\
&= \sum_{k=-\infty}^{\infty}\cos(4k\rho)J_k^4 \\
&= J_0^4(an_j) + 2\sum_{k=1}^{\infty}\cos(4k\rho)J_k^4(an_j), \\
{}^{(b)}Q_j^{(1)}(a,\rho) &= \langle J_0^2(s_+)J_0^2(s_-)\rangle_\tau, \\
{}^{(c)}Q_j^{(2)}(a,\rho) &= \langle J_0(s_+)J_0(s_-)J_0(c_+)J_0(c_-)\rangle_\tau, \\
{}^{(d)}T_j(a,\rho) &= \sum_{k=-\infty}^{\infty}\exp(6ik\rho)J_k^6(an_j) \\
&= J_0^6(an_j) + 2\sum_{k=1}^{\infty}\cos(6k\rho)J_k^6(an_j), \\
{}^{(e)}H_j^{(1)}(a,\mu) &= \left\langle\mathcal{R}\left[S_j^{(1)}(\tau;\ a,\mu,0)\right]\right\rangle_\tau, \\
{}^{(f)}H_j^{(2)}(a,\mu) &= \left\langle\mathcal{R}\left[S_j^{(2)}(\tau;\ a,\mu,0)\right]\right\rangle_\tau, \\
{}^{(g)}\tilde{H}_j^{(1)}(a,\mu_1,\mu_2,\rho) &= \left\langle\mathcal{R}\left[S_j^{(1)}(\tau;\ a,\mu_1,\rho) \times S_j^{(1)}(\tau;\ a,\mu_2,-\rho)\right]\right\rangle_\tau, \\
{}^{(h)}\tilde{H}_j^{(2)}(a,\mu_1,\mu_2,\rho) &= \left\langle\mathcal{R}\left[S_j^{(2)}(\tau;\ a,\mu_1,\rho) \times S_j^{(2)}(\tau;\ a,\mu_2,-\rho)\right]\right\rangle_\tau,
\end{aligned}$$

where

$$S_j^{(1)}(\tau;\ a, \mu, \rho) = \sum_{k=-\infty}^{\infty} e^{3ik\mu} J_k^3(s_+)$$

and

$$S_j^{(2)}(\tau;\ a, \mu, \rho) = \sum_{k=-\infty}^{\infty} e^{3ik\mu} J_k(s_+) J_k(\sigma_+) J_k(\sigma_-).$$

The averages appearing in the above summary are, in general, computed as

$$\langle f(\tau) \rangle = (2/\pi) \int_0^{\pi/2} f(\tau)\, \mathrm{d}\tau, \qquad (2.1.8.39)$$

except $H_j^{(2)}$ and $\tilde{H}_j^{(2)}$ which are computed as

$$\langle f(\tau) \rangle = (3/\pi) \int_0^{\pi/3} f(\tau)\, \mathrm{d}\tau, \qquad (2.1.8.40)$$

where $f(\tau)$ is any of the atomic characteristic functions indicated above. The superscripts preceding the symbols in the above summary are appended to the corresponding symbols in Table 2.1.8.1 on their first occurrence.

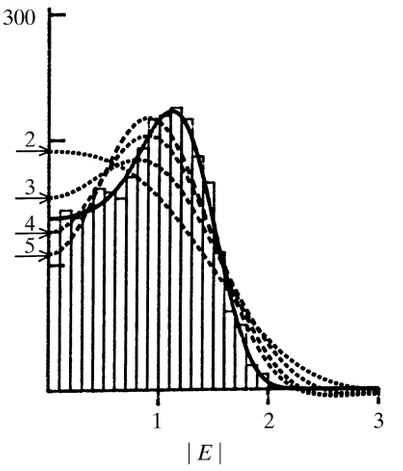

Fig. 2.1.8.1. The same recalculated histogram as in Fig. 2.1.7.1 along with the centric correction-factor p.d.f. [equation (2.1.7.5)], truncated after two, three, four and five terms (dashed lines), and with that accurately computed for the correct space-group Fourier p.d.f. [equations (2.1.8.5) and (2.1.8.22)] (solid line).

2.1.8.6. Other non-ideal Fourier p.d.f.'s

As pointed out above, the representation of the p.d.f.'s by Fourier series is also applicable to effects of noncrystallographic symmetry. Thus, Shmueli *et al.* (1985) obtained the following Fourier coefficient for the bicentric distribution in the space group $P\bar{1}$:

$$C_k = (2/\pi) \int_0^{\pi/2} \left[\prod_{j=1}^{N/4} J_0(4\pi k \alpha n_j \cos\vartheta) \right] \mathrm{d}\vartheta, \qquad (2.1.8.41)$$

to be used with equation (2.1.8.5). Furthermore, if we use the important property of the characteristic function as outlined in Section 2.1.4.1, it is easy to write down the Fourier coefficient for a $P\bar{1}$ asymmetric unit containing a centrosymmetric fragment centred at a noncrystallographic centre and a number of atoms not related by symmetry. This Fourier for the above partially bicentric arrangement is a product of expressions (2.1.8.17) and (2.1.8.41), with the appropriate number of atoms in each factor (Shmueli & Weiss, 1985*a*). While the purely bicentric p.d.f. obtained by using (2.1.8.41) with (2.1.8.5) is significantly different from the ideal bicentric p.d.f. given by equation (2.1.5.13) only when the atomic composition is sufficiently heterogeneous, the above partially bicentric p.d.f. appears to be a useful development even for an equal-atom structure.

The problem of the coexistence of several noncrystallographic centres of symmetry within the asymmetric unit of $P\bar{1}$, and its effect on the p.d.f. of $|E|$, was examined by Shmueli, Weiss & Wilson (1989) by the Fourier method. The latter study indicates that the strongest effect is produced by the presence of a single noncrystallographic centre.

Another kind of noncrystallographic symmetry is that arising from the presence of centrosymmetric fragments in a noncentrosymmetric structure – the subcentric arrangement already discussed in Section 2.1.5.4. A Fourier-series representation of a non-ideal p.d.f. corresponding to this case was developed by Shmueli, Rabinovich & Weiss (1989), and was also applied to the mathematically equivalent effects of dispersion and presence of heavy scatterers in centrosymmetric special positions in a noncentrosymmetric space group.

A variety of other non-ideal p.d.f.'s occur when heavy atoms are present in special positions (Shmueli & Weiss, 1988). Without going into the details of this development, it can be noted that if the atoms are distributed among k types of Wyckoff positions, the characteristic function corresponding to the p.d.f. of $|E|$ is a product of the k characteristic functions, each of which is related to one of these special positions; the same property of the characteristic function as that in Section 2.1.4.1 is here utilized.

2.1.8.7. Comparison of the correction-factor and Fourier approaches

The need for theoretical non-ideal distributions was exemplified by Fig. 2.1.7.1, referred to above, and the performance of the two approaches described above, for this particular example, is shown in Fig. 2.1.8.1. Briefly, the Fourier p.d.f. shows an excellent agreement with the histogram of recalculated $|E|$ values, while the agreement attained by the Hermite correction factor is much less satisfactory, even for the (longest available to us) five-term expansion. It must be pointed out that (i) the inadequacy of 'short' correction factors, in the example shown, is due to the large deviation from the ideal behaviour and (ii) the number of terms used there in the Fourier summation is twenty, whereafter the summation is terminated. Obviously, the computation of twenty (or more) Fourier coefficients is easier than that of five terms in the correction factor. The convergence of the Fourier series is very satisfactory. It appears that the (analytically) exact Fourier approach is the preferred one in cases of large or intermediate deviations, while the correction-factor approach may cope well with small ones. As far as the availability of symmetry-dependent centric and acentric p.d.f.'s is concerned, correction factors are available for all the space groups (see Table 2.1.7.1), while Fourier coefficients of p.d.f.'s are available for the first 206 space groups (see Table 2.1.8.1). It should be pointed out that p.d.f.'s based on the correction-factor method cope very well with cubic symmetries higher than $Fd\bar{3}$, even if the asymmetric unit of the space group is strongly heterogeneous (Rabinovich *et al.*, 1991*b*).

Both approaches described in this section are related to the characteristic function of the required p.d.f. The correction-factor p.d.f.'s (2.1.7.5) and (2.1.7.6) can be obtained by expanding the logarithm of the appropriate characteristic function in a series of cumulants [*e.g.* equation (2.1.4.13); see also Shmueli & Wilson (1982)], truncating the series and performing its term-by-term Fourier inversion. The Fourier p.d.f., on the other hand, is computed by forming a Fourier series whose coefficients are *exact* analytical forms of the characteristic function at points related to the summation indices [*e.g.* equations (2.1.8.5), (2.1.8.9) and (2.1.8.11), and Table 2.1.8.1] and truncating the series when the terms become small enough.

2.2. Direct methods

By C. Giacovazzo

2.2.1. List of symbols and abbreviations

f_j	atomic scattering factor of jth atom
Z_j	atomic number of jth atom
N	number of atoms in the unit cell
m	order of the point group

$$[\sigma_r]_p, [\sigma_r]_q, [\sigma_r]_N, \ldots = \sum_{j=1}^{p} Z_j^r, \sum_{j=1}^{q} Z_j^r, \sum_{j=1}^{N} Z_j^r, \ldots$$

$[\sigma_r]_N$ is always abbreviated to σ_r when N is the number of atoms in the cell

$$\textstyle\sum_p, \sum_q, \sum_N, \ldots = \sum_{j=1}^{p} f_j^2, \sum_{j=1}^{q} f_j^2, \sum_{j=1}^{N} f_j^2, \ldots$$

s.f.	structure factor
n.s.f.	normalized structure factor
cs.	centrosymmetric
ncs.	noncentrosymmetric
s.i.	structure invariant
s.s.	structure seminvariant
$\mathbf{C} = (\mathbf{R}, \mathbf{T})$	symmetry operator; $\mathbf{R}$ is the rotational part, $\mathbf{T}$ the translational part
$\varphi_{\mathbf{h}}$	phase of the structure factor $F_{\mathbf{h}} = \lvert F_{\mathbf{h}}\rvert \exp(i\varphi_{\mathbf{h}})$

2.2.2. Introduction

Direct methods are today the most widely used tool for solving small crystal structures. They work well both for equal-atom molecules and when a few heavy atoms exist in the structure. In recent years the theoretical background of direct methods has been improved to take into account a large variety of prior information (the form of the molecule, its orientation, a partial structure, the presence of pseudosymmetry or of a superstructure, the availability of isomorphous data or of data affected by anomalous-dispersion effects, ...). Owing to this progress and to the increasing availability of powerful computers, the phase problem for small molecules has been solved in practice: a number of effective, highly automated packages are today available to the scientific community.

The combination of direct methods with so-called direct-space methods have recently allowed the *ab initio* crystal structure solution of proteins. The present limit of complexity is about 2500 non-hydrogen atoms in the asymmetric unit, but diffraction data at atomic resolution (~1 Å) are required. Trials are under way to bring this limit to 1.5 Å and have shown some success.

The theoretical background and tables useful for origin specification are given in Section 2.2.3; in Section 2.2.4 the procedures for normalizing structure factors are summarized. Phase-determining formulae (inequalities, probabilistic formulae for triplet, quartet and quintet invariants, and for one- and two-phase s.s.'s, determinantal formulae) are given in Section 2.2.5. In Section 2.2.6 the connection between direct methods and related techniques in real space is discussed. Practical procedures for solving small-molecule crystal structures are described in Sections 2.2.7 and 2.2.8, and references to the most extensively used packages are given in Section 2.2.9. The integration of direct methods, isomorphous replacement and anomalous-dispersion techniques is briefly discussed in Section 2.2.10.

The reader interested in a more detailed description of the topic is referred to a recent textbook (Giacovazzo, 1998).

2.2.3. Origin specification

(*a*) Once the origin has been chosen, the symmetry operators $\mathbf{C}_s \equiv (\mathbf{R}_s, \mathbf{T}_s)$ and, through them, the algebraic form of the s.f. remain fixed.

A shift of the origin through a vector with coordinates $\mathbf{X}_0$ transforms $\varphi_{\mathbf{h}}$ into

$$\varphi'_{\mathbf{h}} = \varphi_{\mathbf{h}} - 2\pi\mathbf{h}\cdot\mathbf{X}_0 \qquad (2.2.3.1)$$

and the symmetry operators $\mathbf{C}_s$ into $\mathbf{C}'_s = (\mathbf{R}'_s, \mathbf{T}'_s)$, where

$$\mathbf{R}'_s = \mathbf{R}_s;\ \ \mathbf{T}'_s = \mathbf{T}_s + (\mathbf{R}_s - \mathbf{I})\mathbf{X}_0 \quad s = 1, 2, \ldots, m. \qquad (2.2.3.2)$$

(*b*) *Allowed* or *permissible origins* (Hauptman & Karle, 1953, 1959) for a given algebraic form of the s.f. are all those points in direct space which, when taken as origin, maintain the same symmetry operators $\mathbf{C}_s$. The allowed origins will therefore correspond to those points having the same symmetry environment in the sense that they are related to the symmetry elements in the same way. For instance, if $\mathbf{T}_s = 0$ for $s = 1, \ldots, 8$, then the allowed origins in *Pmmm* are the eight inversion centres.

To each functional form of the s.f. a set of permissible origins will correspond.

(*c*) A translation between permissible origins will be called a *permissible* or *allowed translation.* Trivial allowed translations correspond to the lattice periods or to their multiples. A change of origin by an allowed translation does not change the algebraic form of the s.f. Thus, according to (2.2.3.2), all origins allowed by a fixed functional form of the s.f. will be connected by translational vectors $\mathbf{X}_p$ such that

$$(\mathbf{R}_s - \mathbf{I})\mathbf{X}_p = \mathbf{V}, \quad s = 1, 2, \ldots, m, \qquad (2.2.3.3)$$

where $\mathbf{V}$ is a vector with zero or integer components.

In centred space groups, an origin translation corresponding to a centring vector $\mathbf{B}_v$ does not change the functional form of the s.f. Therefore all vectors $\mathbf{B}_v$ represent permissible translations. $\mathbf{X}_p$ will then be an allowed translation (Giacovazzo, 1974) not only when, as imposed by (2.2.3.3), the difference $\mathbf{T}'_s - \mathbf{T}_s$ is equal to one or more lattice units, but also when, for any s, the condition

$$(\mathbf{R}_s - \mathbf{I})\mathbf{X}_p = \mathbf{V} + \alpha\mathbf{B}_v, \quad s = 1, 2, \ldots, m; \quad \alpha = 0, 1 \qquad (2.2.3.4)$$

is satisfied.

We will call any set of cs. or ncs. space groups having the same allowed origin translations a Hauptman–Karle group (H–K group). The 94 ncs. primitive space groups, the 62 primitive cs. groups, the 44 ncs. centred space groups and the 30 cs. centred space groups can be collected into 13, 4, 14 and 5 H–K groups, respectively (Hauptman & Karle, 1953, 1956; Karle & Hauptman, 1961; Lessinger & Wondratschek, 1975). In Tables 2.2.3.1–2.2.3.4 the H–K groups are given together with the allowed origin translations.

(*d*) Let us consider a product of structure factors

$$F_{\mathbf{h}_1}^{A_1} \times F_{\mathbf{h}_2}^{A_2} \times \ldots \times F_{\mathbf{h}_n}^{A_n} = \prod_{j=1}^{n} F_{\mathbf{h}_j}^{A_j} = \exp\left(i\sum_{j=1}^{n} A_j\varphi_{\mathbf{h}_j}\right)\prod_{j=1}^{n} |F_{\mathbf{h}_j}|^{A_j}, \qquad (2.2.3.5)$$

A_j being integer numbers.

Copyright © 2010 International Union of Crystallography

The factor $\sum_{j=1}^{n} A_j\varphi_{\mathbf{h}_j}$ is the phase of the product (2.2.3.5). A *structure invariant* (s.i.) is a product (2.2.3.5) such that

$$\sum_{j=1}^{n} A_j\mathbf{h}_j = 0. \qquad (2.2.3.6)$$

Since $|F_{\mathbf{h}_j}|$ are usually known from experiment, it is often said that s.i.'s are combinations of phases

$$\sum_{j=1}^{n} A_j\varphi_{\mathbf{h}_j}, \qquad (2.2.3.7)$$

for which (2.2.3.6) holds.

F_0, $F_{\mathbf{h}}F_{-\mathbf{h}}$, $F_{\mathbf{h}}F_{\mathbf{k}}F_{\overline{\mathbf{h}+\mathbf{k}}}$, $F_{\mathbf{h}}F_{\mathbf{k}}F_{\mathbf{l}}F_{\overline{\mathbf{h}+\mathbf{k}+\mathbf{l}}}$, $F_{\mathbf{h}}F_{\mathbf{k}}F_{\mathbf{l}}F_{\mathbf{p}}F_{\overline{\mathbf{h}+\mathbf{k}+\mathbf{l}+\mathbf{p}}}$ are examples of s.i.'s for $n = 1, 2, 3, 4, 5$.

The value of any s.i. does not change with an arbitrary shift of the space-group origin and thus it will depend on the crystal structure only.

(*e*) A *structure seminvariant* (s.s.) is a product of structure factors [or a combination of phases (2.2.3.7)] whose value is unchanged when the origin is moved by an allowed translation.

Let $\mathbf{X}_p$'s be the permissible origin translations of the space group. Then the product (2.2.3.5) [or the sum (2.2.3.7)] is an s.s., if, in accordance with (2.2.3.1),

$$\sum_{j=1}^{n} A_j(\mathbf{h}_j \cdot \mathbf{X}_p) = r, \quad p = 1, 2, \ldots \qquad (2.2.3.8)$$

where r is a positive integer, null or a negative integer.

Conditions (2.2.3.8) can be written in the following more useful form (Hauptman & Karle, 1953):

$$\sum_{j=1}^{n} A_j\mathbf{h}_{s_j} \equiv 0 \pmod{\boldsymbol{\omega}_s}, \qquad (2.2.3.9)$$

where $\mathbf{h}_{s_j}$ is the vector seminvariantly associated with the vector $\mathbf{h}_j$ and $\boldsymbol{\omega}_s$ is the seminvariant modulus. In Tables 2.2.3.1–2.2.3.4, the reflection $\mathbf{h}_s$ seminvariantly associated with $\mathbf{h} = (h, k, l)$, the seminvariant modulus $\boldsymbol{\omega}_s$ and seminvariant phases are given for every H–K group.

The symbol of any group (*cf.* Giacovazzo, 1974) has the structure $\mathbf{h}_s L\boldsymbol{\omega}_s$, where L stands for the lattice symbol. This symbol is underlined if the space group is cs.

By definition, if the class of permissible origin has been chosen, that is to say, if the algebraic form of the symmetry operators has been fixed, then the value of an s.s. does not depend on the origin but on the crystal structure only.

(*f*) Suppose that we have chosen the symmetry operators $\mathbf{C}_s$ and thus fixed the functional form of the s.f.'s and the set of allowed origins. In order to describe the structure in direct space a unique reference origin must be fixed. Thus the phase-determining process must also require a unique permissible origin congruent to the values assigned to the phases. More specifically, at the beginning of the structure-determining process by direct methods we shall assign as many phases as necessary to define a unique origin among those allowed (and, as we shall see, possibly to fix the enantiomorph). From the theory developed so far it is obvious that arbitrary phases can be assigned to one or more s.f.'s if there is at least one allowed origin which, fixed as the origin of the unit cell, will give those phase values to the chosen reflections. The concept of *linear dependence* will help us to fix the origin.

(*g*) n phases $\varphi_{\mathbf{h}_j}$ are *linearly semidependent* (Hauptman & Karle, 1956) when the n vectors $\mathbf{h}_{s_j}$ seminvariantly associated with the $\mathbf{h}_j$ are linearly dependent modulo $\boldsymbol{\omega}_s$, $\boldsymbol{\omega}_s$ being the seminvariant modulus of the space group. In other words, when

$$\sum_{j=1}^{n} A_j\mathbf{h}_{s_j} \equiv 0 \pmod{\boldsymbol{\omega}_s}, \qquad A_q \not\equiv 0 \pmod{\boldsymbol{\omega}_s} \qquad (2.2.3.10)$$

is satisfied. The second condition means that at least one A_q exists that is not congruent to zero modulo each of the components of $\boldsymbol{\omega}_s$. If (2.2.3.10) is not satisfied for any n-set of integers A_j, the phases $\varphi_{\mathbf{h}_j}$ are *linearly semindependent.* If (2.2.3.10) is valid for $n = 1$ and $A = 1$, then $\mathbf{h}_1$ is said to be linearly semidependent and $\varphi_{\mathbf{h}_1}$ is an s.s. It may be concluded that a seminvariant phase is linearly semidependent, and, *vice versa*, that a phase linearly semidependent is an s.s. In Tables 2.2.3.1–2.2.3.4 the allowed variations (which are those due to the allowed origin translations) for the semindependent phases are given for every H–K group. If $\varphi_{\mathbf{h}_1}$ is linearly semindependent its value can be fixed arbitrarily because at least one origin compatible with the given value exists. Once $\varphi_{\mathbf{h}_1}$ is assigned, the necessary condition to be able to fix a second phase $\varphi_{\mathbf{h}_2}$ is that it should be linearly semindependent of $\varphi_{\mathbf{h}_1}$.

Similarly, the necessary condition to be able arbitrarily to assign a third phase $\varphi_{\mathbf{h}_3}$ is that it should be linearly semindependent from $\varphi_{\mathbf{h}_1}$ and $\varphi_{\mathbf{h}_2}$.

In general, the number of linearly semindependent phases is equal to the dimension of the seminvariant vector $\boldsymbol{\omega}_s$ (see Tables 2.2.3.1–2.2.3.4). The reader will easily verify in (h, k, l) P (2, 2, 2) that the three phases φ_{oee}, φ_{eoe}, φ_{eoo} define the origin (o indicates odd, e even).

(*h*) From the theory summarized so far it is clear that a number of semindependent phases $\varphi_{\mathbf{h}_j}$, equal to the dimension of the seminvariant vector $\boldsymbol{\omega}_s$, may be arbitrarily assigned in order to fix the origin. However, it is not always true that only one allowed origin compatible with the given phases exists. An additional condition is required such that only one permissible origin should lie at the intersection of the lattice planes corresponding to the origin-fixing reflections (or on the lattice plane $\mathbf{h}$ if one reflection is sufficient to define the origin). It may be shown that the condition is verified if the determinant formed with the vectors seminvariantly associated with the origin reflections, reduced modulo $\boldsymbol{\omega}_s$, has the value ± 1. In other words, such a determinant should be primitive modulo $\boldsymbol{\omega}_s$.

For example, in $P\bar{1}$ the three reflections

$$\mathbf{h}_1 = (345), \mathbf{h}_2 = (139), \mathbf{h}_3 = (784)$$

define the origin uniquely because

$$\begin{vmatrix} 3 & 4 & 5 \\ 1 & 3 & 9 \\ 7 & 8 & 4 \end{vmatrix} \xrightarrow{\text{reduced mod (2,2,2)}} \begin{vmatrix} 1 & 0 & 1 \\ 1 & 1 & 1 \\ 1 & 0 & 0 \end{vmatrix} = -1.$$

Furthermore, in $P4mm$ [$\mathbf{h}_s = (h + k, l)$, $\boldsymbol{\omega}_s = (2, 0)$]

$$\mathbf{h}_1 = (5, 2, 0), \quad \mathbf{h}_2 = (6, 2, 1)$$

define the origin uniquely since

$$\begin{vmatrix} 7 & 0 \\ 8 & 1 \end{vmatrix} \xrightarrow{\text{reduced mod (2,0)}} \begin{vmatrix} 1 & 0 \\ 0 & 1 \end{vmatrix} = 1.$$

(*i*) If an s.s. or an s.i. has a general value φ for a given structure, it will have a value $-\varphi$ for the enantiomorph structure. If $\varphi = 0, \pi$ the s.s. has the same value for both enantiomorphs. Once the origin has been assigned, in ncs. space groups the sign of a given s.s. $\varphi \neq 0, \pi$ can be assigned to fix the enantiomorph. In practice it is often advisable to use an s.s. or an s.i. whose value is as near as possible to $\pm\pi/2$.

2.2.4. Normalized structure factors

2.2.4.1. Definition of normalized structure factor

The normalized structure factors E (see also Chapter 2.1) are calculated according to (Hauptman & Karle, 1953)

$$|E_{\mathbf{h}}|^2 = |F_{\mathbf{h}}|^2/\langle|F_{\mathbf{h}}|^2\rangle, \qquad (2.2.4.1)$$

Table 2.2.3.1. *Allowed origin translations, seminvariant moduli and phases for centrosymmetric primitive space groups*

Number of semindependent phases to be specified	3		2		1	1

where $|F_{\mathbf{h}}|^2$ is the squared observed structure-factor magnitude on the absolute scale and $\langle|F_{\mathbf{h}}|^2\rangle$ is the expected value of $|F_{\mathbf{h}}|^2$.

$\langle|F_{\mathbf{h}}|^2\rangle$ depends on the available *a priori* information. Often, but not always, this may be considered as a combination of several typical situations. We mention:

(*a*) No structural information. The atomic positions are considered random variables. Then

$$\langle|F_{\mathbf{h}}|^2\rangle = \varepsilon_{\mathbf{h}} \sum_{j=1}^{N} f_j^2 = \varepsilon_{\mathbf{h}} \sum\nolimits_N$$

so that

$$E_{\mathbf{h}} = \frac{F_{\mathbf{h}}}{(\varepsilon_{\mathbf{h}} \sum\nolimits_N)^{1/2}}. \qquad (2.2.4.2)$$

$\varepsilon_{\mathbf{h}}$ takes account of the effect of space-group symmetry (see Chapter 2.1).

(*b*) P atomic groups having a known configuration but with unknown orientation and position (Main, 1976). Then a certain number of interatomic distances $r_{j_1 j_2}$ are known and

$$\langle|F_{\mathbf{h}}|^2\rangle = \varepsilon_{\mathbf{h}}\left(\sum\nolimits_N + \sum_{i=1}^{P} \sum_{j_1 \neq j_2 = 1}^{M_i} f_{j_1} f_{j_2} \frac{\sin 2\pi q r_{j_1 j_2}}{2\pi q r_{j_1 j_2}}\right),$$

where M_i is the number of atoms in the ith molecular fragment and $q = |\mathbf{h}|$.

(*c*) P atomic groups with a known configuration, correctly oriented, but with unknown position (Main, 1976). Then a certain group of interatomic vectors $\mathbf{r}_{j_1 j_2}$ is fixed and

$$\langle|F_{\mathbf{h}}|^2\rangle = \varepsilon_{\mathbf{h}}\left(\sum\nolimits_N + \sum_{i=1}^{P} \sum_{j_1 \neq j_2 = 1}^{M_i} f_{j_1} f_{j_2} \exp 2\pi i \mathbf{h} \cdot \mathbf{r}_{j_1 j_2}\right).$$

The above formula has been derived on the assumption that primitive positional random variables are uniformly distributed over the unit cell. Such an assumption may be considered unfavourable (Giacovazzo, 1988) in space groups for which the allowed shifts of origin, consistent with the chosen algebraic form for the symmetry operators $\mathbf{C}_s$, are arbitrary displacements along any polar axes. Thanks to the indeterminacy in the choice of origin, the first of the shifts $\boldsymbol{\tau}_i$ (to be applied to the ith fragment in order to translate atoms in the correct positions) may be restricted to a region which is smaller than the unit cell (*e.g.* in $P2$ we are free to specify the origin along the diad axis by restricting $\boldsymbol{\tau}_1$ to the family of vectors $\{\boldsymbol{\tau}_1\}$ of type $[x0z]$). The practical consequence is that $\langle|F_{\mathbf{h}}|^2\rangle$ is significantly modified in polar space groups if $\mathbf{h}$ satisfies

$$\mathbf{h} \cdot \boldsymbol{\tau}_1 = 0,$$

where $\boldsymbol{\tau}_1$ belongs to the family of restricted vectors $\{\boldsymbol{\tau}_1\}$.

(*d*) Atomic groups correctly positioned. Then (Main, 1976; Giacovazzo, 1983*a*)

$$\langle|F_{\mathbf{h}}|^2\rangle = |F_{\mathrm{p},\mathbf{h}}|^2 + \varepsilon_{\mathbf{h}}\sum_q,$$

where $F_{\mathrm{p},\mathbf{h}}$ is the structure factor of the partial known structure and q are the atoms with unknown positions.

(*e*) A pseudotranslational symmetry is present. Let $\mathbf{u}_1, \mathbf{u}_2, \mathbf{u}_3, \ldots$ be the pseudotranslation vectors of order $n_1, n_2, n_3, \ldots$, respectively. Furthermore, let p be the number of atoms (symmetry equivalents included) whose positions are related by pseudotranslational symmetry and q the number of atoms (symmetry equivalents included) whose positions are not related by any pseudotranslation. Then (Cascarano *et al.*, 1985*a*,*b*)

$$\langle|F_{\mathbf{h}}|^2\rangle = \varepsilon_{\mathbf{h}}(\zeta_{\mathbf{h}}\sum_p + \sum_q),$$

where

$$\zeta_{\mathbf{h}} = \frac{(n_1 n_2 n_3 \ldots)\gamma_{\mathbf{h}}}{m}$$

and $\gamma_{\mathbf{h}}$ is the number of times for which algebraic congruences

$$\mathbf{h}\cdot\mathbf{R}_s\mathbf{u}_i \equiv 0 \pmod 1 \quad \text{for } i = 1, 2, 3, \ldots$$

are simultaneously satisfied when s varies from 1 to m. If $\gamma_{\mathbf{h}} = 0$ then $F_{\mathbf{h}}$ is said to be a *superstructure reflection*, otherwise it is a *substructure reflection.*

Often substructures are not ideal: *e.g.* atoms related by pseudotranslational symmetry are ideally located but of different type (replacive deviations from ideality); or they are equal but not ideally located (displacive deviations); or a combination of the two situations occurs. In these cases a correlation exists between the substructure and the superstructure. It has been shown (Mackay, 1953; Cascarano *et al.*, 1988*a*) that the scattering power of the substructural part may be estimated *via* a statistical analysis of diffraction data for ideal pseudotranslational symmetry or for displacive deviations from it, while it is not estimable in the case of replacive deviations.

2.2.4.2. Definition of quasi-normalized structure factor

When probability theory is not used, the *quasi-normalized structure factors* $\mathscr{E}_{\mathbf{h}}$ and the *unitary structure factors* $U_{\mathbf{h}}$ are often used. $\mathscr{E}_{\mathbf{h}}$ and $U_{\mathbf{h}}$ are defined according to

$$|\mathscr{E}_{\mathbf{h}}|^2 = \varepsilon_{\mathbf{h}}|E_{\mathbf{h}}|^2$$

$$U_{\mathbf{h}} = F_{\mathbf{h}}\Big/\left(\sum_{j=1}^{N} f_j\right).$$

Since $\sum_{j=1}^{N} f_j$ is the largest possible value for $F_{\mathbf{h}}$, $U_{\mathbf{h}}$ represents the fraction of $F_{\mathbf{h}}$ with respect to its largest possible value. Therefore

$$0 \leq |U_{\mathbf{h}}| \leq 1.$$

If atoms are equal, then $U_{\mathbf{h}} = \mathscr{E}_{\mathbf{h}}/N^{1/2}$.

2.2.4.3. The calculation of normalized structure factors

N.s.f.'s cannot be calculated by applying (2.2.4.1) to observed s.f.'s because: (*a*) the observed magnitudes $I_{\mathbf{h}}$ (already corrected for Lp factor, absorption, ...) are on a relative scale; (*b*) $\langle|F_{\mathbf{h}}|^2\rangle$ cannot be calculated without having estimated the vibrational motion of the atoms.

This is usually obtained by the well known Wilson plot (Wilson, 1942), according to which observed data are divided into ranges of $s^2 = \sin^2\theta/\lambda^2$ and averages of intensity $\langle I_{\mathbf{h}}\rangle$ are taken in each shell. Reflection multiplicities and other effects of space-group symmetry on intensities must be taken into account when such averages are calculated. The shells are symmetrically overlapped in order to reduce statistical fluctuations and are restricted so that the number of reflections in each shell is reasonably large. For each shell

$$K\langle I\rangle = \langle|F|^2\rangle = \langle|F^{\rm o}|^2\rangle \exp(-2Bs^2) \qquad (2.2.4.3)$$

should be obtained, where K is the scale factor needed to place X-ray intensities on the absolute scale, B is the overall thermal parameter and $\langle|F^{\rm o}|^2\rangle$ is the expected value of $|F|^2$ in which it is assumed that all the atoms are at rest. $\langle|F^{\rm o}|^2\rangle$ depends upon the structural information that is available (see Section 2.2.4.1 for some examples).

Equation (2.2.4.3) may be rewritten as

$$\ln\left\{\frac{\langle I\rangle}{\langle|F^{\rm o}|^2\rangle}\right\} = -\ln K - 2Bs^2,$$

which plotted at various s^2 should be a straight line of which the slope ($2B$) and intercept ($\ln K$) on the logarithmic axis can be obtained by applying a linear least-squares procedure.

Very often molecular geometries produce perceptible departures from linearity in the logarithmic Wilson plot. However, the more extensive the available *a priori* information on the structure is, the closer, on the average, are the Wilson-plot curves to their least-squares straight lines.

Accurate estimates of B and K require good strategies (Rogers & Wilson, 1953) for:

(1) treatment of weak measured data. If weak data are set to zero, there will be bias in the statistics. Methods are, however, available (French & Wilson, 1978) that provide an *a posteriori* estimate of weak (even negative) intensities by means of Bayesian statistics.

2.2.4.4. Probability distributions of normalized structure factors

Under some fairly general assumptions (see Chapter 2.1) probability distribution functions for the variable $|E|$ for cs. and ncs. structures are (see Fig. 2.2.4.1)

$$ {}_{\bar{1}}P(|E|)\,\mathrm{d}|E| = \sqrt{\frac{2}{\pi}}\exp\left(-\frac{E^2}{2}\right)\mathrm{d}|E| \qquad (2.2.4.4)$$

and

$$ {}_{1}P(|E|)\,\mathrm{d}|E| = 2|E|\exp(-|E|^2)\,\mathrm{d}|E|, \qquad (2.2.4.5)$$

respectively. Corresponding cumulative functions are (see Fig. 2.2.4.2)

$$ {}_{\bar{1}}N(|E|) = \sqrt{\frac{2}{\pi}}\int_0^{|E|}\exp\left(-\frac{t^2}{2}\right)\mathrm{d}t = \mathrm{erf}\left(\frac{|E|}{\sqrt{2}}\right),$$

$$ {}_{1}N(|E|) = \int_0^{|E|} 2t\exp(-t^2)\,\mathrm{d}t = 1-\exp(-|E|^2).$$

Some moments of the distributions (2.2.4.4) and (2.2.4.5) are listed in Table 2.2.4.1. In the absence of other indications for a given crystal structure, a cs. or an ncs. space group will be preferred according to whether the statistical tests yield values closer to column 2 or to column 3 of Table 2.2.4.1.

For further details about the distribution of intensities see Chapter 2.1.

2.2.5. Phase-determining formulae

From the earliest periods of X-ray structure analysis several authors (Ott, 1927; Banerjee, 1933; Avrami, 1938) have tried to determine atomic positions directly from diffraction intensities.

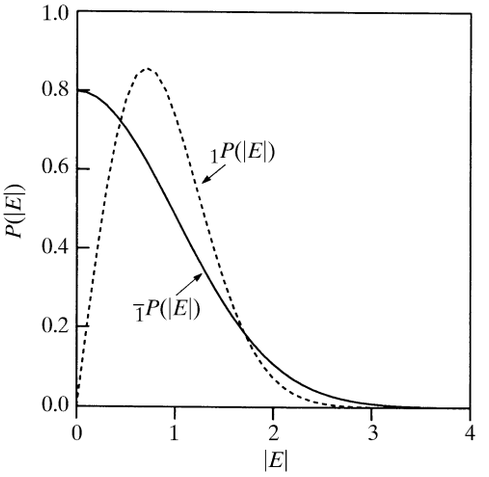

Fig. 2.2.4.1. Probability density functions for cs. and ncs. crystals.

Significant developments are the derivation of inequalities and the introduction of probabilistic techniques *via* the use of joint probability distribution methods (Hauptman & Karle, 1953).

2.2.5.1. Inequalities among structure factors

An extensive system of inequalities exists for the coefficients of a Fourier series which represents a positive function. This can restrict the allowed values for the phases of the s.f.'s in terms of measured structure-factor magnitudes. Harker & Kasper (1948) derived two types of inequalities:

Type 1. A modulus is bound by a combination of structure factors:

$$ |U_{\mathbf{h}}|^2 \le \frac{1}{m}\sum_{s=1}^{m} a_s(-\mathbf{h})U_{\mathbf{h}(\mathbf{I}-\mathbf{R}_s)}, \qquad (2.2.5.1)$$

where m is the order of the point group and $a_s(-\mathbf{h}) = \exp(-2\pi i\mathbf{h}\cdot\mathbf{T}_s)$.

Table 2.2.3.4 (*cont.*)

$(h, l)I(2, 2)$	$(h+k+l)F(2)$	$(h+k+l)F(4)$	$(l)I(0)$	$(l)I(2)$	$(2k-l)I(4)$	$(l)F(0)$	I

2	1	1	1	1	1	1	0

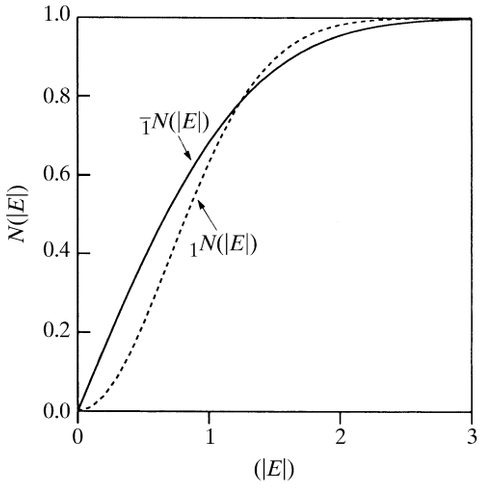

Fig. 2.2.4.2. Cumulative distribution functions for cs. and ncs. crystals.

Applied to low-order space groups, (2.2.5.1) gives

$$\begin{aligned} P1: &\quad |U_{h,k,l}|^2 \le 1 \\ P\bar{1}: &\quad U^2_{h,k,l} \le 0.5 + 0.5U_{2h,2k,2l} \\ P2_1: &\quad |U_{h,k,l}|^2 \le 0.5 + 0.5(-1)^k U_{2h,0,2l}. \end{aligned}$$

The meaning of each inequality is easily understandable: in $P\bar{1}$, for example, $U_{2h,2k,2l}$ must be positive if $|U_{h,k,l}|$ is large enough.

Type 2. The modulus of the sum or of the difference of two structure factors is bound by a combination of structure factors:

$$|U_{\mathbf{h}} \pm U_{\mathbf{h}'}|^2 \le \frac{1}{m}\left\{\sum_{s=1}^{m} a_s(-\mathbf{h})U_{\mathbf{h}(\mathbf{I}-\mathbf{R}_s)} + \sum_{s=1}^{m} a_s(-\mathbf{h}')U_{\mathbf{h}'(\mathbf{I}-\mathbf{R}_s)} \pm 2\mathscr{R}e\left[\sum_{s=1}^{m} a_s(-\mathbf{h}')U_{\mathbf{h}-\mathbf{h}'\mathbf{R}_s}\right]\right\} \quad (2.2.5.2)$$

where $\mathscr{R}e$ stands for 'real part of'. Equation (2.2.5.2) applied to $P1$ gives

$$|U_{\mathbf{h}} \pm U_{\mathbf{h}'}|^2 \le 2 \pm 2|U_{\mathbf{h}-\mathbf{h}'}|\cos\varphi_{\mathbf{h}-\mathbf{h}'}.$$

A variant of (2.2.5.2) valid for cs. space groups is

$$(U_{\mathbf{h}} \pm U_{\mathbf{h}'})^2 \le (1 \pm U_{\mathbf{h}+\mathbf{h}'})(1 \pm U_{\mathbf{h}-\mathbf{h}'}).$$

After Harker & Kasper's contributions, several other inequalities were discovered (Gillis, 1948; Goedkoop, 1950; Okaya & Nitta, 1952; de Wolff & Bouman, 1954; Bouman, 1956; Oda *et al.*, 1961). The most general are the Karle–Hauptman inequalities (Karle & Hauptman, 1950):

$$D_m = \begin{vmatrix} U_0 & U_{-\mathbf{h}_1} & U_{-\mathbf{h}_2} & \cdots & U_{-\mathbf{h}_n} \\ U_{\mathbf{h}_1} & U_0 & U_{\mathbf{h}_1-\mathbf{h}_2} & \cdots & U_{\mathbf{h}_1-\mathbf{h}_n} \\ U_{\mathbf{h}_2} & U_{\mathbf{h}_2-\mathbf{h}_1} & U_0 & \cdots & U_{\mathbf{h}_2-\mathbf{h}_n} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ U_{\mathbf{h}_n} & U_{\mathbf{h}_n-\mathbf{h}_1} & U_{\mathbf{h}_n-\mathbf{h}_2} & \cdots & U_0 \end{vmatrix} \ge 0. \quad (2.2.5.3)$$

The determinant can be of any order but the leading column (or row) must consist of U's with different indices, although, within the column, symmetry-related U's may occur. For $n = 2$ and $\mathbf{h}_2 = 2\mathbf{h}_1 = 2\mathbf{h}$, equation (2.2.5.3) reduces to

$$D_3 = \begin{vmatrix} U_0 & U_{-\mathbf{h}} & U_{-2\mathbf{h}} \\ U_{\mathbf{h}} & U_0 & U_{-\mathbf{h}} \\ U_{2\mathbf{h}} & U_{\mathbf{h}} & U_0 \end{vmatrix} \ge 0,$$

which, for cs. structures, gives the Harker & Kasper inequality

Table 2.2.4.1. *Moments of the distributions (2.2.4.4) and (2.2.4.5)*

$R(E_s)$ is the percentage of n.s.f.'s with amplitude greater than the threshold E_s.

$$U^2_{\mathbf{h}} \le 0.5 + 0.5U_{2\mathbf{h}}.$$

For $m = 3$, equation (2.2.5.3) becomes

$$D_3 = \begin{vmatrix} U_0 & U_{-\mathbf{h}} & U_{-\mathbf{k}} \\ U_{\mathbf{h}} & U_0 & U_{\mathbf{h}-\mathbf{k}} \\ U_{\mathbf{k}} & U_{\mathbf{k}-\mathbf{h}} & U_0 \end{vmatrix} \ge 0,$$

from which

$$1 - |U_{\mathbf{h}}|^2 - |U_{\mathbf{k}}|^2 - |U_{\mathbf{h}-\mathbf{k}}|^2 + 2|U_{\mathbf{h}}U_{\mathbf{k}}U_{\mathbf{h}-\mathbf{k}}|\cos\alpha_{\mathbf{h},\mathbf{k}} \ge 0, \quad (2.2.5.4)$$

where

$$\alpha_{\mathbf{h},\mathbf{k}} = \varphi_{\mathbf{h}} - \varphi_{\mathbf{k}} - \varphi_{\mathbf{h}-\mathbf{k}}.$$

If the moduli $|U_{\mathbf{h}}|$, $|U_{\mathbf{k}}|$, $|U_{\mathbf{h}-\mathbf{k}}|$ are large enough, (2.2.5.4) is not satisfied for all values of $\alpha_{\mathbf{h},\mathbf{k}}$. In cs. structures the eventual check that one of the two values of $\alpha_{\mathbf{h},\mathbf{k}}$ does not satisfy (2.2.5.4) brings about the unambiguous identification of the sign of the product $U_{\mathbf{h}}U_{\mathbf{k}}U_{\mathbf{h}-\mathbf{k}}$.

It was observed (Gillis, 1948) that 'there was a number of cases in which both signs satisfied the inequality, one of them by a comfortable margin and the other by only a relatively small margin. In almost all such cases it was the former sign which was the correct one. That suggests that the method may have some power in reserve in the sense that there are still fundamentally stronger inequalities to be discovered'. Today we identify this power in reserve in the use of probability theory.

2.2.5.2. Probabilistic phase relationships for structure invariants

For any space group (see Section 2.2.3) there are linear combinations of phases with cosines that are, in principle, fixed by the $|E|$ magnitudes alone (s.i.'s) or by the $|E|$ values and the trigonometric form of the structure factor (s.s.'s). This result greatly stimulated the calculation of conditional distribution functions

$$P(\Phi|\{R\}), \quad (2.2.5.5)$$

where $R_{\mathbf{h}} = |E_{\mathbf{h}}|$, $\Phi = \sum A_i\varphi_{\mathbf{h}_i}$ is an s.i. or an s.s. and $\{R\}$ is a suitable set of diffraction magnitudes. The method was first proposed by Hauptman & Karle (1953) and was developed further by several authors (Bertaut, 1955*a*,*b*, 1960; Klug, 1958; Naya *et al.*, 1964, 1965; Giacovazzo, 1980*a*). From a probabilistic point of view the crystallographic problem is clear: the joint distribution $P(E_{\mathbf{h}_1}, \ldots, E_{\mathbf{h}_n})$, from which the conditional distributions (2.2.5.5) can be derived, involves a number of normalized structure factors each of which is a linear sum of random vari-

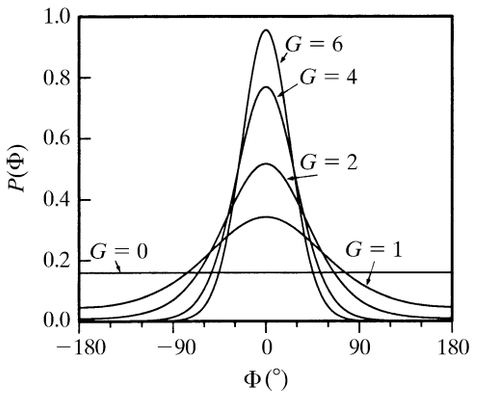

Fig. 2.2.5.1. Curves of (2.2.5.6) for some values of $G = 2\sigma_3\sigma_2^{-3/2}|E_{\mathbf{h}}E_{\mathbf{k}}E_{\mathbf{h}-\mathbf{k}}|$.

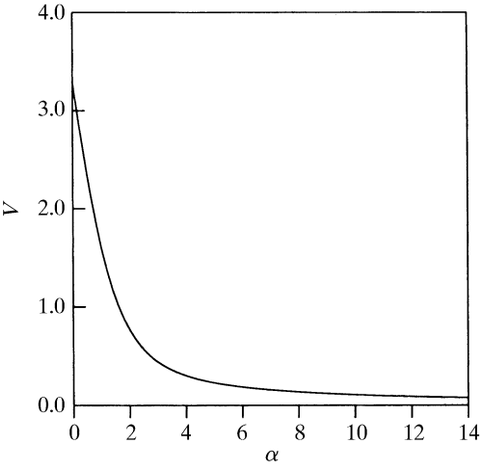

Fig. 2.2.5.2. Variance (in square radians) as a function of α.

ables (the atomic contributions to the structure factors). So, for the probabilistic interpretation of the phase problem, the atomic positions and the reciprocal vectors may be considered as random variables. A further problem is that of identifying, for a given Φ, a suitable set of magnitudes $|E|$ on which Φ primarily depends. The formulation of the *nested neighbourhood principle* first (Hauptman, 1975) fixed the idea of defining a sequence of sets of reflections each contained in the succeeding one and having the property that any s.i. or s.s. may be estimated *via* the magnitudes constituting the various neighbourhoods. A subsequent more general theory, the *representation method* (Giacovazzo, 1977*a*, 1980*b*), arranges for any Φ the set of intensities in a sequence of subsets in order of their expected effectiveness (in the statistical sense) for the estimation of Φ.

In the following sections the main formulae estimating low-order invariants and seminvariants or relating phases to other phases and diffraction magnitudes are given.

2.2.5.3. Triplet relationships

The basic formula for the estimation of the triplet phase $\Phi = \varphi_{\mathbf{h}} - \varphi_{\mathbf{k}} - \varphi_{\mathbf{h}-\mathbf{k}}$ given the parameter $G = 2\sigma_3\sigma_2^{-3/2} \times R_{\mathbf{h}}R_{\mathbf{k}}R_{\mathbf{h}-\mathbf{k}}$ is Cochran's (1955) formula

$$P(\Phi) = [2\pi I_0(G)]^{-1} \exp(G\cos\Phi), \tag{2.2.5.6}$$

where $\sigma_n = \sum_{j=1}^{N} Z_j^n$, Z_j is the atomic number of the jth atom and I_n is the modified Bessel function of order n. In Fig. 2.2.5.1 the distribution $P(\Phi)$ is shown for different values of G.

The conditional probability distribution for $\varphi_{\mathbf{h}}$, given a set of $(\varphi_{\mathbf{k}_j} + \varphi_{\mathbf{h}-\mathbf{k}_j})$ and $G_j = 2\sigma_3\sigma_2^{-3/2}R_{\mathbf{h}}R_{\mathbf{k}_j}R_{\mathbf{h}-\mathbf{k}_j}$, is given (Karle & Hauptman, 1956; Karle & Karle, 1966) by

$$P(\varphi_{\mathbf{h}}) = [2\pi I_0(\alpha)]^{-1} \exp[\alpha\cos(\varphi_{\mathbf{h}} - \beta_{\mathbf{h}})], \tag{2.2.5.7}$$

where

$$\alpha^2 = \left[\sum_{j=1}^{r} G_{\mathbf{h},\mathbf{k}_j}\cos(\varphi_{\mathbf{k}_j} + \varphi_{\mathbf{h}-\mathbf{k}_j})\right]^2 + \left[\sum_{j=1}^{r} G_{\mathbf{h},\mathbf{k}_j}\sin(\varphi_{\mathbf{k}_j} + \varphi_{\mathbf{h}-\mathbf{k}_j})\right]^2, \tag{2.2.5.8}$$

$$\tan\beta_{\mathbf{h}} = \frac{\sum_j G_{\mathbf{h},\mathbf{k}_j}\sin(\varphi_{\mathbf{k}_j} + \varphi_{\mathbf{h}-\mathbf{k}_j})}{\sum_j G_{\mathbf{h},\mathbf{k}_j}\cos(\varphi_{\mathbf{k}_j} + \varphi_{\mathbf{h}-\mathbf{k}_j})}. \tag{2.2.5.9}$$

$\beta_{\mathbf{h}}$ is the most probable value for $\varphi_{\mathbf{h}}$. The variance of $\varphi_{\mathbf{h}}$ may be obtained from (2.2.5.7) and is given by

$$V_{\mathbf{h}} = \frac{\pi^2}{3} + [I_0(\alpha)]^{-1}\sum_{n=1}^{\infty}\frac{I_{2n}(\alpha)}{n^2} - 4[I_0(\alpha)]^{-1}\sum_{n=0}^{\infty}\frac{I_{2n+1}(\alpha)}{(2n+1)^2}, \tag{2.2.5.10}$$

which is plotted in Fig. 2.2.5.2.

Equation (2.2.5.9) is the so-called *tangent formula*. According to (2.2.5.10), the larger is α the more reliable is the relation $\varphi_{\mathbf{h}} = \beta_{\mathbf{h}}$.

For an equal-atom structure $\sigma_3\sigma_2^{-3/2} = N^{-1/2}$.

The basic conditional formula for sign determination of $E_{\mathbf{h}}$ in cs. crystals is Cochran & Woolfson's (1955) formula

$$P^+ = \tfrac{1}{2} + \tfrac{1}{2}\tanh\left(\sigma_3\sigma_2^{-3/2}|E_{\mathbf{h}}|\sum_{j=1}^{r}E_{\mathbf{k}_j}E_{\mathbf{h}-\mathbf{k}_j}\right), \tag{2.2.5.11}$$

where P^+ is the probability that $E_{\mathbf{h}}$ is positive and $\mathbf{k}$ ranges over the set of known values $E_{\mathbf{k}}E_{\mathbf{h}-\mathbf{k}}$. The larger the absolute value of the argument of tanh, the more reliable is the phase indication.

An auxiliary formula exploiting all the $|E|$'s in reciprocal space in order to estimate a single Φ is the $B_{3,0}$ formula (Hauptman & Karle, 1958; Karle & Hauptman, 1958) given by

$$\begin{aligned}|E_{\mathbf{h}_1}E_{\mathbf{h}_2}E_{-\mathbf{h}_1-\mathbf{h}_2}|\cos(\varphi_{\mathbf{h}_1} + \varphi_{\mathbf{h}_2} - \varphi_{\mathbf{h}_1+\mathbf{h}_2}) &\simeq C\langle(|E_{\mathbf{k}}|^p - \overline{|E|^p})(|E_{\mathbf{h}_1+\mathbf{k}}|^p - \overline{|E|^p})(|E_{\mathbf{h}_1+\mathbf{h}_2+\mathbf{k}}|^p - \overline{|E|^p})\rangle_{\mathbf{k}} \\ &\quad - \frac{2\sigma_6}{\sigma_4^{3/2}} + \frac{\sigma_8^{1/2}}{\sigma_4}(|E_{\mathbf{h}_1}|^2 + |E_{\mathbf{h}_2}|^2 + |E_{\mathbf{h}_1+\mathbf{h}_2}|^2)\ldots,\end{aligned} \tag{2.2.5.12}$$

where C is a constant which differs for cs. and ncs. crystals, $\overline{|E|^p}$ is the average value of $|E|^p$ and p is normally chosen to be some small number. Several modifications of (2.2.5.12) have been proposed (Hauptman, 1964, 1970; Karle, 1970*a*; Giacovazzo, 1977*b*).

A recent formula (Cascarano, Giacovazzo, Camalli *et al.*, 1984) exploits information contained within the second representation of Φ, that is to say, within the collection of special quintets (see Section 2.2.5.6):

$$\varphi_{\mathbf{h}_1} + \varphi_{\mathbf{h}_2} - \varphi_{\mathbf{h}_1+\mathbf{h}_2} + \varphi_{\mathbf{k}} - \varphi_{\mathbf{k}},$$

where $\mathbf{k}$ is a free vector. The formula retains the same algebraic form as (2.2.5.6), but

$$G = \frac{2R_{\mathbf{h}_1}R_{\mathbf{h}_2}R_{\mathbf{h}_3}}{\sqrt{N}}(1 + Q), \tag{2.2.5.13}$$

where $[\mathbf{h}_3 = -(\mathbf{h}_1 + \mathbf{h}_2)]$,

$$Q = \sum_{\mathbf{k}} \frac{\sum_{i=1}^{'m} A_{\mathbf{k},i}/N}{1 + \left(\varepsilon_{\mathbf{h}_1}\varepsilon_{\mathbf{h}_2}\varepsilon_{\mathbf{h}_3} + \sum_{i=1}^{'m} B_{\mathbf{k},i}\right)\Big/ 2N},$$

$$\begin{aligned}
A_{\mathbf{k},i} = \varepsilon_{\mathbf{k}}[&\varepsilon_{\mathbf{h}_1+\mathbf{k}\mathbf{R}_i}(\varepsilon_{\mathbf{h}_2-\mathbf{k}\mathbf{R}_i} + \varepsilon_{\mathbf{h}_3-\mathbf{k}\mathbf{R}_i}) \\
&+ \varepsilon_{\mathbf{h}_2+\mathbf{k}\mathbf{R}_i}(\varepsilon_{\mathbf{h}_1-\mathbf{k}\mathbf{R}_i} + \varepsilon_{\mathbf{h}_3-\mathbf{k}\mathbf{R}_i}) \\
&+ \varepsilon_{\mathbf{h}_3+\mathbf{k}\mathbf{R}_i}(\varepsilon_{\mathbf{h}_1-\mathbf{k}\mathbf{R}_i} + \varepsilon_{\mathbf{h}_2-\mathbf{k}\mathbf{R}_i})], \\
B_{\mathbf{k},i} = \varepsilon_{\mathbf{h}_1}[&\varepsilon_{\mathbf{k}}(\varepsilon_{\mathbf{h}_1+\mathbf{k}\mathbf{R}_i} + \varepsilon_{\mathbf{h}_1-\mathbf{k}\mathbf{R}_i}) \\
&+ \varepsilon_{\mathbf{h}_2+\mathbf{k}\mathbf{R}_i}\varepsilon_{\mathbf{h}_3-\mathbf{k}\mathbf{R}_i} + \varepsilon_{\mathbf{h}_2-\mathbf{k}\mathbf{R}_i}\varepsilon_{\mathbf{h}_3+\mathbf{k}\mathbf{R}_i}] \\
&+ \varepsilon_{\mathbf{h}_2}[\varepsilon_{\mathbf{k}}(\varepsilon_{\mathbf{h}_2+\mathbf{k}\mathbf{R}_i} + \varepsilon_{\mathbf{h}_2-\mathbf{k}\mathbf{R}_i}) \\
&+ \varepsilon_{\mathbf{h}_1+\mathbf{k}\mathbf{R}_i}\varepsilon_{\mathbf{h}_3-\mathbf{k}\mathbf{R}_i} + \varepsilon_{\mathbf{h}_1-\mathbf{k}\mathbf{R}_i}\varepsilon_{\mathbf{h}_3+\mathbf{k}\mathbf{R}_i}] \\
&+ \varepsilon_{\mathbf{h}_3}[\varepsilon_{\mathbf{k}}(\varepsilon_{\mathbf{h}_3+\mathbf{k}\mathbf{R}_i} + \varepsilon_{\mathbf{h}_3-\mathbf{k}\mathbf{R}_i}) \\
&+ \varepsilon_{\mathbf{h}_1+\mathbf{k}\mathbf{R}_i}\varepsilon_{\mathbf{h}_2-\mathbf{k}\mathbf{R}_i} + \varepsilon_{\mathbf{h}_1-\mathbf{k}\mathbf{R}_i}\varepsilon_{\mathbf{h}_2+\mathbf{k}\mathbf{R}_i}];
\end{aligned}$$

$\varepsilon = |E|^2 - 1$, $(\varepsilon_{\mathbf{h}_1}\varepsilon_{\mathbf{h}_2}\varepsilon_{\mathbf{h}_3} + \sum_{i=1}^{'m} B_{\mathbf{k},i})$ is assumed to be zero if it is experimentally negative. The prime to the summation warns the reader that precautions have to be taken in order to avoid duplications in the contributions.

G may be positive or negative. In particular, if $G < 0$ the triplet is estimated negative.

The accuracy with which the value of Φ is estimated strongly depends on $\varepsilon_{\mathbf{k}}$. Thus, in practice, only a subset of reciprocal space (the reflections $\mathbf{k}$ with large values of ε) may be used for estimating Φ.

(2.2.5.13) proved to be quite useful in practice. Positive triplet cosines are ranked in order of reliability by (2.2.5.13) markedly better than by Cochran's parameters. Negative estimated triplet cosines may be excluded from the phasing process and may be used as a figure of merit for finding the correct solution in a multisolution procedure.

2.2.5.4. Triplet relationships using structural information

A strength of direct methods is that no knowledge of structure is required for their application. However, when some *a priori* information is available, it should certainly be a weakness of the methods not to make use of this knowledge. The conditional distribution of Φ given $R_{\mathbf{h}}R_{\mathbf{k}}R_{\mathbf{h}-\mathbf{k}}$ and the first three of the five kinds of *a priori* information described in Section 2.2.4.1 is (Main, 1976; Heinermann, 1977*a*)

$$P(\Phi) \simeq \frac{\exp[2QR_1R_2R_3\cos(\Phi - q)]}{2\pi I_0(2QR_1R_2R_3)}, \qquad (2.2.5.14)$$

where

$$Q\exp(iq) = \frac{\sum_{i=1}^{p} g_i(\mathbf{h}_1, \mathbf{h}_2, \mathbf{h}_3)}{\langle|F_{\mathbf{h}_1}|^2\rangle^{1/2}\langle|F_{\mathbf{h}_2}|^2\rangle^{1/2}\langle|F_{\mathbf{h}_3}|^2\rangle^{1/2}}.$$

$\mathbf{h}_1, \mathbf{h}_2, \mathbf{h}_3$ stand for $\mathbf{h}$, $-\mathbf{k}$, $-\mathbf{h}+\mathbf{k}$, and R_1, R_2, R_3 for $R_{\mathbf{h}}$, $R_{\mathbf{k}}$, $R_{\mathbf{h}-\mathbf{k}}$. The quantities $\langle|F_{\mathbf{h}_i}|^2\rangle$ have been calculated in Section 2.2.4.1 according to different categories: $g_i(\mathbf{h}_1, \mathbf{h}_2, \mathbf{h}_3)$ is a suitable average of the product of three scattering factors for the ith atomic group, p is the number of atomic groups in the cell including those related by symmetry elements. We have the following categories.

(*a*) *No structural information*

(2.2.5.14) then reduces to (2.2.5.6).

(*b*) *Randomly positioned and randomly oriented atomic groups*

Then

$$g_i(\mathbf{h}_1, \mathbf{h}_2, \mathbf{h}_3) = \sum_{j,k,l} f_j\, f_k\, f_l \langle\exp[2\pi i(\mathbf{h}_1\cdot\mathbf{r}_{kj} + \mathbf{h}_2\cdot\mathbf{r}_{lj})]\rangle_{\mathrm{R}},$$

where $\langle\ldots\rangle_{\mathrm{R}}$ means rotational average. The average of the exponential term extends over all orientations of the triangle formed by the atoms j, k and l, and is given (Hauptman, 1965) by

$$\begin{aligned}
B(z,t) &= \langle\exp[2\pi i(\mathbf{h}\cdot\mathbf{r} + \mathbf{h}'\cdot\mathbf{r}')]\rangle \\
&= \left(\frac{\pi}{2z}\right)^{1/2}\sum_{n=0}^{\infty}\frac{t^{2n}}{(n!)^2}J_{(4n+1)/2}(z),
\end{aligned}$$

where

$$z = 2\pi[q^2r^2 + 2qrq'r'\cos\varphi_q\cos\varphi_r + q'^2r'^2]^{1/2}$$

and

$$t = [2\pi^2 qrq'r'\sin\varphi_q\sin\varphi_r]/z;$$

q, q', r and r' are the magnitudes of $\mathbf{h}$, $\mathbf{h}'$, $\mathbf{r}$ and $\mathbf{r}'$, respectively; φ_q and φ_r are the angles $(\mathbf{h}, \mathbf{h}')$ and $(\mathbf{r}, \mathbf{r}')$, respectively.

(*c*) *Randomly positioned but correctly oriented atomic groups*

Then

$$\begin{aligned}
g_i(\mathbf{h}_1, \mathbf{h}_2, \mathbf{h}_3) = &\sum_{s=1}^{m}\sum_{j,k,l} f_j\, f_k\, f_l \\
&\times \exp[2\pi i(\mathbf{h}_1\cdot\mathbf{R}_s\mathbf{r}_{kj} + \mathbf{h}_2\cdot\mathbf{R}_s\mathbf{r}_{lk})],
\end{aligned}$$

where the summations over j, k, l are taken over all the atoms in the ith group.

A modified expression for g_i has to be used in polar space groups for special triplets (Giacovazzo, 1988).

Translation functions [see Chapter 2.3; for an overview, see also Beurskens *et al.* (1987)] are also used to determine the position of a correctly oriented molecular fragment.

Such functions can work in direct space [expressed as Patterson convolutions (Buerger, 1959; Nordman, 1985) or electron-density convolutions (Rossmann *et al.*, 1964; Argos & Rossmann, 1980)] or in reciprocal space [expressed as correlation functions (Crowther & Blow, 1967; Karle, 1972; Langs, 1985) or residual functions (Rae, 1977)]. Both the probabilistic methods and the translation functions are quite efficient tools: the decision as to which one to use is often a personal choice.

(*d*) *Atomic groups correctly positioned*

Let p be the number of atoms with known position, q the number of atoms with unknown position, F_p and F_q the corresponding structure factors.

Tangent recycling methods (Karle, 1970*b*) may be used for recovering the complete crystal structure. The phase $\varphi_{p,\mathbf{h}}$ is accepted in the starting set as a useful approximation of $\varphi_{\mathbf{h}}$ if $|F_{p,\mathbf{h}}| > \eta|F_{\mathbf{h}}|$, where η is the fraction of the total scattering power contained in the fragment and where $|F_{\mathbf{h}}|$ is associated with $|E_{\mathbf{h}}| > 1.5$.

Tangent recycling methods are applied (Beurskens *et al.*, 1979) with greater effectiveness to difference s.f.'s $\Delta F = (|F| - |F_p|)\exp(i\varphi_p)$. The weighted tangent formula uses $\Delta F_{\mathbf{h}}$ values in order to convert them to more probable $F_{q,\mathbf{h}}$ values.

From a probabilistic point of view (Giacovazzo, 1983*a*; Camalli *et al.*, 1985) the distribution of $\varphi_{\mathbf{h}}$, given $E'_{p,\mathbf{h}}$ and some products $(E'_{\mathbf{k}} - E'_{p,\mathbf{k}})(E'_{\mathbf{h}-\mathbf{k}} - E'_{p,\mathbf{h}-\mathbf{k}})$, is the von Mises function

$$P(\varphi_{\mathbf{h}}|\ldots) = [2\pi I_0(\alpha)]^{-1}\exp[\alpha\cos(\varphi_{\mathbf{h}} - \theta_{\mathbf{h}})], \qquad (2.2.5.15)$$

where $\theta_{\mathbf{h}}$, the most probable value of $\varphi_{\mathbf{h}}$, is given by

$$\begin{aligned}
\tan\theta_{\mathbf{h}} &\simeq \alpha'_2/\alpha'_1, \qquad (2.2.5.16)\\
\alpha^2 &= \alpha'^2_1 + \alpha'^2_2
\end{aligned}$$

and

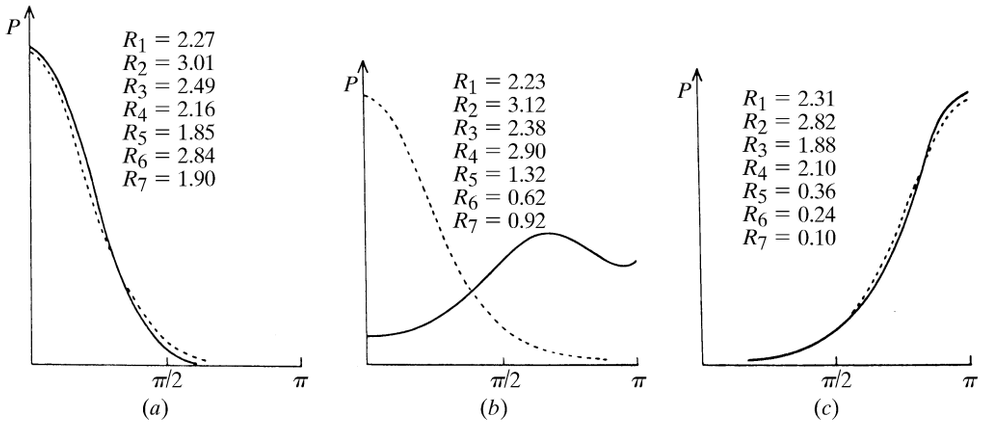

Fig. 2.2.5.3. Distributions (2.2.5.18) (solid curve) and (2.2.5.20) (dashed curve) for the indicated $|E|$ values in three typical cases.

$$\alpha'_1 = 2R'_{\mathbf{h}}\Big\{\mathscr{R}\Big[E'_{p,\,\mathbf{h}} + q^{-1/2}\textstyle\sum_{\mathbf{k}}(E'_{\mathbf{k}} - E'_{p,\,\mathbf{k}}) \times (E'_{\mathbf{h}-\mathbf{k}} - E'_{p,\,\mathbf{h}-\mathbf{k}})\Big]\Big\}$$

$$\alpha'_2 = 2R'_{\mathbf{h}}\Big\{\mathscr{I}\Big[E'_{p,\,\mathbf{h}} + q^{-1/2}\textstyle\sum_{\mathbf{k}}(E'_{\mathbf{k}} - E'_{p,\,\mathbf{k}}) \times (E'_{\mathbf{h}-\mathbf{k}} - E'_{p,\,\mathbf{h}-\mathbf{k}})\Big]\Big\}.$$

$\mathscr{R}$ and $\mathscr{I}$ stand for 'real and imaginary part of', respectively. Furthermore, $E' = F/\sum_q^{1/2}$ is a pseudo-normalized s.f. If no pair $(\varphi_{\mathbf{k}}, \varphi_{\mathbf{h}-\mathbf{k}})$ is known, then

$$\alpha'_1 = 2R'_{\mathbf{h}}R'_{p,\,\mathbf{h}}\cos\varphi_{p,\,\mathbf{h}}$$
$$\alpha'_2 = 2R'_{\mathbf{h}}R'_{p,\,\mathbf{h}}\sin\varphi_{p,\,\mathbf{h}}$$

and (2.2.5.15) reduces to Sim's (1959) equation

$$P(\varphi_{\mathbf{h}}) \simeq [2\pi I_0(G)]^{-1}\exp[G\cos(\varphi_{\mathbf{h}} - \varphi_{p,\,\mathbf{h}})], \qquad (2.2.5.17)$$

where $G = 2R'_{\mathbf{h}}R'_{p,\,\mathbf{h}}$. In this case $\varphi_{p,\,\mathbf{h}}$ is the most probable value of $\varphi_{\mathbf{h}}$.

(*e*) *Pseudotranslational symmetry is present*

Substructure and superstructure reflections are then described by different forms of the structure-factor equation (Böhme, 1982; Gramlich, 1984; Fan *et al.*, 1983), so that probabilistic formulae estimating triplet cosines derived on the assumption that atoms are uniformly dispersed in the unit cell cannot hold. In particular, the reliability of each triplet also depends on, besides $R_{\mathbf{h}}$, $R_{\mathbf{k}}$, $R_{\mathbf{h}-\mathbf{k}}$, the actual $\mathbf{h}$, $\mathbf{k}$, $\mathbf{h}-\mathbf{k}$ indices and on the nature of the pseudotranslation. It has been shown (Cascarano *et al.*, 1985*b*; Cascarano, Giacovazzo & Luić, 1987) that (2.2.5.7), (2.2.5.8), (2.2.5.9) still hold provided $G_{\mathbf{h},\,\mathbf{k}_j}$ is replaced by

$$G'_{\mathbf{h},\,\mathbf{k}_j} = \frac{2R_{\mathbf{h}}R_{\mathbf{k}_j}R_{\mathbf{h}-\mathbf{k}_j}}{\sqrt{N_{\mathbf{h},\,\mathbf{k}}}},$$

where factors E and n_i are defined according to Section 2.2.4.1,

$$N_{\mathbf{h},\mathbf{k}} = \frac{(\zeta_{\mathbf{h}}[\sigma_2]_p + [\sigma_2]_q)(\zeta_{\mathbf{k}}[\sigma_2]_p + [\sigma_2]_q)(\zeta_{\mathbf{h}-\mathbf{k}}[\sigma_2]_p + [\sigma_2]_q)}{\{(\beta/m)[\sigma_3]_p(n_1^2n_2^2n_3^2\ldots) + [\sigma_3]_q\}^2},$$

and β is the number of times for which

$$\mathbf{h}\mathbf{R}_s\cdot\mathbf{u}_1 \equiv 0 \pmod 1 \qquad \mathbf{h}\mathbf{R}_s\cdot\mathbf{u}_2 \equiv 0 \pmod 1 \qquad \mathbf{h}\mathbf{R}_s\cdot\mathbf{u}_3 \equiv 0 \pmod 1\ldots$$
$$\mathbf{k}\mathbf{R}_s\cdot\mathbf{u}_1 \equiv 0 \pmod 1 \qquad \mathbf{k}\mathbf{R}_s\cdot\mathbf{u}_2 \equiv 0 \pmod 1 \qquad \mathbf{k}\mathbf{R}_s\cdot\mathbf{u}_3 \equiv 0 \pmod 1\ldots$$
$$(\mathbf{h}-\mathbf{k})\mathbf{R}_s\cdot\mathbf{u}_1 \equiv 0 \pmod 1 \qquad (\mathbf{h}-\mathbf{k})\mathbf{R}_s\cdot\mathbf{u}_2 \equiv 0 \pmod 1$$
$$(\mathbf{h}-\mathbf{k})\mathbf{R}_s\cdot\mathbf{u}_3 \equiv 0 \pmod 1\ldots$$

are simultaneously satisfied when s varies from 1 to m. The above formulae have been generalized (Cascarano *et al.*, 1988*b*) to the case in which deviations both of replacive and of displacive type from ideal pseudo-translational symmetry occur.

2.2.5.5. Quartet phase relationships

In early papers (Hauptman & Karle, 1953; Simerska, 1956) the phase

$$\Phi = \varphi_{\mathbf{h}} + \varphi_{\mathbf{k}} + \varphi_{\mathbf{l}} - \varphi_{\mathbf{h}+\mathbf{k}+\mathbf{l}}$$

was always expected to be zero. Schenk (1973*a*,*b*) [see also Hauptman (1974)] suggested that Φ primarily depends on the seven magnitudes: $R_{\mathbf{h}}, R_{\mathbf{k}}, R_{\mathbf{l}}, R_{\mathbf{h}+\mathbf{k}+\mathbf{l}}$, called *basis magnitudes*, and $R_{\mathbf{h}+\mathbf{k}}, R_{\mathbf{h}+\mathbf{l}}, R_{\mathbf{k}+\mathbf{l}}$, called *cross magnitudes*.

The conditional probability of Φ in $P1$ given seven magnitudes $(R_1 = R_{\mathbf{h}}, \ldots, R_4 = R_{\mathbf{h}+\mathbf{k}+\mathbf{l}}, R_5 = R_{\mathbf{h}+\mathbf{k}}, R_6 = R_{\mathbf{h}+\mathbf{l}}, R_7 = R_{\mathbf{k}+\mathbf{l}})$ according to Hauptman (1975) is

$$P_7(\Phi) = \frac{1}{L}\exp(-2B\cos\Phi)I_0(2\sigma_3\sigma_2^{-3/2}R_5Y_5) \times I_0(2\sigma_3\sigma_2^{-3/2}R_6Y_6)I_0(2\sigma_3\sigma_2^{-3/2}R_7Y_7),$$

where L is a suitable normalizing constant which can be derived numerically,

$$B = \sigma_2^{-3}(3\sigma_3^2 - \sigma_2\sigma_4)R_1R_2R_3R_4$$
$$Y_5 = [R_1^2R_2^2 + R_3^2R_4^2 + 2R_1R_2R_3R_4\cos\Phi]^{1/2}$$
$$Y_6 = [R_3^2R_1^2 + R_2^2R_4^2 + 2R_1R_2R_3R_4\cos\Phi]^{1/2}$$
$$Y_7 = [R_2^2R_3^2 + R_1^2R_4^2 + 2R_1R_2R_3R_4\cos\Phi]^{1/2}.$$

For equal atoms $\sigma_2^{-3}(3\sigma_3^2 - \sigma_2\sigma_4) = 2/N$. Denoting

$$C = R_1R_2R_3R_4/N,$$
$$Z_5 = 2Y_5/\sqrt{N}, \quad Z_6 = 2Y_6/\sqrt{N}, \quad Z_7 = 2Y_7/\sqrt{N}$$

gives

$$P_7(\Phi) = \frac{1}{L}\exp(-4C\cos\Phi) \times I_0(R_5Z_5)I_0(R_6Z_6)I_0(R_7Z_7). \qquad (2.2.5.18)$$

Fig. 2.2.5.3 shows the distribution (2.2.5.18) for three typical cases. It is clear from the figure that the cosine estimated near π or in the middle range will be in poorer agreement with the true values than the cosine near 0 because of the relatively larger values of the variance. In principle, however, the formula is able to estimate negative or enantiomorph-sensitive quartet cosines from the seven magnitudes.

In the cs. case (2.2.5.18) is replaced (Hauptman & Green, 1976) by

Table 2.2.5.1. *List of quartets symmetry equivalent to* $\Phi = \Phi_1$ *in the class mmm*

Quartets	Basis vectors				Cross vectors		
Φ_1	$(1, 2, 3)$	$(\bar{1}, 5, \bar{3})$	$(\bar{1}, \bar{5}, 8)$	$(1, \bar{2}, \bar{8})$	$(0, 7, 0)$	$(0, \bar{3}, 11)$	$(\bar{2}, 0, 5)$
Φ_2	$(\bar{1}, 2, 3)$	$(1, 5, \bar{3})$	$(\bar{1}, \bar{5}, 8)$	$(1, \bar{2}, \bar{8})$	$(0, 7, 0)$	$(\bar{2}, \bar{3}, 11)$	$(0, 0, 5)$
Φ_3	$(1, 2, \bar{3})$	$(\bar{1}, 5, 3)$	$(\bar{1}, \bar{5}, 8)$	$(1, \bar{2}, \bar{8})$	$(0, 7, 0)$	$(0, \bar{3}, 5)$	$(\bar{2}, 0, 11)$
Φ_4	$(\bar{1}, 2, \bar{3})$	$(1, 5, 3)$	$(\bar{1}, \bar{5}, 8)$	$(1, \bar{2}, \bar{8})$	$(0, 7, 0)$	$(\bar{2}, \bar{3}, 5)$	$(0, 0, 11)$
Φ_5	$(\bar{1}, 2, 3)$	$(\bar{1}, 5, \bar{3})$	$(1, \bar{5}, 8)$	$(1, \bar{2}, \bar{8})$	$(\bar{2}, 7, 0)$	$(0, \bar{3}, 11)$	$(0, 0, 5)$
Φ_6	$(1, 2, 3)$	$(\bar{1}, \bar{5}, \bar{3})$	$(\bar{1}, 5, 8)$	$(1, \bar{2}, \bar{8})$	$(0, \bar{3}, 0)$	$(0, 7, 11)$	$(\bar{2}, 0, 5)$
Φ_7	$(\bar{1}, 2, 3)$	$(1, \bar{5}, \bar{3})$	$(\bar{1}, 5, 8)$	$(1, \bar{2}, \bar{8})$	$(0, \bar{3}, 0)$	$(\bar{2}, 7, 11)$	$(0, 0, 5)$
Φ_8	$(\bar{1}, 2, \bar{3})$	$(\bar{1}, 5, 3)$	$(1, \bar{5}, 8)$	$(1, \bar{2}, \bar{8})$	$(\bar{2}, 7, 0)$	$(0, \bar{3}, 5)$	$(0, 0, 11)$
Φ_9	$(1, 2, \bar{3})$	$(\bar{1}, \bar{5}, 3)$	$(\bar{1}, 5, 8)$	$(1, \bar{2}, \bar{8})$	$(0, \bar{3}, 0)$	$(0, 7, 5)$	$(\bar{2}, 0, 11)$
Φ_{10}	$(\bar{1}, 2, \bar{3})$	$(1, \bar{5}, 3)$	$(\bar{1}, 5, 8)$	$(1, \bar{2}, \bar{8})$	$(0, \bar{3}, 0)$	$(\bar{2}, 7, 5)$	$(0, 0, 11)$
Φ_{11}	$(\bar{1}, 2, 3)$	$(\bar{1}, \bar{5}, \bar{3})$	$(1, 5, 8)$	$(1, \bar{2}, \bar{8})$	$(\bar{2}, \bar{3}, 0)$	$(0, 7, 11)$	$(0, 0, 5)$

$$P^{\pm} \simeq \frac{1}{L}\exp(\mp 2C)\cosh(R_5 Z_5^{\pm}) \times \cosh(R_6 Z_6^{\pm})\cosh(R_7 Z_7^{\pm}), \qquad (2.2.5.19)$$

where $P^{\pm}$ is the probability that the sign of $E_1E_2E_3E_4$ is positive or negative, and

$$Z_5^{\pm} = \frac{1}{N^{1/2}}(R_1R_2 \pm R_3R_4),$$
$$Z_6^{\pm} = \frac{1}{N^{1/2}}(R_1R_3 \pm R_2R_4),$$
$$Z_7^{\pm} = \frac{1}{N^{1/2}}(R_1R_4 \pm R_2R_3).$$

The normalized probability may be derived by $P^+/(P^+ + P^-)$. More simple probabilistic formulae were derived independently by Giacovazzo (1975, 1976):

$$P_7(\Phi) = [2\pi I_0(G)]^{-1}\exp(G\cos\Phi), \qquad (2.2.5.20)$$

where

$$G = \frac{2C(1 + \varepsilon_5 + \varepsilon_6 + \varepsilon_7)}{1 + Q/(2N)} \qquad (2.2.5.21)$$

$$Q = (\varepsilon_1\varepsilon_2 + \varepsilon_3\varepsilon_4)\varepsilon_5 + (\varepsilon_1\varepsilon_3 + \varepsilon_2\varepsilon_4)\varepsilon_6 + (\varepsilon_1\varepsilon_4 + \varepsilon_2\varepsilon_3)\varepsilon_7 \qquad (2.2.5.22)$$

and $\varepsilon_i = (|E_i|^2 - 1)$. Q is never allowed to be negative.

According to (2.2.5.20) $\cos\Phi$ is expected to be positive or negative according to whether $(\varepsilon_5 + \varepsilon_6 + \varepsilon_7 + 1)$ is positive or negative: the larger is C, the more reliable is the phase indication. For $N \geq 150$, (2.2.5.18) and (2.2.5.20) are practically equivalent in all cases. If N is small, (2.2.5.20) is in good agreement with (2.2.5.18) for quartets strongly defined as positive or negative, but in poor agreement for enantiomorph-sensitive quartets (see Fig. 2.2.5.3).

In cs. cases the sign probability for $E_1E_2E_3E_4$ is

$$P^+ = \tfrac{1}{2} + \tfrac{1}{2}\tanh(G/2), \qquad (2.2.5.23)$$

where G is defined by (2.2.5.21).

All three cross magnitudes are not always in the set of measured reflections. From marginal distributions the following formulae arise (Giacovazzo, 1977*c*; Heinermann, 1977*b*):

(*a*) in the ncs. case, if R_7, or R_6 and R_7, or R_5 and R_6 and R_7, are not in the measurements, then (2.2.5.18) is replaced by

$$P(\Phi|R_1, \ldots, R_6) \simeq \frac{1}{L'}\exp(-2C\cos\Phi)I_0(R_5Z_5)I_0(R_6Z_6),$$

or

$$P(\Phi|R_1, \ldots, R_5) \simeq \frac{1}{L''}I_0(R_5Z_5),$$

or

$$P(\Phi|R_1, \ldots, R_4) \simeq \frac{1}{L'''}\exp(2C\cos\Phi),$$

respectively.

(*b*) in the same situations, we have for cs. cases

$$P^{\pm} \simeq \frac{1}{L'}\exp(\mp C)\cosh(R_5Z_5^{\pm})\cosh(R_6Z_6^{\pm}),$$

or

$$P^{\pm} \simeq \frac{1}{L''}\cosh(R_5Z_5^{\pm}),$$

or

$$P^{\pm} = \frac{1}{L'''}\exp(\pm C) \simeq 0.5 + 0.5\tanh(\pm C),$$

respectively.

Equations (2.2.5.20) and (2.2.5.23) are easily modifiable when some cross magnitudes are not in the measurements. If R_i is not measured then (2.2.5.20) or (2.2.5.23) are still valid provided that in G it is assumed that $\varepsilon_i = 0$. For example, if R_7 and R_6 are not in the data then (2.2.5.21) and (2.2.5.22) become

$$G = \frac{2C(1 + \varepsilon_5)}{1 + Q/(2N)}, \qquad Q = (\varepsilon_1\varepsilon_2 + \varepsilon_3\varepsilon_4)\varepsilon_5.$$

In space groups with symmetry higher than $P\bar{1}$ more symmetry-equivalent quartets can exist of the type

$$\psi = \varphi_{\mathbf{h}\boldsymbol{R}_\alpha} + \varphi_{\mathbf{k}\boldsymbol{R}_\beta} + \varphi_{\mathbf{l}\boldsymbol{R}_\gamma} + \varphi_{(\overline{\mathbf{h}+\mathbf{k}+\mathbf{l}})\boldsymbol{R}_\delta},$$

where $\boldsymbol{R}_\alpha, \boldsymbol{R}_\beta, \boldsymbol{R}_\gamma, \boldsymbol{R}_\delta$ are rotation matrices of the space group. The set $\{\psi\}$ is called the *first representation* of Φ. In this case Φ primarily depends on more than seven magnitudes. For example, let us consider in *Pmmm* the quartet

$$\Phi = \varphi_{123} + \varphi_{\bar{1}5\bar{3}} + \varphi_{\bar{1}\bar{5}8} + \varphi_{1\bar{2}\bar{8}}.$$

Quartets symmetry equivalent to Φ and respective cross terms are given in Table 2.2.5.1.

Experimental tests on the application of the representation concept to quartets have been made (Busetta *et al.*, 1980). It was shown that quartets with more than three cross magnitudes are more accurately estimated than other quartets. Also, quartets with a cross reflection which is systematically absent were shown to be of significant importance in direct methods. In this context it is noted that systematically absent reflections are not usually included in the set of diffraction data. This custom, not exceptionable when only triplet relations are used, can give rise to a loss of information when quartets are used. In fact the usual programs of direct methods discard quartets as soon as one of the cross reflections is not measured, so that systematic absences are

dealt with in the same manner as those reflections which are outside the sphere of measurements.

2.2.5.6. Quintet phase relationships

A quintet phase

$$\Phi = \varphi_{\mathbf{h}} + \varphi_{\mathbf{k}} + \varphi_{\mathbf{l}} + \varphi_{\mathbf{m}} + \varphi_{\overline{\mathbf{h+k+l+m}}}$$

may be considered as the sum of three suitable triplets or the sum of a triplet and a quartet, *i.e.*

$$\Phi = (\varphi_{\mathbf{h}} + \varphi_{\mathbf{k}} - \varphi_{\mathbf{h+k}}) + (\varphi_{\mathbf{l}} + \varphi_{\mathbf{m}} - \varphi_{\mathbf{l+m}}) + (\varphi_{\mathbf{h+k}} + \varphi_{\mathbf{l+m}} + \varphi_{\overline{\mathbf{h+k+l+m}}})$$

or

$$\Phi = (\varphi_{\mathbf{h}} + \varphi_{\mathbf{k}} - \varphi_{\mathbf{h+k}}) + (\varphi_{\mathbf{l}} + \varphi_{\mathbf{m}} + \varphi_{\overline{\mathbf{h+k+l+m}}} + \varphi_{\mathbf{h+k}}).$$

It depends primarily on 15 magnitudes: the five *basis magnitudes*

$$R_{\mathbf{h}}, \quad R_{\mathbf{k}}, \quad R_{\mathbf{l}}, \quad R_{\mathbf{m}}, \quad R_{\mathbf{h+k+l+m}},$$

and the ten *cross magnitudes*

$$R_{\mathbf{h+k}}, \quad R_{\mathbf{h+l}}, \quad R_{\mathbf{h+m}}, \quad R_{\mathbf{k+l+m}}, \quad R_{\mathbf{k+l}},$$
$$R_{\mathbf{k+m}}, \quad R_{\mathbf{h+l+m}}, \quad R_{\mathbf{l+m}}, \quad R_{\mathbf{h+k+m}}, \quad R_{\mathbf{h+k+l}}.$$

In the following we will denote

$$R_1 = R_{\mathbf{h}}, \quad R_2 = R_{\mathbf{k}}, \ldots, \quad R_{15} = R_{\mathbf{h+k+l}}.$$

Conditional distributions of Φ in $P1$ and $P\bar{1}$ given the 15 magnitudes have been derived by several authors and allow in favourable circumstances in ncs. space groups the quintets having Φ near 0 or near π or near $\pm\pi/2$ to be identified. Among others, we remember:

(*a*) the semi-empirical expression for $P_{15}(\Phi)$ suggested by Van der Putten & Schenk (1977):

$$P(\Phi|\ldots) \simeq \frac{1}{L}\exp\left[\left(6 - \sum_{j=6}^{15} R_j^2\right) 2C\cos\Phi\right] \prod_{j=6}^{15} I_0(2R_jY_j),$$

where

$$C = N^{-3/2}R_1R_2R_3R_4R_5$$

and Y_j is an expression related to the jth of the ten quartets connected with the quintet Φ;

(*b*) the formula by Fortier & Hauptman (1977), valid in $P\bar{1}$, which is able to predict the sign of a quintet by means of an expression which involves a summation over 1024 sets of signs;

(*c*) the expression by Giacovazzo (1977*d*), according to which

$$P_{15}(\Phi) \simeq [2\pi I_0(G)]^{-1} \exp(G\cos\Phi), \qquad (2.2.5.24)$$

where

$$G = \frac{2C}{1 + 6(N)^{1/2}}\left[\frac{1 + A + B}{1 + D/(2N)}\right] \qquad (2.2.5.25)$$

and where

$$A = \sum_{i=6}^{15} \varepsilon_i,$$

$$B = \varepsilon_6\varepsilon_{13} + \varepsilon_6\varepsilon_{15} + \varepsilon_6\varepsilon_{14} + \varepsilon_7\varepsilon_{11} + \varepsilon_7\varepsilon_{15} + \varepsilon_7\varepsilon_{12} + \varepsilon_8\varepsilon_{10} + \varepsilon_8\varepsilon_{14} + \varepsilon_8\varepsilon_{12} + \varepsilon_{10}\varepsilon_{15} + \varepsilon_{10}\varepsilon_9 + \varepsilon_{11}\varepsilon_{14} + \varepsilon_{11}\varepsilon_9 + \varepsilon_{13}\varepsilon_9 + \varepsilon_{13}\varepsilon_{12},$$

$$D = \varepsilon_1\varepsilon_2\varepsilon_6 + \varepsilon_1\varepsilon_3\varepsilon_7 + \varepsilon_1\varepsilon_4\varepsilon_8 + \varepsilon_1\varepsilon_5\varepsilon_9 + \varepsilon_1\varepsilon_{10}\varepsilon_{15} + \varepsilon_1\varepsilon_{11}\varepsilon_{14} + \varepsilon_1\varepsilon_{13}\varepsilon_{12} + \varepsilon_2\varepsilon_3\varepsilon_{10} + \varepsilon_2\varepsilon_4\varepsilon_{11} + \varepsilon_2\varepsilon_5\varepsilon_{12} + \varepsilon_2\varepsilon_7\varepsilon_{15} + \varepsilon_2\varepsilon_8\varepsilon_{14} + \varepsilon_2\varepsilon_{13}\varepsilon_9 + \varepsilon_3\varepsilon_4\varepsilon_{13} + \varepsilon_3\varepsilon_5\varepsilon_{14} + \varepsilon_3\varepsilon_6\varepsilon_{15} + \varepsilon_3\varepsilon_8\varepsilon_{12} + \varepsilon_3\varepsilon_{11}\varepsilon_9 + \varepsilon_4\varepsilon_5\varepsilon_{15} + \varepsilon_4\varepsilon_6\varepsilon_{14} + \varepsilon_4\varepsilon_7\varepsilon_{12} + \varepsilon_4\varepsilon_{10}\varepsilon_9 + \varepsilon_5\varepsilon_6\varepsilon_{13} + \varepsilon_5\varepsilon_7\varepsilon_{11} + \varepsilon_5\varepsilon_8\varepsilon_{10}.$$

For cs. cases (2.2.5.24) reduces to

$$P^+ \simeq 0.5 + 0.5\tanh(G/2). \qquad (2.2.5.26)$$

Positive or negative quintets may be identified according to whether G is larger or smaller than zero.

If R_i is not measured then (2.2.5.24) and (2.2.5.25) are still valid provided that in (2.2.5.25) $\varepsilon_i = 0$.

If the symmetry is higher than in $P\bar{1}$ then more symmetry-equivalent quintets can exist of the type

$$\psi = \varphi_{\mathbf{h}\boldsymbol{R}_\alpha} + \varphi_{\mathbf{k}\boldsymbol{R}_\beta} + \varphi_{\mathbf{l}\boldsymbol{R}_\gamma} + \varphi_{\mathbf{m}\boldsymbol{R}_\delta} + \varphi_{(\overline{\mathbf{h+k+l+m}})\boldsymbol{R}_\varepsilon},$$

where $\boldsymbol{R}_\alpha, \ldots, \boldsymbol{R}_\varepsilon$ are rotation matrices of the space groups. The set $\{\psi\}$ is called the first representation of Φ. In this case Φ primarily depends on more than 15 magnitudes which all have to be taken into account for a careful estimation of Φ (Giacovazzo, 1980*a*).

A wide use of quintet invariants in direct-methods procedures is prevented for two reasons: (*a*) the large correlation of positive quintet cosines with positive triplets; (*b*) the large computing time necessary for their estimation [quintets are phase relationships of order $1/(N\sqrt{N})$, so a large number of quintets have to be estimated in order to pick up a sufficient percentage of reliable ones].

2.2.5.7. Determinantal formulae

In a crystal structure with N identical atoms the joint probability distribution of n normalized s.f.'s $E_{\mathbf{h}_1+\mathbf{k}}, E_{\mathbf{h}_2+\mathbf{k}}, \ldots, E_{\mathbf{h}_n+\mathbf{k}}$ under the following conditions:

(*a*) the structure is kept fixed whereas $\mathbf{k}$ is the primitive random variable;

(*b*) $E_{\mathbf{h}_i-\mathbf{h}_j}$, $i, j = 1, \ldots, n$, have values which are known *a priori*;

is given (Tsoucaris, 1970) [see also Castellano *et al.* (1973) and Heinermann *et al.* (1979)] by

$$P(E_1, E_2, \ldots, E_n) = (2\pi)^{-n/2} D_n^{-1/2} \exp(-\tfrac{1}{2}Q_n) \qquad (2.2.5.27)$$

for cs. structures and

$$P(E_1, E_2, \ldots, E_n) = (2\pi)^{-n} D_n^{-1/2} \exp(-Q_n) \qquad (2.2.5.28)$$

for ncs. structures. In (2.2.5.27) and (2.2.5.28) we have denoted

$$D_n = \lambda, \qquad Q_n = \sum_{p,q=1}^{n} \Lambda_{pq} E_p E_q^*$$
$$E_j = E_{\mathbf{h}_j+\mathbf{k}}, \qquad U_{pq} = U_{\mathbf{h}_p-\mathbf{h}_q}, \qquad j, p, q = 1, \ldots, n.$$

Λ_{pq} is an element of $\boldsymbol{\lambda}^{-1}$, and $\boldsymbol{\lambda}$ is the covariance matrix with elements

$$\langle E_{\mathbf{h}_p+\mathbf{k}} E_{\mathbf{h}_q+\mathbf{k}} \rangle = U_{\mathbf{h}_p-\mathbf{h}_q}$$

$$\boldsymbol{\lambda} = \begin{vmatrix} 1 & U_{12} & \dots & U_{1q} & \dots & U_{1n} \\ U_{21} & 1 & \dots & U_{2q} & \dots & U_{2n} \\ \vdots & \vdots & \ddots & \vdots & \ddots & \vdots \\ U_{p1} & U_{p2} & \dots & U_{pq} & \dots & U_{pn} \\ \vdots & \vdots & \ddots & \vdots & \ddots & \vdots \\ U_{n1} & U_{n2} & \dots & U_{nq} & \dots & 1 \end{vmatrix}.$$

λ is a K–H determinant: therefore $D_n \geq 0$. Let us call

$$\Delta_{n+1} = \frac{1}{N} \begin{vmatrix} 1 & U_{12} & \dots & U_{1n} & E_{\mathbf{h}_1+\mathbf{k}} \\ U_{21} & 1 & \dots & U_{2n} & E_{\mathbf{h}_2+\mathbf{k}} \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ U_{n1} & U_{n2} & \dots & 1 & E_{\mathbf{h}_n+\mathbf{k}} \\ E_{-\mathbf{h}_1-\mathbf{k}} & E_{-\mathbf{h}_2-\mathbf{k}} & \dots & E_{-\mathbf{h}_n-\mathbf{k}} & N \end{vmatrix};$$

the K–H determinant obtained by adding to $\boldsymbol{\lambda}$ the last column and line formed by $E_1, E_2, \dots, E_n$, and $E_1^*, E_2^*, \dots, E_n^*$, respectively. Then (2.2.5.27) and (2.2.5.28) may be written

$$P(E_1, E_2, \dots, E_n) = (2\pi)^{-n/2} D_n^{-1/2} \exp\left[N \frac{\Delta_{n+1} - D_n}{2D_n}\right] \quad (2.2.5.29)$$

and

$$P(E_1, E_2, \dots, E_n) = (2\pi)^{-n} D_n^{-1/2} \exp\left[N \frac{\Delta_{n+1} - D_n}{D_n}\right], \quad (2.2.5.30)$$

respectively. Because D_n is a constant, the maximum values of the conditional joint probabilities (2.2.5.29) and (2.2.5.30) are obtained when Δ_{n+1} is a maximum. Thus the *maximum determinant rule* may be stated (Tsoucaris, 1970; Lajzérowicz & Lajzérowicz, 1966): among all sets of phases which are compatible with the inequality

$$\Delta_{n+1}(E_1, E_2, \dots, E_n) \geq 0$$

the most probable one is that which leads to a maximum value of Δ_{n+1}.

If only one phase, *i.e.* φ_q, is unknown whereas all other phases and moduli are known then (de Rango *et al.*, 1974; Podjarny *et al.*, 1976) for cs. crystals

$$P^{\pm}(E_q) \simeq 0.5 + 0.5 \tanh \left\{ \pm |E_q| \sum_{\substack{p=1 \\ p \neq q}}^{n} \Lambda_{pq} E_p \right\}, \quad (2.2.5.31)$$

and for ncs. crystals

$$P(\varphi_q) = [2\pi I_0(G_q)]^{-1} \exp\{G_q \cos(\varphi_q - \theta_q)\}, \quad (2.2.5.32)$$

where

$$G_q \exp(i\theta_q) = 2|E_q| \sum_{p \neq q=1}^{n} \Lambda_{pq} E_p.$$

Equations (2.2.5.31) and (2.2.5.32) generalize (2.2.5.11) and (2.2.5.7), respectively, and reduce to them for $n = 3$. Fourth-order determinantal formulae estimating triplet invariants in cs. and ncs. crystals, and making use of the entire data set, have recently been secured (Karle, 1979, 1980*a*).

Advantages, limitations and applications of determinantal formulae can be found in the literature (Heinermann *et al.*, 1979; de Rango *et al.*, 1975, 1985). Taylor *et al.* (1978) combined K–H determinants with a magic-integer approach. The computing time, however, was larger than that required by standard computing techniques. The use of K–H matrices has been made faster and more effective by de Gelder *et al.* (1990) (see also de Gelder, 1992). They developed a phasing procedure (*CRUNCH*) which uses random phases as starting points for the maximization of the K–H determinants.

2.2.5.8. Algebraic relationships for structure seminvariants

According to the representations method (Giacovazzo, 1977*a*, 1980*a*,*b*):

(i) any s.s. Φ may be estimated *via* one or more s.i.'s $\{\psi\}$, whose values differ from Φ by a constant arising because of symmetry;

(ii) two types of s.s.'s exist, first-rank and second-rank s.s.'s, with different algebraic properties:

(iii) conditions characterizing s.s.'s of first rank for any space group may be expressed in terms of seminvariant moduli and seminvariantly associated vectors. For example, for all the space groups with point group 422 [Hauptman–Karle group $(h + k, l)$ $P(2, 2)$] the one-phase s.s.'s of first rank are characterized by

$$(h, k, l) \equiv 0 \bmod (2, 2, 0) \text{ or } (2, 0, 2) \text{ or } (0, 2, 2)$$
$$(h \pm k, l) \equiv 0 \bmod (0, 2) \text{ or } (2, 0).$$

The more general expressions for the s.s.'s of first rank are

(*a*) $\Phi = \varphi_{\mathbf{u}} = \varphi_{\mathbf{h}(\boldsymbol{I}-\boldsymbol{R}_\alpha)}$ for one-phase s.s.'s;

(*b*) $\Phi = \varphi_{\mathbf{u}_1} + \varphi_{\mathbf{u}_2} = \varphi_{\mathbf{h}_1-\mathbf{h}_2\boldsymbol{R}_\beta} + \varphi_{\mathbf{h}_2-\mathbf{h}_1\boldsymbol{R}_\alpha}$ for two-phase s.s.'s;

(*c*) $\Phi = \varphi_{\mathbf{u}_1} + \varphi_{\mathbf{u}_2} + \varphi_{\mathbf{u}_3} = \varphi_{\mathbf{h}_1-\mathbf{h}_2\boldsymbol{R}_\beta} + \varphi_{\mathbf{h}_2-\mathbf{h}_3\boldsymbol{R}_\gamma} + \varphi_{\mathbf{h}_3-\mathbf{h}_1\boldsymbol{R}_\alpha}$ for three-phase s.s.'s;

(*d*) $\Phi = \varphi_{\mathbf{u}_1} + \varphi_{\mathbf{u}_2} + \varphi_{\mathbf{u}_3} + \varphi_{\mathbf{u}_4} = \varphi_{\mathbf{h}_1-\mathbf{h}_2\boldsymbol{R}_\beta} + \varphi_{\mathbf{h}_2-\mathbf{h}_3\boldsymbol{R}_\gamma} + \varphi_{\mathbf{h}_3-\mathbf{h}_4\boldsymbol{R}_\delta} + \varphi_{\mathbf{h}_4-\mathbf{h}_1\boldsymbol{R}_\alpha}$

for four-phase s.s.'s; *etc.*

In other words:

(*a*) $\varphi_{\mathbf{u}}$ is an s.s. of first rank if at least one $\mathbf{h}$ and at least one rotation matrix $\boldsymbol{R}_\alpha$ exist such that $\mathbf{u} = \mathbf{h}(\boldsymbol{I} - \boldsymbol{R}_\alpha)$. $\varphi_{\mathbf{u}}$ may be estimated *via* the special triplet invariants

$$\{\psi\} = \varphi_{\mathbf{u}} - \varphi_{\mathbf{h}} + \varphi_{\mathbf{h}\boldsymbol{R}_\alpha}. \quad (2.2.5.33)$$

The set $\{\psi\}$ is called the *first representation* of $\varphi_{\mathbf{u}}$.

(*b*) $\Phi = \varphi_{\mathbf{u}_1} + \varphi_{\mathbf{u}_2}$ is an s.s. of first rank if at least two vectors $\mathbf{h}_1$ and $\mathbf{h}_2$ and two rotation matrices $\boldsymbol{R}_\alpha$ and $\boldsymbol{R}_\beta$ exist such that

$$\begin{cases} \mathbf{u}_1 = \mathbf{h}_1 - \mathbf{h}_2\boldsymbol{R}_\beta \\ \mathbf{u}_2 = \mathbf{h}_2 - \mathbf{h}_1\boldsymbol{R}_\alpha. \end{cases} \quad (2.2.5.34)$$

Φ may then be estimated *via* the special quartet invariants

$$\{\psi\} = \varphi_{\mathbf{u}_1\boldsymbol{R}_\alpha} + \varphi_{\mathbf{u}_2} - \varphi_{\mathbf{h}_2} + \varphi_{\mathbf{h}_2\boldsymbol{R}_\beta\boldsymbol{R}_\alpha} \quad (2.2.5.35a)$$

and

$$\{\psi\} = \{\varphi_{\mathbf{u}_1} + \varphi_{\mathbf{u}_2\boldsymbol{R}_\beta} - \varphi_{\mathbf{h}_1} + \varphi_{\mathbf{h}_1\boldsymbol{R}_\alpha\boldsymbol{R}_\beta}\}. \quad (2.2.5.35b)$$

For example, $\Phi = \varphi_{123} + \varphi_{\bar{7}\bar{2}\bar{5}}$ in $P2_1$ may be estimated *via*

$$\{\psi\} = \varphi_{123} + \varphi_{\bar{7}\bar{2}\bar{5}} - \varphi_{\bar{3}K\bar{1}} + \varphi_{3K1}$$

and

$$\{\psi\} = \varphi_{123} + \varphi_{7\bar{2}5} - \varphi_{4K4} + \varphi_{\bar{4}K\bar{4}},$$

where K is a free index.

The set of special quartets (2.2.5.35*a*) and (2.2.5.35*b*) constitutes the *first representations* of Φ.

Structure seminvariants of the second rank can be characterized as follows: suppose that, for a given seminvariant Φ, it is not possible to find a vectorial index $\mathbf{h}$ and a rotation matrix $\boldsymbol{R}_\alpha$ such that $\Phi - \varphi_{\mathbf{h}} + \varphi_{\mathbf{h}\boldsymbol{R}_\alpha}$ is a structure invariant. Then Φ is a structure

seminvariant of the second rank and a set of structure invariants ψ can certainly be formed, of type

$$\{\psi\} = \Phi + \varphi_{\mathbf{h}\boldsymbol{R}_p} - \varphi_{\mathbf{h}\boldsymbol{R}_q} + \varphi_{\mathbf{l}\boldsymbol{R}_i} - \varphi_{\mathbf{l}\boldsymbol{R}_j},$$

by means of suitable indices $\mathbf{h}$ and $\mathbf{l}$ and rotation matrices $\boldsymbol{R}_p$, $\boldsymbol{R}_q$, $\boldsymbol{R}_i$ and $\boldsymbol{R}_j$. As an example, for symmetry class 222, φ_{240} or φ_{024} or φ_{204} are s.s.'s of the first rank while φ_{246} is an s.s. of the second rank.

The procedure may easily be generalized to s.s.'s of any order of the first and of the second rank. So far only the role of one-phase and two-phase s.s.'s of the first rank in direct procedures is well documented (see references quoted in Sections 2.2.5.9 and 2.2.5.10).

2.2.5.9. Formulae estimating one-phase structure seminvariants of the first rank

Let $E_{\mathbf{H}}$ be our one-phase s.s. of the first rank, where

$$\mathbf{H} = \mathbf{h}(\boldsymbol{I} - \boldsymbol{R}_n). \tag{2.2.5.36}$$

In general, more than one rotation matrix $\boldsymbol{R}_n$ and more than one vector $\mathbf{h}$ are compatible with (2.2.5.36). The set of special triplets

$$\{\psi\} = \{\varphi_{\mathbf{H}} - \varphi_{\mathbf{h}} + \varphi_{\mathbf{h}\boldsymbol{R}_n}\}$$

is the first representation of $E_{\mathbf{H}}$. In cs. space groups the probability that $E_{\mathbf{H}} > 0$, given $|E_{\mathbf{H}}|$ and the set $\{|E_{\mathbf{h}}|\}$, may be estimated (Hauptman & Karle, 1953; Naya *et al.*, 1964; Cochran & Woolfson, 1955) by

$$P^+(E_{\mathbf{H}}) \simeq 0.5 + 0.5 \tanh \sum_{\mathbf{h},\,n} G_{\mathbf{h},\,n}(-1)^{2\mathbf{h}\cdot\mathbf{T}_n}, \tag{2.2.5.37}$$

where

$$G_{\mathbf{h},\,n} = |E_{\mathbf{H}}|\varepsilon_{\mathbf{h}}/(2\sqrt{N}), \text{ and } \varepsilon = |E|^2 - 1.$$

In (2.2.5.37), the summation over n goes within the set of matrices $\boldsymbol{R}_n$ for which (2.2.5.35*a*,*b*) is compatible, and $\mathbf{h}$ varies within the set of vectors which satisfy (2.2.5.36) for each $\boldsymbol{R}_n$. Equation (2.2.5.36) is actually a generalized way of writing the so-called $\sum_1$ relationships (Hauptman & Karle, 1953).

If $\varphi_{\mathbf{H}}$ is a phase restricted by symmetry to $\theta_{\mathbf{H}}$ and $\theta_{\mathbf{H}} + \pi$ in an ncs. space group then (Giacovazzo, 1978)

$$P(\varphi_{\mathbf{H}} = \theta_{\mathbf{H}}) \simeq 0.5 + 0.5 \tanh \left\{ \sum_{\mathbf{h},\,n} G_{\mathbf{h},\,n} \cos(\theta_{\mathbf{H}} - 2\pi\mathbf{h}\cdot\mathbf{T}_n) \right\}. \tag{2.2.5.38}$$

If $\varphi_{\mathbf{H}}$ is a general phase then $\varphi_{\mathbf{H}}$ is distributed according to

$$P(\varphi_{\mathbf{H}}) \simeq \frac{1}{L} \exp\{\alpha \cos(\varphi_{\mathbf{H}} - \theta_{\mathbf{H}})\},$$

where

$$\tan\theta_{\mathbf{H}} = \frac{\left(\sum_{\mathbf{h},\,n} G_{\mathbf{h},\,n} \sin 2\pi\mathbf{h}\cdot\mathbf{T}_n\right)}{\left(\sum_{\mathbf{h},\,n} G_{\mathbf{h},\,n} \cos 2\pi\mathbf{h}\cdot\mathbf{T}_n\right)} \tag{2.2.5.39}$$

with a reliability measured by

$$\alpha = \left\{ \left(\sum_{\mathbf{h},\,n} G_{\mathbf{h},\,n} \sin 2\pi\mathbf{h}\cdot\mathbf{T}_n \right)^2 + \left(\sum_{\mathbf{h},\,n} G_{\mathbf{h},\,n} \cos 2\pi\mathbf{h}\cdot\mathbf{T}_n \right)^2 \right\}^{1/2}.$$

The second representation of $\varphi_{\mathbf{H}}$ is the set of special quintets

$$\{\psi\} = \{\varphi_{\mathbf{H}} - \varphi_{\mathbf{h}} + \varphi_{\mathbf{h}\boldsymbol{R}_n} + \varphi_{\mathbf{k}\boldsymbol{R}_j} - \varphi_{\mathbf{k}\boldsymbol{R}_j}\} \tag{2.2.5.40}$$

provided that $\mathbf{h}$ and $\boldsymbol{R}_n$ vary over the vectors and matrices for which (2.2.5.36) is compatible, $\mathbf{k}$ over the asymmetric region of the reciprocal space, and $\boldsymbol{R}_j$ over the rotation matrices in the space group. Formulae estimating $\varphi_{\mathbf{H}}$ *via* the second representation in all the space groups [all the base and cross magnitudes of the quintets (2.2.5.40) now constitute the *a priori* information] have been secured (Giacovazzo, 1978; Cascarano & Giacovazzo, 1983; Cascarano, Giacovazzo, Calabrese *et al.*, 1984). Such formulae contain, besides the contribution of order $N^{-1/2}$ provided by the first representation, a supplementary (not negligible) contribution of order $N^{-3/2}$ arising from quintets.

Denoting

$$E_1 = E_{\mathbf{H}},\ E_2 = E_{\mathbf{h}},\ E_3 = E_{\mathbf{k}},$$
$$E_{4,\,j} = E_{\mathbf{h}+\mathbf{k}\boldsymbol{R}_j},\ E_{5,\,j} = E_{\mathbf{H}+\mathbf{k}\boldsymbol{R}_j},$$

formulae (2.2.5.37), (2.2.5.38), (2.2.5.39) still hold provided that $\sum_{\mathbf{h},\,n} G_{\mathbf{h},\,n}$ is replaced by

$$\sum_{\mathbf{h},\,n} G_{\mathbf{h},\,n} + \sum_{\mathbf{h},\,\mathbf{k},\,n}{}' \frac{|E_{\mathbf{H}}|}{2N^{3/2}} \frac{A_{\mathbf{h},\,\mathbf{k},\,n}}{1 + B_{\mathbf{h},\,\mathbf{k},\,n}},$$

where

$$A_{\mathbf{h},\,\mathbf{k},\,n} = \left[(2|E_2|^2 - 1)\varepsilon_3 \left(\sum_{\substack{\boldsymbol{R}_i = \boldsymbol{R}_j \\ \boldsymbol{R}_j + \boldsymbol{R}_i\boldsymbol{R}_n = 0}} \varepsilon_{4,\,i}\varepsilon_{5,\,j} + \sum_{\substack{\boldsymbol{R}_j = \boldsymbol{R}_i\boldsymbol{R}_n \\ \boldsymbol{R}_i = \boldsymbol{R}_j\boldsymbol{R}_n}} \varepsilon_{4,\,i}\varepsilon_{4,\,j} \right) - \frac{\varepsilon_3}{2} \sum_{j=1}^{m} \varepsilon_{4,\,j} - \tfrac{1}{2} \sum_{\substack{\boldsymbol{R}_j = \boldsymbol{R}_i \\ \boldsymbol{R}_j + \boldsymbol{R}_i\boldsymbol{R}_n = 0}} \varepsilon_{4,\,i}\varepsilon_{5,\,j} \right] \Big/ N,$$

$$B_{\mathbf{h},\,\mathbf{k},\,n} = \left[\varepsilon_1\varepsilon_3 \sum_{j=1}^{m} \varepsilon_{5,\,j} + \varepsilon_1 \sum_{\substack{\boldsymbol{R}_j = \boldsymbol{R}_i\boldsymbol{R}_n \\ \boldsymbol{R}_i = \boldsymbol{R}_j\boldsymbol{R}_n}} \varepsilon_{4,\,i}\varepsilon_{4,\,j} + \varepsilon_2\varepsilon_3 \sum_{j=1}^{m} \varepsilon_{4,\,j} + \varepsilon_2 \sum_{\substack{\boldsymbol{R}_j = \boldsymbol{R}_i \\ \boldsymbol{R}_j + \boldsymbol{R}_i\boldsymbol{R}_n = 0}} \varepsilon_{4,\,i}\varepsilon_{5,\,j} + \tfrac{1}{4}\varepsilon_1 H_4(E_2) \right] \Big/ (2N).$$

m is the number of symmetry operators and $H_4(E) = E^4 - 6E^2 + 3$ is the Hermite polynomial of order four.

$B_{\mathbf{h},\,\mathbf{k},\,n}$ is assumed to be zero if it is computed negative. The prime to the summation warns the reader that precautions have to be taken in order to avoid duplication in the contributions.

2.2.5.10. Formulae estimating two-phase structure seminvariants of the first rank

Two-phase s.s.'s of the first rank were first evaluated in some cs. space groups by the method of coincidence by Grant *et al.* (1957); the idea was extended to ncs. space groups by Debaerdemaeker & Woolfson (1972), and in a more general way by Giacovazzo (1977*e*,*f*).

The technique was based on the combination of the two triplets

$$\varphi_{\mathbf{h}_1} + \varphi_{\mathbf{h}_2} \simeq \varphi_{\mathbf{h}_1+\mathbf{h}_2}$$
$$\varphi_{\mathbf{h}_1} + \varphi_{\mathbf{h}_2\boldsymbol{R}} \simeq \varphi_{\mathbf{h}_1+\mathbf{h}_2\boldsymbol{R}},$$

which, subtracted from one another, give

$$\varphi_{\mathbf{h}_1+\mathbf{h}_2\boldsymbol{R}} - \varphi_{\mathbf{h}_1+\mathbf{h}_2} \simeq \varphi_{\mathbf{h}_2\boldsymbol{R}} - \varphi_{\mathbf{h}_2} \simeq -2\pi\mathbf{h}\cdot\mathbf{T}.$$

If all four $|E|$'s are sufficiently large, an estimate of the two-phase seminvariant $\varphi_{\mathbf{h}_1+\mathbf{h}_2\boldsymbol{R}} - \varphi_{\mathbf{h}_1+\mathbf{h}_2}$ is available.

Probability distributions valid in $P2_1$ according to the neighbourhood principle have been given by Hauptman & Green (1978). Finally, the theory of representations was combined by Giacovazzo (1979*a*) with the joint probability distribution method in order to estimate two-phase s.s.'s in all the space groups.

According to representation theory, the problem is that of evaluating $\Phi = \varphi_{\mathbf{u}_1} + \varphi_{\mathbf{u}_2}$ *via* the special quartets (2.2.5.35*a*) and (2.2.5.35*b*). Thus, contributions of order N^{-1} will appear in the probabilistic formulae, which will be functions of the basis and of the cross magnitudes of the quartets (2.2.5.35) . Since more pairs of matrices $\boldsymbol{R}_\alpha$ and $\boldsymbol{R}_\beta$ can be compatible with (2.2.5.34), and for each pair $(\boldsymbol{R}_\alpha, \boldsymbol{R}_\beta)$ more pairs of vectors $\mathbf{h}_1$ and $\mathbf{h}_2$ may satisfy (2.2.5.34), several quartets can in general be exploited for estimating Φ. The simplest case occurs in $P\bar{1}$ where the two quartets (2.2.5.35) suggest the calculation of the six-variate distribution function $(\mathbf{u}_1 = \mathbf{h}_1 + \mathbf{h}_2, \mathbf{u}_2 = \mathbf{h}_1 - \mathbf{h}_2)$

$$P(E_{\mathbf{h}_1}, E_{\mathbf{h}_2}, E_{\mathbf{h}_1+\mathbf{h}_2}, E_{\mathbf{h}_1-\mathbf{h}_2}, E_{2\mathbf{h}_1}, E_{2\mathbf{h}_2})$$

which leads to the probability formula

$$P^+ \simeq 0.5 + 0.5 \tanh\left(\frac{|E_{\mathbf{h}_1+\mathbf{h}_2} E_{\mathbf{h}_1-\mathbf{h}_2}|}{2N} \cdot \frac{A}{1+B}\right),$$

where P^+ is the probability that the product $E_{\mathbf{h}_1+\mathbf{h}_2} E_{\mathbf{h}_1-\mathbf{h}_2}$ is positive, and

$$\begin{aligned} A &= \varepsilon_{\mathbf{h}_1} + \varepsilon_{\mathbf{h}_2} + 2\varepsilon_{\mathbf{h}_1}\varepsilon_{\mathbf{h}_2} + \varepsilon_{\mathbf{h}_1}\varepsilon_{2\mathbf{h}_1} + \varepsilon_{\mathbf{h}_2}\varepsilon_{2\mathbf{h}_2} \\ B &= (\varepsilon_{\mathbf{h}_1}\varepsilon_{\mathbf{h}_2}\varepsilon_{\mathbf{u}_1} + \varepsilon_{\mathbf{h}_1}\varepsilon_{\mathbf{h}_2}\varepsilon_{\mathbf{u}_2} \\ &\quad + \varepsilon_{\mathbf{u}_1}\varepsilon_{\mathbf{u}_2}\varepsilon_{2\mathbf{h}_1} + \varepsilon_{\mathbf{u}_1}\varepsilon_{\mathbf{u}_2}\varepsilon_{2\mathbf{h}_2})/(2N). \end{aligned}$$

It may be seen that in favourable cases $P^+ < 0.5$.

For the sake of brevity, the probabilistic formulae for the general case are not given and the reader is referred to the original papers.

2.2.6. Direct methods in real and reciprocal space: Sayre's equation

The statistical treatment suggested by Wilson for scaling observed intensities corresponds, in direct space, to the origin peak of the Patterson function, so it is not surprising that a general correspondence exists between probabilistic formulation in reciprocal space and algebraic properties in direct space.

For a structure containing atoms which are fully resolved from one another, the operation of raising $\rho(\mathbf{r})$ to the nth power retains the condition of resolved atoms but changes the shape of each atom. Let

$$\rho(\mathbf{r}) = \sum_{j=1}^{N} \rho_j(\mathbf{r} - \mathbf{r}_j),$$

where $\rho_j(\mathbf{r})$ is an atomic function and $\mathbf{r}_j$ is the coordinate of the 'centre' of the atom. Then the Fourier transform of the electron density can be written as

$$\begin{aligned} F_{\mathbf{h}} &= \sum_{j=1}^{N} \int_V \rho_j(\mathbf{r} - \mathbf{r}_j) \exp(2\pi i \mathbf{h}\cdot\mathbf{r})\, \mathrm{d}V \\ &= \sum_{j=1}^{N} f_j \exp(2\pi i \mathbf{h}\cdot\mathbf{r}_j). \end{aligned} \tag{2.2.6.1}$$

If the atoms do not overlap

$$\rho^n(\mathbf{r}) = \left[\sum_{j=1}^{N} \rho_j(\mathbf{r} - \mathbf{r}_j)\right]^n \simeq \sum_{j=1}^{N} \rho_j^n(\mathbf{r} - \mathbf{r}_j)$$

and its Fourier transform gives

$$\begin{aligned} {}_nF_{\mathbf{h}} &= \int_V \rho^n(\mathbf{r}) \exp(2\pi i \mathbf{h}\cdot\mathbf{r})\, \mathrm{d}V \\ &= \sum_{j=1}^{N} {}_nf_j \exp(2\pi i \mathbf{h}\cdot\mathbf{r}_j). \end{aligned} \tag{2.2.6.2}$$

${}_nf_j$ is the scattering factor for the jth peak of $\rho^n(\mathbf{r})$:

$${}_nf_j(\mathbf{h}) = \int_V \rho_j^n(\mathbf{r}) \exp(2\pi i \mathbf{h}\cdot\mathbf{r})\, \mathrm{d}\mathbf{r}.$$

We now introduce the condition that all atoms are equal, so that $f_j \equiv f$ and ${}_nf_j \equiv {}_nf$ for any j. From (2.2.6.1) and (2.2.6.2) we may write

$$F_{\mathbf{h}} = \frac{f}{{}_nf} {}_nF_{\mathbf{h}} = \theta_n \, {}_nF_{\mathbf{h}}, \tag{2.2.6.3}$$

where θ_n is a function which corrects for the difference of shape of the atoms with electron distributions $\rho(\mathbf{r})$ and $\rho^n(\mathbf{r})$. Since

$$\begin{aligned} \rho^n(\mathbf{r}) &= \rho(\mathbf{r}) \ldots \rho(\mathbf{r}) \\ &= \frac{1}{V^n} \sum_{\substack{\mathbf{h}_1,\ldots,\mathbf{h}_n \\ -\infty}}^{+\infty} F_{\mathbf{h}_1} \ldots F_{\mathbf{h}_n} \exp[-2\pi i(\mathbf{h}_1 + \ldots + \mathbf{h}_n)\cdot\mathbf{r}], \end{aligned}$$

the Fourier transform of both sides gives

$$\begin{aligned} {}_nF_{\mathbf{h}} &= \frac{1}{V^n} \sum_{\substack{\mathbf{h}_1,\ldots,\mathbf{h}_n \\ -\infty}}^{+\infty} F_{\mathbf{h}_1} \ldots F_{\mathbf{h}_n} \int_V \exp[2\pi i(\mathbf{h} - \mathbf{h}_1 - \ldots - \mathbf{h}_n)\cdot\mathbf{r}]\, \mathrm{d}V \\ &= \frac{1}{V^{n-1}} \sum_{\substack{\mathbf{h}_1,\ldots,\mathbf{h}_{n-1} \\ -\infty}}^{+\infty} F_{\mathbf{h}_1} F_{\mathbf{h}_2} \ldots F_{\mathbf{h}-\mathbf{h}_1-\mathbf{h}_2-\ldots-\mathbf{h}_{n-1}}, \end{aligned}$$

from which the following relation arises:

$$F_{\mathbf{h}} = \theta_n \frac{1}{V^{n-1}} \sum_{\substack{\mathbf{h}_1,\ldots,\mathbf{h}_{n-1} \\ -\infty}}^{+\infty} F_{\mathbf{h}_1} F_{\mathbf{h}_2} \ldots F_{\mathbf{h}-\mathbf{h}_1-\mathbf{h}_2-\ldots-\mathbf{h}_{n-1}}. \tag{2.2.6.4}$$

For $n = 2$, equation (2.2.6.4) reduces to Sayre's (1952) equation [but see also Hughes (1953)]

$$F_{\mathbf{h}} = \theta_2 \frac{1}{V} \sum_{\mathbf{k}} F_{\mathbf{k}} F_{\mathbf{h}-\mathbf{k}}. \tag{2.2.6.5}$$

If the structure contains resolved isotropic atoms of two types, P and Q, it is impossible to find a factor θ_2 such that the relation $F_{\mathbf{h}} = \theta_2 \, {}_2F_{\mathbf{h}}$ holds, since this would imply values of θ_2 such that $({}_2f)_P = \theta_2(f)_P$ and $({}_2f)_Q = \theta_2(f)_Q$ simultaneously. However, the following relationship can be stated (Woolfson, 1958):

$$F_{\mathbf{h}} = \frac{A_s}{V} \sum_{\mathbf{k}} F_{\mathbf{k}} F_{\mathbf{h}-\mathbf{k}} + \frac{B_s}{V^2} \sum_{\mathbf{k},\mathbf{l}} F_{\mathbf{k}} F_{\mathbf{l}} F_{\mathbf{h}-\mathbf{k}-\mathbf{l}}, \tag{2.2.6.6}$$

where A_s and B_s are adjustable parameters of $(\sin\theta)/\lambda$. Equation (2.2.6.6) can easily be generalized to the case of structures containing resolved atoms of more than two types (von Eller, 1973).

Besides the algebraic properties of the electron density, Patterson methods also can be developed so that they provide phase indications. For example, it is possible to find the reciprocal counterpart of the function

$$P_n(\mathbf{u}_1, \mathbf{u}_2, \ldots, \mathbf{u}_n) = \int_V \rho(\mathbf{r})\rho(\mathbf{r}+\mathbf{u}_1)\ldots\rho(\mathbf{r}+\mathbf{u}_n)\, \mathrm{d}V. \tag{2.2.6.7}$$

For $n = 1$ the function (2.2.6.7) coincides with the usual Patterson function $P(\mathbf{u})$; for $n = 2$, (2.2.6.7) reduces to the double Patterson function $P_2(\mathbf{u}_1, \mathbf{u}_2)$ introduced by Sayre (1953). Expansion of $P_2(\mathbf{u}_1, \mathbf{u}_2)$ as a Fourier series yields

$$P_2(\mathbf{u}_1, \mathbf{u}_2) = \frac{1}{V^2} \sum_{\mathbf{h}_1, \mathbf{h}_2} E_{\mathbf{h}_1} E_{\mathbf{h}_2} E_{\mathbf{h}_3} \exp[-2\pi i(\mathbf{h}_1 \cdot \mathbf{u}_1 + \mathbf{h}_2 \cdot \mathbf{u}_2)]. \tag{2.2.6.8}$$

Vice versa, the value of a triplet invariant may be considered as the Fourier transform of the double Patterson.

Among the main results relating direct- and reciprocal-space properties it may be remembered:

(*a*) from the properties of $P_2(\mathbf{u}_1, \mathbf{u}_2)$ the following relationship may be obtained (Vaughan, 1958)

$$E_{\mathbf{h}_1} E_{\mathbf{h}_2} E_{\mathbf{h}_1+\mathbf{h}_2} - N^{-3/2} \simeq A_1 \langle (|E_{\mathbf{k}}|^2 - 1)(|E_{\mathbf{h}_1+\mathbf{k}}|^2 - 1)(|E_{-\mathbf{h}_2+\mathbf{k}}|^2 - 1) \rangle_{\mathbf{k}} - B_1,$$

which is clearly related to (2.2.5.12);

(*b*) the zero points in the Patterson function provide information about the value of a triplet invariant (Anzenhofer & Hoppe, 1962; Allegra, 1979);

(*c*) the Hoppe sections (Hoppe, 1963) of the double Patterson provide useful information for determining the triplet signs (Krabbendam & Kroon, 1971; Simonov & Weissberg, 1970);

(*d*) one phase s.s.'s of the first rank can be estimated *via* the Fourier transform of single Harker sections of the Patterson (Ardito *et al.*, 1985), *i.e.*

$$F_{\mathbf{H}} \sim \frac{1}{L} \exp(2\pi i \mathbf{h} \cdot \mathbf{T}_n) \int_{HS(\mathbf{I}, \mathbf{C}_n)} P(\mathbf{u}) \exp(2\pi i \mathbf{h} \cdot \mathbf{u}) \, \mathrm{d}\mathbf{u}, \tag{2.2.6.9}$$

where (see Section 2.2.5.9) $\mathbf{H} = \mathbf{h}(\mathbf{I} - \mathbf{R}_n)$ is the s.s., $\mathbf{u}$ varies over the complete Harker section corresponding to the operator $\mathbf{C}_n$ [in symbols $HS(\mathbf{I}, \mathbf{C}_n)$] and L is a constant which takes into account the dimensionality of the Harker section.

If no spurious peak is on the Harker section, then (2.2.6.9) is an exact relationship. Owing to the finiteness of experimental data and to the presence of spurious peaks, (2.2.6.9) cannot be considered in practice an exact relation: it works better when heavy atoms are in the chemical formula.

More recently (Cascarano, Giacovazzo, Luić *et al.*, 1987), a special least-squares procedure has been proposed for discriminating spurious peaks among those lying on Harker sections and for improving positional and thermal parameters of heavy atoms.

(*e*) translation and rotation functions (see Chapter 2.3), when defined in direct space, always have their counterpart in reciprocal space.

2.2.7. Scheme of procedure for phase determination: the small-molecule case

A traditional procedure for phase assignment may be schematically presented as follows:

Stage 1: *Normalization of s.f.'s.* See Section 2.2.4.

Stage 2: *(Possible) estimation of one-phase s.s.'s.* The computing program recognizes the one-phase s.s.'s and applies the proper formulae (see Section 2.2.5.9).

Each phase is associated with a reliability value, to allow the user to regard as known only those phases with reliability higher than a given threshold.

Stage 3: *Search of the triplets.* The reflections are listed for decreasing $|E|$ values and, related to each $|E|$ value, all possible triplets are reported (this is the so-called $\sum_2$ list). The value $G = 2|E_{\mathbf{h}} E_{\mathbf{k}} E_{\mathbf{h}-\mathbf{k}}|/\sqrt{N}$ is associated with every triplet for an evaluation of its efficiency. Usually reflections with $|E| < E_s$ (E_s may range from 1.2 to 1.6) are omitted from this stage onward.

Stage 4: *Definition of the origin and enantiomorph.* This stage is carried out according to the theory developed in Section 2.2.3. Phases chosen for defining the origin and enantiomorph, one-phase seminvariants estimated at stage 2, and symbolic phases described at stage 5 are the only phases known at the beginning of the phasing procedure. This set of phases is conventionally referred to as the *starting set*, from which iterative application of the tangent formula will derive new phase estimates.

Stage 5: *Assignment of one or more (symbolic or numerical) phases.* In complex structures the number of phases assigned for fixing the origin and the enantiomorph may be inadequate as a basis for further phase determination. Furthermore, only a few one-phase s.s.'s can be determined with sufficient reliability to make them qualify as members of the starting set. Symbolic phases may then be associated with some (generally from 1 to 6) high-modulus reflections (symbolic addition procedures). Iterative application of triplet relations leads to the determination of other phases which, in part, will remain expressed by symbols (Karle & Karle, 1966).

In other procedures (multisolution procedures) each symbol is assigned four phase values in turn: $\pi/4, 3\pi/4, 5\pi/4, 7\pi/4$. If p symbols are used, in at least one of the possible 4^p solutions each symbolic phase has unit probability of being within 45° of its true value, with a mean error of 22.5°.

To find a good starting set a *convergence method* (Germain *et al.*, 1970) is used according to which: (*a*)

$$\langle \alpha_{\mathbf{h}} \rangle = \sum_j G_j I_1(G_j)/I_0(G_j)$$

is calculated for all reflections (j runs over the set of triplets containing $\mathbf{h}$); (*b*) the reflection is found with smallest $\langle \alpha \rangle$ not already in the starting set; it is retained to define the origin if the origin cannot be defined without it; (*c*) the reflection is eliminated if it is not used for origin definition. Its $\langle \alpha \rangle$ is recorded and $\langle \alpha \rangle$ values for other reflections are updated; (*d*) the cycle is repeated from (*b*) until all reflections are eliminated; (*e*) the reflections with the smallest $\langle \alpha \rangle$ at the time of elimination go into the starting set; (*f*) the cycle from (*a*) is repeated until all reflections have been chosen.

Stage 6: *Application of tangent formula.* Phases are determined in reverse order of elimination in the convergence procedure. In order to ensure that poorly determined phases $\varphi_{\mathbf{k}_j}$ and $\varphi_{\mathbf{h}-\mathbf{k}_j}$ have little effect in the determination of other phases a weighted tangent formula is normally used (Germain *et al.*, 1971):

$$\tan \varphi_{\mathbf{h}} = \frac{\sum_j w_{\mathbf{k}_j} w_{\mathbf{h}-\mathbf{k}_j} |E_{\mathbf{k}_j} E_{\mathbf{h}-\mathbf{k}_j}| \sin(\varphi_{\mathbf{k}_j} + \varphi_{\mathbf{h}-\mathbf{k}_j})}{\sum_j w_{\mathbf{k}_j} w_{\mathbf{h}-\mathbf{k}_j} |E_{\mathbf{k}_j} E_{\mathbf{h}-\mathbf{k}_j}| \cos(\varphi_{\mathbf{k}_j} + \varphi_{\mathbf{h}-\mathbf{k}_j})}, \tag{2.2.7.1}$$

where

$$w_{\mathbf{h}} = \min(0.2\alpha, 1).$$

Once a large number of contributions are available in (2.2.7.1) for a given $\varphi_{\mathbf{h}}$, then the value of $\alpha_{\mathbf{h}}$ quickly becomes greater than 5, and so assigns an unrealistic unitary weight to $\varphi_{\mathbf{h}}$. In this respect a different weighting scheme may be proposed (Hull & Irwin, 1978) according to which

$$w = \psi \exp(-x^2) \int_0^x \exp(t^2) \, \mathrm{d}t, \tag{2.2.7.2}$$

where $x = \alpha/\langle \alpha \rangle$ and $\psi = 1.8585$ is a constant chosen so that $w = 1$ when $x = 1$. Except for ψ, the right-hand side of (2.2.7.2) is the Dawson integral which assumes its maximum value at $x = 1$ (see Fig. 2.2.7.1): when $\alpha > \langle \alpha \rangle$ or $\alpha < \langle \alpha \rangle$ then $w < 1$ and so the agreement between α and $\langle \alpha \rangle$ is promoted.

Alternative weighting schemes for the tangent formula are frequently used [for example, see Debaerdemaeker *et al.* (1985)]. In one (Giacovazzo, 1979*b*), the values $\alpha_{\mathbf{k}_j}$ and $\alpha_{\mathbf{h}-\mathbf{k}_j}$ (which are

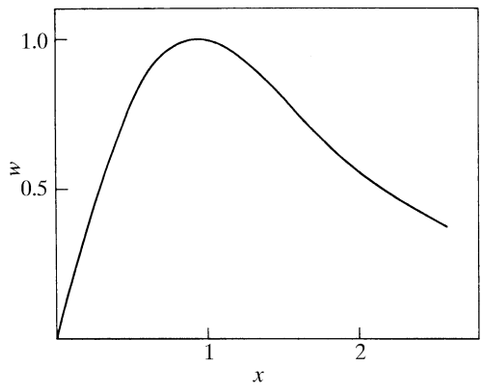

Fig. 2.2.7.1. The form of w as given by (2.2.7.2).

usually available in direct procedures) are considered as additional *a priori* information so that (2.2.7.1) may be replaced by

$$\tan\varphi_{\mathbf{h}} \simeq \frac{\sum_j \beta_j \sin(\varphi_{\mathbf{k}_j} + \varphi_{\mathbf{h}-\mathbf{k}_j})}{\sum_j \beta_j \cos(\varphi_{\mathbf{k}_j} + \varphi_{\mathbf{h}-\mathbf{k}_j})}, \tag{2.2.7.3}$$

where β_j is the solution of the equation

$$D_1(\beta_j) = D_1(G_j) D_1(\alpha_{\mathbf{k}_j}) D_1(\alpha_{\mathbf{h}-\mathbf{k}_j}). \tag{2.2.7.4}$$

In (2.2.7.4),

$$G_j = 2|E_{\mathbf{h}} E_{\mathbf{k}_j} E_{\mathbf{h}-\mathbf{k}_j}|\sqrt{N}$$

or the corresponding second representation parameter, and $D_1(x) = I_1(x)/I_0(x)$ is the ratio of two modified Bessel functions.

In order to promote (in accordance with the aims of Hull and Irwin) the agreement between α and $\langle\alpha\rangle$, the distribution of α may be used (Cascarano, Giacovazzo, Burla *et al.*, 1984; Burla *et al.*, 1987); in particular, the first two moments of the distribution: accordingly,

$$w = \left\{\exp\left[\frac{-(\alpha - \langle\alpha\rangle)^2}{2\sigma_\alpha^2}\right]\right\}^{1/3}$$

may be used, where σ_α^2 is the estimated variance of α.

Stage 7: *Figures of merit.* The correct solution is found among several by means of figures of merit (FOMs) which are expected to be extreme for the correct solution. Largely used are (Germain *et al.*, 1970)

$$(a) \qquad \text{ABSFOM} = \sum_{\mathbf{h}} \alpha_{\mathbf{h}} / \sum_{\mathbf{h}} \langle\alpha_{\mathbf{h}}\rangle,$$

which is expected to be unity for the correct solution.

$$(b) \qquad \text{PSI0} = \frac{\sum_{\mathbf{h}} \left|\sum_{\mathbf{k}} E_{\mathbf{k}} E_{\mathbf{h}-\mathbf{k}}\right|}{\sum_{\mathbf{h}} \left(\sum_{\mathbf{k}} |E_{\mathbf{k}} E_{\mathbf{h}-\mathbf{k}}|^2\right)^{1/2}}.$$

The summation over $\mathbf{k}$ includes (Cochran & Douglas, 1957) the strong $|E|$'s for which phases have been determined, and indices $\mathbf{h}$ correspond to very small $|E_{\mathbf{h}}|$. Minimal values of PSI0 (≤ 1.20) are expected to be associated with the correct solution.

$$(c) \qquad R_\alpha = \frac{\sum_{\mathbf{h}} |\alpha_{\mathbf{h}} - \langle\alpha_{\mathbf{h}}\rangle|}{\sum_{\mathbf{h}} \langle\alpha_{\mathbf{h}}\rangle}.$$

That is, the Karle & Karle (1966) residual between the actual and the estimated α's. After scaling of $\alpha_{\mathbf{h}}$ on $\langle\alpha_{\mathbf{h}}\rangle$ the correct solution should be characterized by the smallest R_α values.

$$(d) \qquad \text{NQEST} = \sum_j G_j \cos\Phi_j,$$

where G is defined by (2.2.5.21) and

$$\Phi = \varphi_{\mathbf{h}} - \varphi_{\mathbf{k}} - \varphi_{\mathbf{l}} - \varphi_{\mathbf{h}-\mathbf{k}-\mathbf{l}}$$

are quartet invariants characterized by large basis magnitudes and small cross magnitudes (De Titta *et al.*, 1975; Giacovazzo, 1976). Since G is expected to be negative as well as $\cos\Phi$, the value of NQEST is expected to be positive and a maximum for the correct solution.

Figures of merit are then combined as

$$\begin{aligned}\text{CFOM} = {} & w_1 \frac{\text{ABSFOM} - \text{ABSFOM}_{\min}}{\text{ABSFOM}_{\max} - \text{ABSFOM}_{\min}} \\ & + w_2 \frac{\text{PSI0}_{\max} - \text{PSI0}}{\text{PSI0}_{\max} - \text{PSI0}_{\min}} \\ & + w_3 \frac{R_{\alpha_{\max}} - R_\alpha}{R_{\alpha_{\max}} - R_{\alpha_{\min}}} \\ & + w_4 \frac{\text{NQEST} - \text{NQEST}_{\min}}{\text{NQEST}_{\max} - \text{NQEST}_{\min}},\end{aligned}$$

where w_i are empirical weights proportional to the confidence of the user in the various FOMs.

Different FOMs are often used by some authors in combination with those described above: for example, enantiomorph triplets and quartets are supplementary FOMs (Van der Putten & Schenk, 1977; Cascarano, Giacovazzo & Viterbo, 1987).

Different schemes of calculating and combining FOMs are also used: one scheme (Cascarano, Giacovazzo & Viterbo, 1987) uses

$$(a1) \qquad \text{CPHASE} = \frac{\sum w_j G_j \cos(\Phi_j - \theta_j) + w_j G_j \cos\Phi_j}{\sum_{\text{s.i.+s.s.}} w_j G_j D_1(G_j)},$$

where the first summation in the numerator extends over symmetry-restricted one-phase and two-phase s.s.'s (see Sections 2.2.5.9 and 2.2.5.10), and the second summation in the numerator extends over negative triplets estimated *via* the second representation formula [equation (2.2.5.13)] and over negative quartets. The value of CPHASE is expected to be close to unity for the correct solution.

(*a*2) $\alpha_{\mathbf{h}}$ for strong triplets and $E_{\mathbf{k}} E_{\mathbf{h}-\mathbf{k}}$ contributions for PSI0 triplets may be considered random variables: the agreements between their actual and their expected distributions are considered as criteria for identifying the correct solution.

(*a*3) correlation among some FOMs is taken into account.

According to this scheme, each FOM (as well as the CFOM) is expected to be unity for the correct solution. Thus one or more figures are available which constitute a sort of criterion (on an absolute scale) concerning the correctness of the various solutions: FOMs (and CFOM) $\simeq 1$ probably denote correct solutions, CFOMs $\ll 1$ should indicate incorrect solutions.

Stage 8: *Interpretation of E maps.* This is carried out in up to four stages (Koch, 1974; Main & Hull, 1978; Declercq *et al.*, 1973):

(*a*) peak search;

(*b*) separation of peaks into potentially bonded clusters;

(*c*) application of stereochemical criteria to identify possible molecular fragments;

(*d*) comparison of the fragments with the expected molecular structure.

2.2.8. Other multisolution methods applied to small molecules

In very complex structures a large initial set of known phases seems to be a basic requirement for a structure to be determined.

Table 2.2.8.1. *Magic-integer sequences for small numbers of phases (n) together with the number of sets produced and the root-mean-square error in the phases*

n	Sequence								No. of sets	R.m.s. error (°)
1	1								4	26
2	2	3							12	29
3	3	4	5						20	37
4	5	7	8	9					32	42
5	8	11	13	14	15				50	45
6	13	18	21	23	24	25			80	47
7	21	29	34	37	39	40	41		128	48
8	34	47	55	60	63	65	66	67	206	49

This aim can be achieved, for example, by introducing a large number of permutable phases into the initial set. However, the introduction of every new symbol implies a fourfold increase in computing time, which, even in fast computers, quickly leads to computing-time limitations. On the other hand, a relatively large starting set is not in itself enough to ensure a successful structure determination. This is the case, for example, when the triplet invariants used in the initial steps differ significantly from zero. New strategies have therefore been devised to solve more complex structures.

(1) *Magic-integer methods*

In the classical procedure described in Section 2.2.7, the unknown phases in the starting set are assigned all combinations of the values $\pm\pi/4$, $\pm 3\pi/4$. For n unknown phases in the starting set, 4^n sets of phases arise by quadrant permutation; this is a number that increases very rapidly with n. According to White & Woolfson (1975), phases can be represented for a sequence of n integers by the equations

$$\varphi_i = m_i x \pmod{2\pi}, \quad i = 1, \ldots, n. \tag{2.2.8.1}$$

The set of equations can be regarded as the parametric equation of a straight line in n-dimensional phase space. The nature and size of errors connected with magic-integer representations have been investigated by Main (1977) who also gave a recipe for deriving magic-integer sequences which minimize the r.m.s. errors in the represented phases (see Table 2.2.8.1). To assign a phase value, the variable x in equation (2.2.8.1) is given a series of values at equal intervals in the range $0 < x < 2\pi$. The enantiomorph is defined by exploring only the appropriate half of the n-dimensional space.

A different way of using the magic-integer method (Declercq *et al.*, 1975) is the *primary–secondary P–S method* which may be described schematically in the following way:

(a) Origin- and enantiomorph-fixing phases are chosen and some one-phase s.s.'s are estimated.

(b) Nine phases [this is only an example: very long magic-integer sequences may be used to represent primary phases (Hull *et al.*, 1981; Debaerdemaeker & Woolfson, 1983)] are represented with the approximated relationships:

$$\begin{cases} \varphi_{i_1} = 3x \\ \varphi_{i_2} = 4x \\ \varphi_{i_3} = 5x \end{cases} \qquad \begin{cases} \varphi_{j_1} = 3y \\ \varphi_{j_2} = 4y \\ \varphi_{j_3} = 5y \end{cases} \qquad \begin{cases} \varphi_{p_1} = 3z \\ \varphi_{p_2} = 4z \\ \varphi_{p_3} = 5z. \end{cases}$$

Phases in (a) and (b) consistitute the *primary set.*

(c) The phases in the *secondary set* are those defined through $\sum_2$ relationships involving pairs of phases from the primary set: they, too, can be expressed in magic-integer form.

(d) All the triplets that link together the phases in the combined primary and secondary set are now found, other than triplets used to obtain secondary reflections from the primary ones. The general algebraic form of these triplets will be

$$m_1 x + m_2 y + m_3 z + b \equiv 0 \pmod 1,$$

where b is a phase constant which arises from symmetry translation. It may be expected that the 'best' value of the unknown x, y, z corresponds to a maximum of the function

$$\psi(x, y, z) = \sum |E_1 E_2 E_3| \cos 2\pi(m_1 x + m_2 y + m_3 z + b),$$

with $0 \le x, y, z < 1$. It should be noticed that ψ is a Fourier summation which can easily be evaluated. In fact, ψ is essentially a figure of merit for a large number of phases evaluated in terms of a small number of magic-integer variables and gives a measure of the internal consistency of $\sum_2$ relationships. The ψ map generally presents several peaks and therefore can provide several solutions for the variables.

(2) *The random-start method*

These are procedures which try to solve crystal structures by starting from random initial phases (Baggio *et al.*, 1978; Yao, 1981). They may be so described:

(a) A number of reflections (say NUM $\sim$ 100 or larger) at the bottom of the CONVERGE map are selected. These, and the relationships which link them, form the system for which trial phases will be found.

(b) A pseudo-random number generator is used to generate M sets of NUM random phases. Each of the M sets is refined and extended by the tangent formula or similar methods.

(3) *Accurate calculation of s.i.'s and s.s.'s with* 1, 2, 3, 4, ..., n *phases*

Having a large set of good phase relationships allows one to overcome difficulties in the early stages and in the refinement process of the phasing procedure. Accurate estimates of s.i.'s and s.s.'s may be achieved by the application of techniques such as the representation method or the neighbourhood principle (Hauptman, 1975; Giacovazzo, 1977*a*, 1980*b*). So far, second-representation formulae are available for triplets and one-phase seminvariants; in particular, reliably estimated negative triplets can be recognized, which is of great help in the phasing process (Cascarano, Giacovazzo, Camalli *et al.*, 1984). Estimation of higher-order s.s.'s with upper representations or upper neighbourhoods is rather difficult, both because the procedures are time consuming and because the efficiency of the present joint probability distribution techniques deteriorates with complexity. However, further progress can be expected in the field.

(4) *Modified tangent formulae and least-squares determination and refinement of phases*

The problem of deriving the individual phase angles from triplet relationships is greatly overdetermined: indeed the number of triplets, in fact, greatly exceeds the number of phases so that any $\varphi_{\mathbf{h}}$ may be determined by a least-squares approach (Hauptman *et al.*, 1969). The function to be minimized may be

$$M = \frac{\sum_{\mathbf{k}} w_{\mathbf{k}} [\cos(\varphi_{\mathbf{h}} - \varphi_{\mathbf{k}} - \varphi_{\mathbf{h}-\mathbf{k}}) - C_{\mathbf{k}}]^2}{\sum w_{\mathbf{k}}},$$

where $C_{\mathbf{k}}$ is the estimate of the cosine obtained by probabilistic or other methods.

Effective least-squares procedures based on linear equations (Debaerdemaeker & Woolfson, 1983; Woolfson, 1977) can also be used. A triplet relationship is usually represented by

$$(\varphi_p \pm \varphi_q \pm \varphi_r + b) \approx 0 \pmod{2\pi}, \tag{2.2.8.2}$$

where b is a factor arising from translational symmetry. If (2.2.8.2) is expressed in cycles and suitably weighted, then it may be written as

$$w(\varphi_p \pm \varphi_q \pm \varphi_r + b) = wn,$$

where n is some integer. If the integers were known then the equation would appear (in matrix notation) as

$$\boldsymbol{A}\boldsymbol{\Phi} = \boldsymbol{C}, \tag{2.2.8.3}$$

giving the least-squares solution

$$\boldsymbol{\Phi} = (\boldsymbol{A}^T\boldsymbol{A})^{-1}\boldsymbol{A}^T\boldsymbol{C}. \tag{2.2.8.4}$$

When approximate phases are available, the nearest integers may be found and equations (2.2.8.3) and (2.2.8.4) constitute the basis for further refinement.

Modified tangent procedures are also used, such as (Sint & Schenk, 1975; Busetta, 1976)

$$\tan\varphi_{\mathbf{h}} \simeq \frac{\sum_j G_{\mathbf{h},\mathbf{k}_j}\sin(\varphi_{\mathbf{k}_j}+\varphi_{\mathbf{h}-\mathbf{k}_j}-\Delta_j)}{\sum G_{\mathbf{h},\mathbf{k}_j}\cos(\varphi_{\mathbf{k}_j}+\varphi_{\mathbf{h}-\mathbf{k}_j}-\Delta_j)},$$

where Δ_j is an estimate for the triplet phase sum $(\varphi_{\mathbf{h}}-\varphi_{\mathbf{k}_j}-\varphi_{\mathbf{h}-\mathbf{k}_j})$.

(5) *Techniques based on the positivity of Karle–Hauptman determinants*

(The main formulae have been briefly described in Section 2.2.5.7.) The maximum determinant rule has been applied to solve small structures (de Rango, 1969; Vermin & de Graaff, 1978) *via* determinants of small order. It has, however, been found that their use (Taylor *et al.*, 1978) is not of sufficient power to justify the larger amount of computing time required by the technique as compared to that required by the tangent formula.

(6) *Tangent techniques using simultaneously triplets, quartets, ...*

The availability of a large number of phase relationships, in particular during the first stages of a direct procedure, makes the phasing process easier. However, quartets are sums of two triplets with a common reflection. If the phase of this reflection (and/or of the other cross terms) is known then the quartet probability formulae described in Section 2.2.5.5 cannot hold. Similar considerations may be made for quintet relationships. Thus triplet, quartet and quintet formulae described in the preceding paragraphs, if used without modifications, will certainly introduce systematic errors in the tangent refinement process.

A method which takes into account correlation between triplets and quartets has been described (Giacovazzo, 1980*c*) [see also Freer & Gilmore (1980) for a first application], according to which

$$\tan\varphi_{\mathbf{h}} \simeq \frac{\sum_{\mathbf{k}} G\sin(\varphi_{\mathbf{k}}+\varphi_{\mathbf{h}-\mathbf{k}}) - \sum_{\mathbf{k},\mathbf{l}} G'\sin(\varphi_{\mathbf{k}}+\varphi_{\mathbf{l}}+\varphi_{\mathbf{h}-\mathbf{k}-\mathbf{l}})}{\sum_{\mathbf{k}} G\cos(\varphi_{\mathbf{k}}+\varphi_{\mathbf{h}-\mathbf{k}}) - \sum_{\mathbf{k},\mathbf{l}} G'\cos(\varphi_{\mathbf{k}}+\varphi_{\mathbf{l}}+\varphi_{\mathbf{h}-\mathbf{k}-\mathbf{l}})},$$

where G' takes into account both the magnitudes of the cross terms of the quartet and the fact that their phases may be known.

(7) *Integration of Patterson techniques and direct methods (Egert & Sheldrick, 1985) [see also Egert (1983, and references therein)]*

A fragment of known geometry is oriented in the unit cell by real-space Patterson rotation search (see Chapter 2.3) and its position is found by application of a translation function (see Section 2.2.5.4 and Chapter 2.3) or by maximizing the weighted sum of the cosines of a small number of strong translation-sensitive triple phase invariants, starting from random positions. Suitable FOMs rank the most reliable solutions.

(8) *Maximum entropy methods*

A common starting point for all direct methods is a stochastic process according to which crystal structures are thought of as being generated by randomly placing atoms in the asymmetric unit of the unit cell according to some *a priori* distribution. A non-uniform prior distribution of atoms $p(\mathbf{r})$ gives rise to a source of random atomic positions with entropy (Jaynes, 1957)

$$H(p) = -\int_V p(\mathbf{r})\log p(\mathbf{r})\,\mathrm{d}\mathbf{r}.$$

The maximum value $H_{\max} = \log V$ is reached for a uniform prior $p(\mathbf{r}) = 1/V$.

The strength of the restrictions introduced by $p(\mathbf{r})$ is not measured by $H(p)$ but by $H(p) - H_{\max}$, given by

$$H(p) - H_{\max} = -\int_V p(\mathbf{r})\log[\,p(\mathbf{r})/m(\mathbf{r})]\,\mathrm{d}\mathbf{r},$$

where $m(\mathbf{r}) = 1/V$. Accordingly, if a prior prejudice $m(\mathbf{r})$ exists, which maximizes H, the revised relative entropy is

$$S(p) = -\int_V p(\mathbf{r})\log[\,p(\mathbf{r})/m(\mathbf{r})]\,\mathrm{d}\mathbf{r}.$$

The maximization problem was solved by Jaynes (1957). If $G_j(p)$ are linear constraint functionals defined by given constraint functions $C_j(\mathbf{r})$ and constraint values c_j, *i.e.*

$$G_j(p) = \int_V p(\mathbf{r})C_j(\mathbf{r})\,\mathrm{d}\mathbf{r} = c_j,$$

the most unbiased probability density $p(\mathbf{r})$ under prior prejudice $m(\mathbf{r})$ is obtained by maximizing the entropy of $p(\mathbf{r})$ relative to $m(\mathbf{r})$. A standard variational technique suggests that the constrained maximization is equivalent to the unconstrained maximization of the functional

$$S(p) + \sum_j \lambda_j G_j(p),$$

where the λ_j's are Lagrange multipliers whose values can be determined from the constraints.

Such a technique has been applied to the problem of finding good electron-density maps in different ways by various authors (Wilkins *et al.*, 1983; Bricogne, 1984; Navaza, 1985; Navaza *et al.*, 1983).

Maximum entropy methods are strictly connected with traditional direct methods: in particular it has been shown that:

(*a*) the maximum determinant rule (see Section 2.2.5.7) is strictly connected (Britten & Collins, 1982; Piro, 1983; Narayan & Nityananda, 1982; Bricogne, 1984);

(*b*) the construction of conditional probability distributions of structure factors amounts precisely to a reciprocal-space evaluation of the entropy functional $S(p)$ (Bricogne, 1984).

Maximum entropy methods are under strong development: important contributions can be expected in the near future even if a multipurpose robust program has not yet been written.

2.2.9. Some references to direct-methods packages: the small-molecule case

Some references for direct-methods packages are given below. Other useful packages using symbolic addition or multisolution procedures do exist but are not well documented.

2.2.10. Direct methods in macromolecular crystallography

2.2.10.1. Introduction

The smallest protein molecules contain about 400 non-hydrogen atoms, so they cannot be solved *ab initio* by the algorithms specified in Sections 2.2.7 and 2.2.8. However, traditional direct methods are applied for:

(*a*) improvement of the accuracy of the available phases (refinement process);

(*b*) extension of phases from lower to higher resolution (phase-extension process).

The application of standard tangent techniques to (*a*) and (*b*) has not been found to be very satisfactory (Coulter & Dewar, 1971; Hendrickson *et al.*, 1973; Weinzierl *et al.*, 1969). Tangent methods, in fact, require atomicity and non-negativity of the electron density. Both these properties are not satisfied if data do not extend to atomic resolution ($d > 1.2$ Å). Because of series termination and other errors the electron-density map at $d > 1.2$ Å presents large negative regions which will appear as false peaks in the squared structure. However, tangent methods use only a part of the information given by the Sayre equation (2.2.6.5). In fact, (2.2.6.5) express two equations relating the radial and angular parts of the two sides, so obtaining a large degree of overdetermination of the phases. To achieve this Sayre (1972) [see also Sayre & Toupin (1975)] suggested minimizing (2.2.10.1) by least squares as a function of the phases:

$$\sum_{\mathbf{h}} \left| a_{\mathbf{h}} F_{\mathbf{h}} - \sum_{\mathbf{k}} F_{\mathbf{k}} F_{\mathbf{h}-\mathbf{k}} \right|^2 . \qquad (2.2.10.1)$$

Even if tests on rubredoxin (extensions of phases from 2.5 to 1.5 Å resolution) and insulin (Cutfield *et al.*, 1975) (from 1.9 to 1.5 Å resolution) were successful, the limitations of the method are its high cost and, especially, the higher efficiency of the least-squares method. Equivalent considerations hold for the application of determinantal methods to proteins [see Podjarny *et al.* (1981); de Rango *et al.* (1985) and literature cited therein].

A question now arises: why is the tangent formula unable to solve protein structures? Fan *et al.* (1991) considered the question from a first-principle approach and concluded that:

(1) the triplet phase probability distribution is very flat for proteins (N is very large) and close to the uniform distribution;

(2) low-resolution data create additional problems for direct methods since the number of available phase relationships per reflection is small.

Sheldrick (1990) suggested that direct methods are not expected to succeed if fewer than half of the reflections in the range 1.1–1.2 Å are observed with $|F| > 4\sigma(|F|)$ (a condition seldom satisfied by protein data).

The most complete analysis of the problem has been made by Giacovazzo, Guagliardi *et al.* (1994). They observed that the expected value of α (see Section 2.2.7) suggested by the tangent formula for proteins is comparable with the variance of the α parameter. In other words, for proteins the signal determining the phase is comparable with the noise, and therefore the phase indication is expected to be unreliable.

Quite relevant results have recently been obtained by integrating direct methods with some additional experimental information. In particular, we will describe the combination of direct methods with:

(*a*) direct-space techniques for the *ab initio* crystal structure solution of proteins;

(*b*) isomorphous-replacement (SIR–MIR) techniques;

(*c*) anomalous-dispersion (SAD–MAD) techniques;

(*d*) molecular replacement.

Point (*d*) will not be treated here, as it is described extensively in *IT* F, Part 13.

2.2.10.2. Ab initio crystal structure solution of proteins

Ab initio techniques do not require prior information of any atomic positions. The recent tremendous increase in computing speed led to direct methods evolving towards the rapid development of multisolution techniques. The new algorithms of the program *Shake-and-Bake* (Weeks *et al.*, 1994; Weeks & Miller, 1999; Hauptman *et al.*, 1999) allowed an impressive extension of the structural complexity amenable to direct phasing. In particular we mention: (*a*) the minimal principle (De Titta *et al.*, 1994), according to which the phase problem is considered as a constrained global optimization problem; (*b*) the refinement procedure, which alternately uses direct- and reciprocal-space techniques; and (*c*) the parameter-shift optimization technique (Bhuiya & Stanley, 1963), which aims at reducing the value of the minimal function (Hauptman, 1991; De Titta *et al.*, 1994). An effective variant of *Shake-and Bake* is *SHELXD* (Sheldrick, 1998) which cyclically alternates tangent refinement in reciprocal space with peak-list optimisation procedures in real space (Sheldrick & Gould, 1995). Detailed information on these programs is available in *IT* F (2001), Part 16.

A different approach is used by *ACORN* (Foadi *et al.*, 2000), which first locates a small fragment of the molecule (eventually by molecular-replacement techniques) to obtain a useful nonrandom starting set of phases, and then refines them by means of solvent-flattening techniques.

The program *SIR2004* (Burla *et al.*, 2005) uses the tangent formula as well as automatic Patterson techniques to obtain a first imperfect structural model; then direct-space techniques are used to refine the model. The Patterson approach is based on the use of the superposition minimum function (Buerger, 1959; Richardson & Jacobson, 1987; Sheldrick, 1992; Pavelcík, 1988; Pavelcík *et al.*, 1992; Burla *et al.*, 2004). It may be worth noting that even this approach is of multisolution type: up to 20 trial solutions are provided by using as pivots the highest maxima in the superposition minimum function.

It is today possible to solve structures up to 2500 non-hydrogen atoms in the asymmetric unit provided data at atomic (about 1 Å) resolution are available. Proteins with data at quasi-atomic resolution (say up to 1.5–1.6 Å) can also be solved, but with greater difficulties (Burla *et al.*, 2005). A simple evaluation of the potential of the *ab initio* techniques suggests that the structural complexity range and the resolution limits amenable to the *ab*

initio approach could be larger in the near future. The approach will profit by general technical advances like the increasing speed of computers and by the greater efficiency of informatic tools (*e.g.* faster Fourier-transform techniques). It could also profit from new specific crystallographic algorithms (for example, Oszlányi & Süto, 2004). It is of particular interest that extrapolating moduli and phases of nonmeasured reflections beyond the experimental resolution limit makes the *ab initio* phasing process more efficient, and leads to crystal structure solution even in cases in which the standard programs do not succeed (Caliandro *et al.*, 2005*a*,*b*). Moreover, the use of the extrapolated values improves the quality of the final electron-density maps and makes it easier to recognize the correct one among several trial structures.

2.2.10.3. Integration of direct methods with isomorphous replacement techniques

SIR–MIR cases are characterized by a situation in which there is one native protein and one or more heavy-atom substructures. In this situation the phasing procedure may be a two-step process: in the first stage the heavy-atom positions are identified by Patterson techniques (Rossmann, 1961; Okaya *et al.*, 1955) or by direct methods (Mukherjee *et al.*, 1989). In the second step the protein phases are estimated by exploiting the substructure information. Direct methods are able to contribute to both steps (see Sections 2.2.10.5 and 2.2.10.6). In Section 2.2.10.4 we show that direct methods are also able to suggest alternative one-step procedures by estimating structure invariants from isomorphous data.

2.2.10.4. SIR–MIR case: one-step procedures

The theoretical basis was established by Hauptman (1982*a*): his primary interest was to establish the two-phase and three-phase structure invariants by exploiting the experimental information provided by isomorphous data. The protein phases could be directly assigned *via* a tangent procedure.

Let us denote the modulus of the isomorphous difference as

$$\Delta F = |F_{\rm d}| - |F_{\rm p}|$$

where the subscripts d and p denote the derivative and the protein, respectively.

Denote also by f_j and g_j atomic scattering factors for the atom labelled j in a pair of isomorphous structures, and let $E_{\mathbf{h}}$ and $G_{\mathbf{h}}$ denote corresponding normalized structure factors. Then

$$E_{\mathbf{h}} = |E_{\mathbf{h}}| \exp(i\varphi_{\mathbf{h}}) = \alpha_{20}^{-1/2} \sum_{j=1}^{N} f_j \exp(2\pi i \mathbf{h}\cdot\mathbf{r}_j),$$

$$G_{\mathbf{h}} = |G_{\mathbf{h}}| \exp(i\psi_{\mathbf{h}}) = \alpha_{02}^{-1/2} \sum_{j=1}^{N} g_j \exp(2\pi i \mathbf{h}\cdot\mathbf{r}_j),$$

where

$$\alpha_{mn} = \sum_{j=1}^{N} f_j^m g_j^n.$$

The conditional probability of the two-phase structure invariant $\Phi = \varphi_{\mathbf{h}} - \psi_{\mathbf{h}}$ given $|E_{\mathbf{h}}|$ and $|G_{\mathbf{h}}|$ is (Hauptman, 1982*a*)

$$P(\Phi\big||E|, |G|) \simeq [2\pi I_0(Q)]^{-1} \exp(Q\cos\Phi),$$

where

$$Q = |EG|[2\alpha/(1-\alpha^2)],$$
$$\alpha = \alpha_{11}/(\alpha_{20}^{1/2}\alpha_{02}^{1/2}).$$

Three-phase structure invariants were evaluated by considering that eight invariants exist for a given triple of indices **h**, **k**, **l** ($\mathbf{h}+\mathbf{k}+\mathbf{l}=0$):

$$\Phi_1 = \varphi_{\mathbf{h}} + \varphi_{\mathbf{k}} + \varphi_{\mathbf{l}} \qquad \Phi_2 = \varphi_{\mathbf{h}} + \varphi_{\mathbf{k}} + \psi_{\mathbf{l}}$$
$$\Phi_3 = \varphi_{\mathbf{h}} + \psi_{\mathbf{k}} + \varphi_{\mathbf{l}} \qquad \Phi_4 = \psi_{\mathbf{h}} + \varphi_{\mathbf{k}} + \varphi_{\mathbf{l}}$$
$$\Phi_5 = \varphi_{\mathbf{h}} + \psi_{\mathbf{k}} + \psi_{\mathbf{l}} \qquad \Phi_6 = \psi_{\mathbf{h}} + \varphi_{\mathbf{k}} + \psi_{\mathbf{l}}$$
$$\Phi_7 = \psi_{\mathbf{h}} + \psi_{\mathbf{k}} + \varphi_{\mathbf{l}} \qquad \Phi_8 = \psi_{\mathbf{h}} + \psi_{\mathbf{k}} + \psi_{\mathbf{l}}.$$

So, for the estimation of any Φ_j, the joint probability distribution

$$P(E_{\mathbf{h}}, E_{\mathbf{k}}, E_{\mathbf{l}}, G_{\mathbf{h}}, G_{\mathbf{k}}, G_{\mathbf{l}})$$

has to be studied, from which eight conditional probability densities can be obtained:

$$P(\Phi_i\big||E_{\mathbf{h}}|, |E_{\mathbf{k}}|, |E_{\mathbf{l}}|, |G_{\mathbf{h}}|, |G_{\mathbf{k}}|, |G_{\mathbf{l}}|) \simeq [2\pi I_0(Q_j)]^{-1} \exp[Q_j \cos\Phi_j]$$

for $j = 1, \ldots, 8$.

The analytical expressions of Q_j are too intricate and are not given here (the reader is referred to the original paper). We only say that Q_j may be positive or negative, so that reliable triplet phase estimates near 0 or near π are possible: the larger $|Q_j|$, the more reliable the phase estimate.

A useful interpretation of the formulae in terms of experimental parameters was suggested by Fortier *et al.* (1984): according to them, distributions do not depend, as in the case of the traditional three-phase invariants, on the total number of atoms per unit cell but rather on the scattering difference between the native protein and the derivative (that is, on the scattering of the heavy atoms in the derivative).

Hauptman's formulae were generalized by Giacovazzo *et al.* (1988): the new expressions were able to take into account the resolution effects on distribution parameters. The formulae are completely general and include as special cases native protein and heavy-atom isomorphous derivatives as well as X-ray and neutron diffraction data. Their complicated algebraic forms are easily reduced to a simple expression in the case of a native protein heavy-atom derivative: in particular, the reliability parameter for Φ_1 is

$$Q_1 = 2[\sigma_3/\sigma_2^{3/2}]_{\rm p}|E_{\mathbf{h}}E_{\mathbf{k}}E_{\mathbf{l}}| + 2[\sigma_3/\sigma_2^{3/2}]_{\rm H}\Delta_{\mathbf{h}}\Delta_{\mathbf{k}}\Delta_{\mathbf{l}}, \qquad (2.2.10.2)$$

where indices p and H warn that parameters have to be calculated over protein atoms and over heavy atoms, respectively, and

$$\Delta = (F_{\rm d} - F_{\rm p})/(\textstyle\sum f_j^2)_{\rm H}^{1/2}.$$

Δ is a pseudo-normalized difference (with respect to the heavy-atom structure) between moduli of structure factors.

Equation (2.2.10.2) may be compared with Karle's (1983) algebraic rule: if the sign of $\Delta_{\mathbf{h}}\Delta_{\mathbf{k}}\Delta_{\mathbf{l}}$ is plus then the value of Φ_1 is estimated to be zero; if its sign is minus then the expected value of Φ_1 is close to π. In practice Karle's rule agrees with (2.2.10.2) only if the Cochran-type term in (2.2.10.2) may be neglected. Furthermore, (2.2.10.2) shows that large reliability values do not depend on the triple product of structure-factor differences, but on the triple product of pseudo-normalized differences.

A similar mathematical approach has been applied to estimate quartet invariants *via* isomorphous data. The result may be summarized as follows: a quartet is a phase relationship of order $N_{\rm H}^{-1}$ (Giacovazzo & Siliqi, 1996*a*,*b*; see also Kyriakidis *et al.*, 1996), with reliability factor equal to

$$G = \frac{2\Delta_{\mathbf{h}}\Delta_{\mathbf{k}}\Delta_{\mathbf{l}}\Delta_{\mathbf{h}+\mathbf{k}+\mathbf{l}}}{Q_4 N_{\mathrm{H}}} \times \left\{1 + \left(\Delta^2_{\mathbf{h}+\mathbf{k}} - 1\right) + \left(\Delta^2_{\mathbf{h}+\mathbf{l}} - 1\right) + \left(\Delta^2_{\mathbf{k}+\mathbf{l}} - 1\right)\right\}, \quad (2.2.10.3)$$

where Q_4 is a suitable normalizing factor.

As previously stressed, equations (2.2.10.2) and (2.2.10.3) are valid if the lack of isomorphism and the errors in the measurements are assumed to be negligible. At first sight this approach seems more appealing than the traditional two-step procedures, however it did not prove to be competitive with them. The main reason is the absence in the Hauptman and Giacovazzo approaches of a probabilistic treatment of the errors: such a treatment, on the contrary, is basic for the traditional SIR–MIR techniques [see Blow & Crick (1959) and Terwilliger & Eisenberg (1987) for two related approaches].

The problem of the errors in the probabilistic scenario defined by the joint probability distribution functions approach has recently been overcome by Giacovazzo *et al.* (2001). In their probabilistic calculations the following assumptions were made:

$$|F_{\mathrm{d}j}| \exp(i\varphi_j) = |F_{\mathrm{p}}| \exp(i\varphi_{\mathrm{p}}) + F_{\mathrm{H}j} \exp(i\varphi_{\mathrm{H}j}) + |\mu_j| \exp(i\theta_j), \quad (2.2.10.4)$$

where j refers to the jth derivative. $|\mu_j| \exp(i\theta_j)$ is the error, which can include model as well as measurement errors.

A more realistic expression for the reliability factor G of triplet invariants is obtained by including the expression (2.2.10.4) in the probabilistic approach. Then the reliability parameter of the triplet invariants is transformed into (Giacovazzo *et al.*, 2001)

$$G = 2[\sigma_3/\sigma_2^{3/2}]_{\mathrm{p}} R_{\mathrm{p}1} R_{\mathrm{p}2} R_{\mathrm{p}3} + 2[\sigma_3/\sigma_2^{3/2}]_{\mathrm{H}} \frac{\Delta_1\Delta_2\Delta_3}{[1 + (\sigma^2_{\mu 1})_{\mathrm{H}}][1 + (\sigma^2_{\mu 2})_{\mathrm{H}}][1 + (\sigma^2_{\mu 3})_{\mathrm{H}}]}, \quad (2.2.10.5)$$

where $(\sigma^2_{\mu})_{\mathrm{H}} = |\mu|^2/(\Sigma f_j^2)_{\mathrm{H}}$.

Equation (2.2.10.5) suggests how the error influences the reliability of the triplet estimate: even quite a small value of $|\mu|^2$ may be critical if the scattering power of the heavy-atom substructure is a very small percentage of the derivative scattering power.

A one-step procedure has been implemented in a computer program (Giacovazzo *et al.*, 2002): it has been shown that the method is able to derive automatically, from the experimental data and without any user intervention, good quality (*i.e.* perfectly interpretable) electron-density maps.

2.2.10.5. SIR–MIR case: the two-step procedure. Finding the heavy-atom substructure by direct methods

The first trials for finding the heavy-atom substructure were based on the following assumption: the modulus of the isomorphous difference,

$$\Delta F = |F_{\mathrm{d}}| - |F_{\mathrm{p}}|,$$

is assumed at a first approximation as an estimate of the heavy-atom structure factor F_{H}. Perutz (1956) approximated $|F_{\mathrm{H}}|^2$ with the difference $(|F_{\mathrm{d}}|^2 - |F_{\mathrm{p}}|^2)$. Blow (1958) and Rossmann (1960) suggested a better approximation: $|F_{\mathrm{H}}|^2 \simeq |\Delta F|^2$. A deeper analysis was performed by Phillips (1966), Dodson & Vijayan (1971), Blessing & Smith (1999) and Grosse-Kunstleve & Brunger (1999). The use of direct methods requires the normalization of $|\Delta F|$ and application of the tangent formula (Wilson, 1978).

A sounder procedure has been suggested by Giacovazzo *et al.* (2004): they studied, for the SIR case, the joint probability distribution function

$$P(E_{\mathrm{H}}, E_{\mathrm{p}}, E_{\mathrm{d}})$$

under the following assumptions:

(*a*) the atomic positions of the native protein structure and the positions of the heavy atoms in the derivative structure are the primitive random variables of the probabilistic approach;

(*b*)

$$|F_{\mathrm{d}}| \exp(i\varphi_{\mathrm{d}}) = |F_{\mathrm{p}}| \exp(i\varphi_{\mathrm{p}}) + |F_{\mathrm{H}}| \exp(i\varphi_{\mathrm{H}}) + |\mu_{\mathrm{d}}| \exp(i\theta_{\mathrm{d}}) \quad (2.2.10.6)$$

is the structure factor of the derivative.

Then the conditional distribution $P(R_{\mathrm{H}}|R_{\mathrm{p}}, R_{\mathrm{d}})$ may be derived, from which $\langle R_{\mathrm{H}}|R_{\mathrm{p}}, R_{\mathrm{d}}\rangle$ may be obtained. In terms of structure factors

$$\langle |F_{\mathrm{H}}|^2 \rangle = \frac{\sum_{\mathrm{H}}}{\left(\sum_{\mathrm{H}} + \langle |\mu_{\mathrm{d}}|^2 \rangle\right)} \left[\langle |\mu_{\mathrm{d}}|^2 \rangle + \frac{\sum_{\mathrm{H}}}{\left(\sum_{\mathrm{H}} + \langle |\mu_{\mathrm{d}}|^2 \rangle\right)} \Delta^2_{\mathrm{iso}} \right]. \quad (2.2.10.7)$$

The effect of the errors on the evaluation of the moduli $|F_{\mathrm{H}}|^2$ may be easily derived: if $\langle |\mu_{\mathrm{d}}|^2 \rangle = 0$, equation (2.2.10.7) confirms Blow and Rossmann's approximation $\langle |F_{\mathrm{H}}|^2 \rangle \simeq |\Delta F|^2$. If $\langle |\mu_{\mathrm{d}}|^2 \rangle \neq 0$ Blow and Rossmann's estimate should be affected by a systematic error, increasing with $\langle |\mu_{\mathrm{d}}|^2 \rangle$.

2.2.10.6. SIR–MIR case: protein phasing by direct methods

Let us suppose that the various heavy-atom substructures have been determined. They may be used as additional prior information for a more accurate estimate of the φ_{p} values. To this purpose the distributions

$$P(E_{\mathrm{p}}, \mathbf{E}'_{\mathrm{d}}|\mathbf{E}'_{\mathrm{H}}) \equiv P(E_{\mathrm{p}}, E'_{\mathrm{d}1}, \ldots, E'_{\mathrm{d}n}|E'_{\mathrm{H}1}, \ldots, E'_{\mathrm{H}n}) \quad (2.2.10.8)$$

may be used under the assumption (2.2.10.6). $E'_{\mathrm{d}j}$ and $E'_{\mathrm{H}j}$, for $j = 1, \ldots, n$, are the structure factors of the jth derivative and of the jth heavy-atom substructure, respectively, both normalized with respect to the protein. Any joint probability density (2.2.10.8) may be reliably approximated by a multidimensional Gaussian distribution (Giacovazzo & Siliqi, 2002), from which the following conditional distribution is obtained:

$$P(\varphi_{\mathrm{p}}|R_{\mathrm{p}}, \mathbf{R}'_{\mathrm{d}}, \mathbf{E}'_{\mathrm{H}}) \simeq [2\pi I_0(G)]^{-1} \exp[\alpha_{\mathrm{p}} \cos(\varphi_{\mathrm{p}} - \theta_{\mathrm{p}})]$$

where θ_{p}, the expected value of φ_{p}, is given by

$$\tan\theta_{\mathrm{p}} = \frac{\sum_{j=1}^{n} G_j \sin\varphi_{\mathrm{H}j}}{\sum_{j=1}^{n} G_j \cos\varphi_{\mathrm{H}j}} = \frac{T}{B}$$

and $G_j = 2|F_{\mathrm{H}j}|\Delta F/\mu_j^2$.

$\alpha_{\mathrm{p}} = (T^2 + B^2)^{1/2}$ is the reliability factor of the phase estimate. A robust phasing procedure has been established which, starting from the observed moduli $|F_{\mathrm{p}}|, |F_{\mathrm{d}j}|, j = 1, \ldots, n$, is able to automatically provide, without any user intervention, a high-quality electron-density map of the protein (Giacovazzo *et al.*, 2002).

2.2.10.7. Integration of anomalous-dispersion techniques with direct methods

If the frequency of the radiation is close to an absorption edge of an atom, then that atom will scatter the X-rays anomalously (see Chapter 2.4) according to $f = f' + if''$. This results in the breakdown of Friedel's law. It was soon realized that the Bijvoet difference could also be used in the determination of phases (Peerdeman & Bijvoet, 1956; Ramachandran & Raman, 1956;

Okaya & Pepinsky, 1956). Since then, a great deal of work has been done both from algebraic (see Chapter 2.4) and from probabilistic points of view. In this section we are only interested in the second.

SAD (single anomalous dispersion) and MAD (multiple anomalous dispersion) techniques can be used. Both are characterized by one protein structure and one anomalous-scatterer substructure. The experimental diffraction data differ only because of the different anomalous scattering (not because of different anomalous-scatterer substructures). In the MAD case the anomalous-scatterer substructure is in some way 'overdetermined' by the data and, therefore, it is more convenient to use a two-step procedure: first define the positions of the anomalous scatterers, and then estimate the protein phase values. For completeness, we describe the one-step procedures in Section 2.2.10.8. These are based on the estimation of the structure invariants and on the application of the tangent formula. The two-step procedures are described in the Sections 2.2.10.9 and 2.2.10.10.

2.2.10.8. The SAD case: the one-step procedures

Probability distributions of diffraction intensities and of selected functions of diffraction intensities for dispersive structures have been given by various authors [Parthasarathy & Srinivasan (1964), see also Srinivasan & Parthasarathy (1976) and relevant literature cited therein]. We describe here some probabilistic formulae for estimating invariants of low order.

(*a*) *Estimation of two-phase structure invariants.* The conditional probability distribution of $\Phi = \varphi_{\mathbf{h}} + \varphi_{-\mathbf{h}}$ given $R_{\mathbf{h}}$ and $G_{\mathbf{h}}$ (normalized moduli of $F_{\mathbf{h}}$ and $F_{-\mathbf{h}}$, respectively) (Hauptman, 1982*b*; Giacovazzo, 1983*b*) is

$$P(\Phi|R_{\mathbf{h}}, G_{\mathbf{h}}) \simeq [2\pi I_0(Q)]^{-1} \exp[Q\cos(\Phi - q)], \qquad (2.2.10.9)$$

where

$$\begin{aligned} Q &= \frac{2R_{\mathbf{h}}G_{\mathbf{h}}}{\sqrt{c}}[c_1^2 + c_2^2]^{1/2}, \\ \cos q &= \frac{c_1}{[c_1^2 + c_2^2]^{1/2}}, \qquad \sin q = \frac{c_2}{[c_1^2 + c_2^2]^{1/2}}, \\ c_1 &= \sum_{j=1}^{N}(f_j'^2 - f_j''^2)/\sum, \\ c_2 &= 2\sum_{j=1}^{N} f_j' f_j''/\sum, \\ c &= [1 - (c_1^2 + c_2^2)]^2, \\ \sum &= \sum_{j=1}^{N}(f_j'^2 + f_j''^2). \end{aligned}$$

q is the most probable value of Φ: a large value of the parameter Q suggests that the phase relation $\Phi = q$ is reliable. Large values of Q are often available in practice: q, however, may be considered an estimate of $|\Phi|$ rather than of Φ because the enantiomorph is not fixed in (2.2.10.9). A formula for the estimation of Φ in centrosymmetric structures has been provided by Giacovazzo (1987).

(*b*) *Estimation of triplet invariants.* Kroon *et al.* (1977) first incorporated anomalous diffraction in order to estimate triplet invariants. Their work was based on an analysis of the complex double Patterson function. Subsequent probabilistic considerations (Heinermann *et al.*, 1978) confirmed their results, which can be so expressed:

$$\sin\bar{\Phi} = \frac{|\tau|^2 - |\bar{\tau}|^2}{4\tau''[\frac{1}{2}(|\tau|^2 + |\bar{\tau}|^2) - |\tau''|^2]^{1/2}}, \qquad (2.2.10.10)$$

where $(\mathbf{h} + \mathbf{k} + \mathbf{l} = 0)$,

$$\begin{aligned} \tau &= E_{\mathbf{h}}E_{\mathbf{k}}E_{\mathbf{l}} = R_{\mathbf{h}}R_{\mathbf{k}}R_{\mathbf{l}}\exp(i\Phi_{\mathbf{h},\mathbf{k}}), \\ \bar{\tau} &= E_{-\mathbf{h}}E_{-\mathbf{k}}E_{-\mathbf{l}} = G_{\mathbf{h}}G_{\mathbf{k}}G_{\mathbf{l}}\exp(i\Phi_{\bar{\mathbf{h}},\bar{\mathbf{k}}}), \\ \bar{\Phi} &= \tfrac{1}{2}(\Phi_{\mathbf{h},\mathbf{k}} - \Phi_{\bar{\mathbf{h}},\bar{\mathbf{k}}}), \end{aligned}$$

and τ'' is the contribution of the imaginary part of τ, which may be approximated in favourable conditions by

$$\begin{aligned} \tau'' = 2f''[&f_{\mathbf{h}}'f_{\mathbf{k}}' + f_{\mathbf{h}}'f_{\mathbf{l}}' + f_{\mathbf{k}}f_{\mathbf{l}}] \\ &\times [1 + S(R_{\mathbf{h}}^2 + R_{\mathbf{k}}^2 + R_{\mathbf{l}}^2 - 3)], \end{aligned}$$

where S is a suitable scale factor.

Equation (2.2.10.10) gives two possible values for $\bar{\Phi}$ (Φ and $\pi - \Phi$). Only if $R_{\mathbf{h}}R_{\mathbf{k}}R_{\overline{\mathbf{h}+\mathbf{k}}}$ is large enough may this phase ambiguity be resolved by choosing the angle nearest to zero.

The evaluation of triplet phases by means of anomalous dispersion has been further pursued by Hauptman (1982*b*) and independently by Giacovazzo (1983*b*). Owing to the breakdown of Friedel's law there are eight distinct triplet invariants which can contemporaneously be exploited:

$$\begin{aligned} \Phi_1 &= \varphi_{\mathbf{h}} + \varphi_{\mathbf{k}} + \varphi_{\mathbf{l}}, & \Phi_2 &= -\varphi_{-\mathbf{h}} + \varphi_{\mathbf{k}} + \varphi_{\mathbf{l}} \\ \Phi_3 &= \varphi_{\mathbf{h}} - \varphi_{-\mathbf{k}} + \varphi_{\mathbf{l}}, & \Phi_4 &= \varphi_{\mathbf{h}} + \varphi_{\mathbf{k}} - \varphi_{-\mathbf{l}} \\ \Phi_5 &= \varphi_{-\mathbf{h}} + \varphi_{-\mathbf{k}} + \varphi_{-\mathbf{l}}, & \Phi_6 &= -\varphi_{\mathbf{h}} + \varphi_{-\mathbf{k}} + \varphi_{-\mathbf{l}} \\ \Phi_7 &= \varphi_{-\mathbf{h}} - \varphi_{\mathbf{k}} + \varphi_{-\mathbf{l}}, & \Phi_8 &= \varphi_{-\mathbf{h}} + \varphi_{-\mathbf{k}} - \varphi_{\mathbf{l}}. \end{aligned}$$

Given

$$\begin{aligned} R_1 &= |E_{\mathbf{h}}| & R_2 &= |E_{\mathbf{k}}| & R_3 &= |E_{\mathbf{h}+\mathbf{k}}| \\ G_1 &= |E_{-\mathbf{h}}| & G_2 &= |E_{-\mathbf{k}}| & R_3 &= |E_{-\mathbf{h}-\mathbf{k}}| \\ \varphi_1 &= \varphi_{\mathbf{h}} & \varphi_2 &= \varphi_{\mathbf{k}} & \varphi_3 &= \varphi_{\mathbf{h}+\mathbf{k}} \\ \psi_1 &= \varphi_{-\mathbf{h}} & \psi_2 &= \varphi_{-\mathbf{k}} & \psi_3 &= \varphi_{-\mathbf{h}-\mathbf{k}}, \end{aligned}$$

Hauptman and Giacovazzo found the following conditional distribution:

$$P(\Phi|R_j, G_j, j = 1, 2, 3) \simeq \left[2\pi I_0(\Omega)\right]^{-1}\exp[\Omega\cos(\Phi - \omega)]. \qquad (2.2.10.11)$$

The definitions of Ω and ω are rather extensive and so the reader is referred to the published papers. We only add that Ω is always positive and that ω, the expected value of Φ, may lie anywhere between 0 and 2π. Understanding the role of the various parameters in equation (2.2.10.11) is not easy. Giacovazzo *et al.* (2003) found an equivalent simpler expression from which interpretable estimates of the parameters were obtained. In the same paper the limitations of the approach (*versus* the two-step procedures) were clarified.

2.2.10.9. SAD–MAD case: the two-step procedures. Finding the anomalous-scatterer substructure by direct methods

The anomalous-scatterer substructure is traditionally determined by the techniques suggested by Karle and Hendrickson (Karle, 1980*b*; Hendrickson, 1985; Pähler *et al.*, 1990; Terwilliger, 1994). The introduction of selenium into proteins as selenomethionine encouraged the second-generation direct methods programs [*Shake and Bake* by Miller *et al.* (1994); *Half bake* by Sheldrick (1998); *SIR2000-N* by Burla *et al.* (2001); *ACORN* by Foadi *et al.* (2000)] to locate Se atoms. Since the number of Se atoms may be quite large (up to 200), direct methods rather than Patterson techniques seem to be preferable. *Shake and Bake*, *Half Bake* and *ACORN* obtain the coordinates of the anomalous scatterers from a single-wavelength set of data. When more sets of diffraction data are available the solutions obtained by the other sets are used to confirm the correct solution.

A different approach has been suggested in two recent papers (Burla *et al.*, 2002; Burla, Carrozzini *et al.*, 2003): the estimates of the amplitudes of the structure factors of the anomalously scattering substructure are derived, *via* the rigorous method of the joint probability distribution functions, from the experimental diffraction moduli relative to n wavelengths. To do that, first the joint distribution

$$\begin{aligned} P_n = P(&A_{\rm oa}, A_1^+, A_2^+, \ldots, A_n^+, A_1^-, A_2^-, \ldots, A_n^-, \\ &B_{\rm oa}, B_1^+, B_2^+, \ldots, B_n^+, B_1^-, B_2^-, \ldots, B_n^-) \\ &= \pi^{-(2n+1)}(\det\, K)^{1/2} \exp(-\tfrac{1}{2}\mathbf{T}^T\mathbf{K}^{-1}\mathbf{T}) \end{aligned}$$

is calculated, where $A_{\rm oa}, B_{\rm oa}, E_{\rm oa}, A_i^+, B_i^+, A_i^-, B_i^-$ are the real and imaginary components of $E_{\rm oa}$, E_i^+, E_i^-, respectively, $\mathbf{K}$ is a symmetric square matrix of order $(4n + 2)$, $\mathbf{K}^{-1} = \{\lambda_{ij}\}$ is its inverse, and $\mathbf{T}$ is a suitable vector with components defined in terms of the variables $A_{\rm oa}, A_1^+, A_2^+, \ldots, B_n^-$. $E_{\rm oa}$ is the normalized structure factor of the anomalous scatterer substructure calculated by neglecting anomalous scattering components. Then the conditional distribution

$$P(R_{\rm oa}|R_1, \ldots, R_n, G_1, \ldots, G_n)$$

is derived, from which

$$\langle R_{\rm oa}|R_1, \ldots, G_n\rangle = \tfrac{1}{2}(\pi/\lambda_{11})^{1/2}[1 + 4X^2/(\pi\lambda_{11})]^{1/2} \quad (2.2.10.12)$$

is obtained, where

$$\begin{aligned} X^2 &= Q_1^2 + Q_2^2 \\ Q_1 &= \lambda_{12}R_1 + \lambda_{13}R_2 + \ldots + \lambda_{1,n+1}R_n + \lambda_{1,n+2}G_1 + \ldots \\ &\quad + \lambda_{1,2n+1}G_n \\ Q_2 &= \lambda_{1,2n+3}R_1 + \lambda_{1,2n+4}R_2 + \ldots + \lambda_{1,3n+2}R_n + \ldots - \lambda_{1,3n+3}G_1 \\ &\quad - \ldots - \lambda_{1,4n+2}G_n. \end{aligned}$$

The standard deviation of the estimate is also calculated:

$$\sigma_{R_{\rm oa}} = \left[\langle R_{\rm oa}^2|\ldots\rangle - \langle R_{\rm oa}|\ldots\rangle^2\right]^{1/2} = \left[\left(1 - \frac{\pi}{4}\right)\lambda_{11}^{-1}\right]^{1/2},$$

from which

$$\frac{\langle R_{\rm oa}|\ldots\rangle}{\sigma_{R_{\rm oa}}} = \left[\frac{(\pi/4) + (X^2)/\lambda_{11}}{1 - (\pi/4)}\right]^{1/2}. \quad (2.2.10.13)$$

The advantage of the above approach is that the estimates can simultaneously exploit both the anomalous and the dispersive differences. The computing procedure proposed by Burla, Carrozzini *et al.* (2003) is the following:

(i) The sets S_j, $j = 1, \ldots, n$, of the observed magnitudes (say $|F^+|$, $|F^-|$) are stored for all the n wavelengths.

(ii) The Wilson method is applied to put the sets S_j on their absolute scales.

(iii) Equations (2.2.10.12) and (2.2.10.13) are applied to obtain the values $\langle R_{\rm oa}|\ldots\rangle$ and $\langle R_{\rm oa}|\ldots\rangle/\sigma_{R_{\rm oa}}$.

(iv) The triplet invariants involving the reflections with the highest $\langle R_{\rm oa}|\ldots\rangle/\sigma_{R_{\rm oa}}$ values are evaluated and the tangent formula is applied *via* a random starting approach.

(v) The direct-space refinement techniques of *SIR2002* (Burla, Camalli *et al.*, 2003) are used to extend the phase information to a larger set of reflections: only 30% of the reflections with the smallest values of $\langle R_{\rm oa}|\ldots\rangle$ remain unphased. Automatic cycles of least-squares refinement improve the substructure model provided by the trial solutions.

(vi) Suitable figures of merit are used to recognize the correct substructure models.

The application of the above procedure to several MAD cases showed that the various wavelength combinations are not equally informative. A criterion based on the correlation among the various $\Delta_{\rm ano}$ values was also provided (see also Schneider & Sheldrick, 2002) for predicting the most informative combinations.

2.2.10.10. SAD–MAD case: protein phasing by direct methods

Once the anomalous-scatterer substructure has been found, the corresponding structure factors $E_{a1}^+, \ldots, E_{an}^+, E_{a1}^-, \ldots, E_{an}^-$ are known in modulus and phase. Then the conditional joint probability distribution

$$P\left(E_1^+, \ldots, E_n^+, E_1^-, \ldots, E_n^-|E_{a1}^+, \ldots, E_{an}^+, E_{a1}^-, \ldots, E_{an}^-\right)$$

may be calculated (Giacovazzo & Siliqi, 2004), from which the conditional distribution

$$P\left(\varphi_1^+|E_{ai}^+, E_{ai}^-, R_i, G_i, i = 1, \ldots, 2\right)$$

may be derived.

It has been shown that the most probable phase of φ_1^+, say θ_1^+, is the phase of the vector

$$\begin{aligned} &\sum_{j=1}^{n}\left[w_j^+E_{aj}^+ + w_j^-E_{aj}^{-*}\right] \\ &\quad + \sum_{j,p=1,p>j}^{n}\left[w_{jp}(E_{aj}^+ - E_{ap}^+) + w_{n+j,n+p}\left(E_{aj}^{-*} - E_{ap}^{-*}\right)\right] \\ &\quad + \sum_{j,p=1}^{n} w_{j,n+p}\left(E_{aj}^+ - E_{ap}^{-*}\right)] \end{aligned} \quad (2.2.10.14)$$

and the reliability parameter of the phase estimate is nothing other than the modulus of (2.2.10.14). The first term in (2.2.10.14) is a Sim-like contribution; the other terms, through the weights w, take into account the errors and the experimental differences $(R_j - R_p)$, $(G_j - G_p)$ and $(R_j - G_p)$.

2.3. Patterson and molecular replacement techniques, and the use of noncrystallographic symmetry in phasing

By L. Tong, M. G. Rossmann and E. Arnold

2.3.1. Introduction

2.3.1.1. Background

Historically, the Patterson has been used in a variety of ways to effect the solutions of crystal structures. While some simple structures (Ketelaar & de Vries, 1939; Hughes, 1940; Speakman, 1949; Shoemaker *et al.*, 1950) were solved by direct analysis of Patterson syntheses, alternative methods have largely superseded this procedure. An early innovation was the heavy-atom method which depends on the location of a small number of relatively strong scatterers (Harker, 1936). Image-seeking methods and Patterson superposition techniques were first contemplated in the late 1930s (Wrinch, 1939) and applied sometime later (Beevers & Robertson, 1950; Clastre & Gay, 1950; Garrido, 1950*a*; Buerger, 1959). This experience provided the encouragement for computerized vector-search methods to locate individual atoms automatically (Mighell & Jacobson, 1963; Kraut, 1961; Hamilton, 1965; Simpson *et al.*, 1965) or to position known molecular fragments in unknown crystal structures (Nordman & Nakatsu, 1963; Huber, 1965). The Patterson function has been used extensively in conjunction with the isomorphous replacement method (Rossmann, 1960; Blow, 1958) or anomalous dispersion (Rossmann, 1961*a*) to determine the position of heavy-atom substitution. Pattersons have been used to detect the presence and relative orientation of multiple copies of a given chemical motif in the crystallographic asymmetric unit in the same or different crystals (Rossmann & Blow, 1962). Finally, the orientation and placement of known molecular structures ('molecular replacement') into unknown crystal structures can be accomplished *via* Patterson techniques.

The function, introduced by Patterson in 1934 (Patterson, 1934*a*,*b*), is a convolution of electron density with itself and may be defined as

$$P(\mathbf{u}) = \int_V \rho(\mathbf{x}) \cdot \rho(\mathbf{u}+\mathbf{x})\, \mathrm{d}\mathbf{x}, \qquad (2.3.1.1)$$

where $P(\mathbf{u})$ is the 'Patterson' function at $\mathbf{u}$, $\rho(\mathbf{x})$ is the crystal's periodic electron density and V is the volume of the unit cell. The Patterson function, or F^2 series, can be calculated directly from the experimentally derived X-ray intensities as

$$P(\mathbf{u}) = \frac{2}{V^2} \sum_{\mathbf{h}}^{\text{hemisphere}} |\mathbf{F}_\mathbf{h}|^2 \cos 2\pi\mathbf{h}\cdot\mathbf{u}. \qquad (2.3.1.2)$$

The derivation of (2.3.1.2) from (2.3.1.1) can be found in this volume (see Section 1.3.4.2.1.6) along with a discussion of the physical significance and symmetry of the Patterson function, although the principal properties will be restated here.

The Patterson can be considered to be a vector map of all the pairwise interactions between the atoms in a unit cell. The vectors in a Patterson correspond to vectors in the real (direct) crystal cell but translated to the Patterson origin. Their weights are proportional to the product of densities at the tips of the vectors in the real cell. The Patterson unit cell has the same size as the real crystal cell. The symmetry of the Patterson comprises the Laue point group of the crystal cell plus any additional lattice symmetry due to Bravais centring. The reduction of the real space group to the Laue symmetry is produced by the translation of all vectors to the Patterson origin and the introduction of a centre of symmetry. The latter is a consequence of the relationship between the vectors **AB** and **BA**. The Patterson symmetries for all 230 space groups are tabulated in *IT* A (2005).

An analysis of Patterson peaks can be obtained by considering N atoms with form factors f_i in the unit cell. Then

$$\mathbf{F}_\mathbf{h} = \sum_{i=1}^{N} f_i \exp(2\pi i \mathbf{h}\cdot\mathbf{x}_i).$$

Using Friedel's law,

$$\begin{aligned} |\mathbf{F}_\mathbf{h}|^2 &= \mathbf{F}_\mathbf{h}\cdot\mathbf{F}_\mathbf{h}^* \\ &= \left[\sum_{i=1}^{N} f_i \exp(2\pi i\mathbf{h}\cdot\mathbf{x}_i)\right]\left[\sum_{j=1}^{N} f_j \exp(-2\pi i\mathbf{h}\cdot\mathbf{x}_j)\right], \end{aligned}$$

which can be decomposed to

$$|\mathbf{F}_\mathbf{h}|^2 = \sum_{i=1}^{N} f_i^2 + \sum_{i\neq j}^{N}\sum_{j}^{N} f_i f_j \exp[2\pi i\mathbf{h}\cdot(\mathbf{x}_i-\mathbf{x}_j)]. \qquad (2.3.1.3)$$

On substituting (2.3.1.3) in (2.3.1.2), we see that the Patterson consists of the sum of N^2 total interactions of which N are of weight f_i^2 at the origin and $N(N-1)$ are of weight $f_i f_j$ at $\mathbf{x}_i - \mathbf{x}_j$.

The weight of a peak in a real cell is given by

$$w_i = \int_U \rho_i(\mathbf{x})\, \mathrm{d}\mathbf{x} = Z_i \text{ (the atomic number)},$$

where U is the volume of the atom i. By analogy, the weight of a peak in a Patterson (form factor $f_i f_j$) will be given by

$$w_{ij} = \int_U P_{ij}(\mathbf{u})\, \mathrm{d}\mathbf{u} = Z_i Z_j.$$

Although the maximum height of a peak will depend on the spread of the peak, it is reasonable to assume that heights of peaks in a Patterson are proportional to the products of the atomic numbers of the interacting atoms.

There are a total of N^2 interactions in a Patterson due to N atoms in the crystal cell. These can be represented as an $N\times N$ square matrix whose elements $\mathbf{u}_{ij}$, w_{ij} indicate the position and weight of the peak produced between atoms i and j (Table 2.3.1.1). The N vectors corresponding to the diagonal of this matrix are located at the Patterson origin and arise from the convolution of each atom with itself. This leaves $N(N-1)$ vectors whose locations depend on the relative positions of all of the atoms in the crystal cell and whose weights depend on the atom types related by the vector. Complete specification of the unique non-origin Patterson vectors requires description of only the $N(N-1)/2$ elements in either the upper or the lower triangle of this matrix, since the two sets of vectors represented by the two triangles are related by a centre of symmetry

Table 2.3.1.1. *Matrix representation of Patterson peaks*

The $N \times N$ matrix represents the position $\mathbf{u}_{ij}$ and weights w_{ij} of atomic interactions in a Patterson arising from N atoms at $\mathbf{x}_i$ and weight w_i in the real cell.

	$\mathbf{x}_1, w_1$	$\mathbf{x}_2, w_2$	...	$\mathbf{x}_N, w_N$
$\mathbf{x}_1, w_1$	$\mathbf{u}_{11} = \mathbf{x}_1 - \mathbf{x}_1$, $w_{11} = w_1^2$	$\mathbf{u}_{12} = \mathbf{x}_1 - \mathbf{x}_2$, $w_{12} = w_1 w_2$	...	$\mathbf{u}_{1N} = \mathbf{x}_1 - \mathbf{x}_N$, $w_{1N} = w_1 w_N$
$\mathbf{x}_2, w_2$	$\mathbf{x}_2 - \mathbf{x}_1, w_2 w_1$	$0, w_2^2$	...	$\mathbf{x}_2 - \mathbf{x}_N, w_2 w_N$
$\vdots$	$\vdots$	$\vdots$	$\ddots$	$\vdots$
$\mathbf{x}_N, w_N$	$\mathbf{x}_N - \mathbf{x}_1, w_N w_1$	$\mathbf{x}_N - \mathbf{x}_2, w_N w_2$	...	$0, w_N^2$

$[\mathbf{u}_{ij} \equiv \mathbf{x}_i - \mathbf{x}_j = -\mathbf{u}_{ij} \equiv -(\mathbf{x}_j - \mathbf{x}_i)]$. Patterson vector positions are usually represented as $\langle uvw \rangle$, where u, v and w are expressed as fractions of the Patterson cell axes.

2.3.1.2. Limits to the number of resolved vectors

If we assume a constant number of atoms per unit volume, the number of atoms N in a unit cell increases in direct proportion with the volume of the unit cell. Since the number of non-origin peaks in the Patterson function is $N(N-1)$ and the Patterson cell is the same size as the real cell, the problem of overlapping peaks in the Patterson function becomes severe as N increases. To make matters worse, the breadth of a Patterson peak is roughly equal to the sum of the breadth of the original atoms. The effective width of a Patterson peak will also increase with increasing thermal motion, although this effect can be artificially reduced by sharpening techniques. Naturally, a loss of attainable resolution at high scattering angles will affect the resolution of atomic peaks in the real cell as well as peaks in the Patterson cell. If U is the van der Waals volume per average atom, then the fraction of the cell occupied by atoms will be $f = NU/V$. Similarly, the fraction of the cell occupied by Patterson peaks will be $2UN(N-1)/V$ or $2f(N-1)$. With the reasonable assumption that $f \simeq 0.1$ for a typical organic crystal, then the cell can contain at most five atoms ($N \leq 5$) for there to be no overlap, other than by coincidence, of the peaks in the Patterson. As N increases there will occur a background of peaks on which are superimposed features related to systematic properties of the structure.

The contrast of selected Patterson peaks relative to the general background level can be enhanced by a variety of techniques. For instance, the presence of heavy atoms not only enhances the size of a relatively small number of peaks but ordinarily ensures a larger separation of the peaks due to the light-atom skeleton on which the heavy atoms are hung. That is, the factor f (above) is substantially reduced. Another example is the effect of systematic atomic arrangements (*e.g.* α-helices or aromatic rings) resulting in multiple peaks which stand out above the background. In the isomorphous replacement method, isomorphous difference Pattersons are utilized in which the contrast of the Patterson interactions between the heavy atoms is enhanced by removal of the predominant interactions which involve the rest of the structure.

2.3.1.3. Modifications: origin removal, sharpening etc.

A. L. Patterson, in his first in-depth exposition of his newly discovered F^2 series (Patterson, 1935), introduced the major modifications to the Patterson which are still in use today. He illustrated, with one-dimensional Fourier series, the techniques of removing the Patterson origin peak, sharpening the overall function and also removing peaks due to atoms in special positions. Each one of these modifications can improve the interpretability of Pattersons, especially those of simple structures. Whereas the recommended extent of such modifications is controversial (Buerger, 1966), most studies which utilize Patterson functions do incorporate some of these techniques [see, for example, Jacobson *et al.* (1961), Braun *et al.* (1969) and Nordman (1980*a*)]. Since Patterson's original work, other workers have suggested that the Patterson function itself might be modified; Fourier inversion of the modified Patterson then provides a new and perhaps more tractable set of structure factors (McLachlan & Harker, 1951; Simonov, 1965; Raman, 1966; Corfield & Rosenstein, 1966). Karle & Hauptman (1964) suggested that an improved set of structure factors could be obtained from an origin-removed Patterson modified such that it was everywhere non-negative and that Patterson density values less than a bonding distance from the origin were set to zero. Nixon (1978) was successful in solving a structure which had previously resisted solution by using a set of structure factors which had been obtained from a Patterson in which the largest peaks had been attenuated.

The N origin peaks [see expression (2.3.1.3)] may be removed from the Patterson by using coefficients

$$|\mathbf{F}_{\mathbf{h},\,\mathrm{mod}}|^2 = |\mathbf{F}_{\mathbf{h}}|^2 - \sum_{i=1}^{N} f_i^2.$$

A Patterson function using these modified coefficients will retain all interatomic vectors. However, the observed structure factors $\mathbf{F}_{\mathbf{h}}$ must first be placed on an absolute scale (Wilson, 1942) in order to match the scattering-factor term. In practice, Patterson origins can also be removed by using coefficients

$$\left|\mathbf{F}_{\mathbf{h},\mathrm{mod}}\right|^2 = \left|\mathbf{F}_{\mathbf{h}}\right|^2 - \langle \left|\mathbf{F}_{\mathbf{h}}\right|^2 \rangle,$$

where $\langle \left|\mathbf{F}_{\mathbf{h}}\right|^2 \rangle$ is the average reflection intensity, usually calculated in several resolution shells. This formula has the advantage that the observed structure factors do not need to be on absolute scale.

Analogous to origin removal, the vector interactions due to atoms in known positions can also be removed from the Patterson function. Patterson showed that non-origin Patterson peaks arising from known atoms 1 and 2 may be removed by using the expression

$$|\mathbf{F}_{\mathbf{h},\,\mathrm{mod}}|^2 = |\mathbf{F}_{\mathbf{h}}|^2 - \sum_{i=1}^{N} f_i^2 t_i^2 - 2 f_1 f_2 t_1 t_2 \cos 2\pi \mathbf{h} \cdot (\mathbf{x}_1 - \mathbf{x}_2),$$

where $\mathbf{x}_1$ and $\mathbf{x}_2$ are the positions of atoms 1 and 2 and t_1 and t_2 are their respective thermal correction factors. Using one-dimensional Fourier series, Patterson illustrated how interactions due to known atoms can obscure other information.

Patterson also introduced a means by which the peaks in a Patterson function may be artificially sharpened. He considered the effect of thermal motion on the broadening of electron-density peaks and consequently their Patterson peaks. He suggested that the F^2 coefficients could be corrected for thermal effects by simulating the atoms as point scatterers and proposed using a modified set of coefficients

$$|\mathbf{F}_{\mathbf{h},\,\mathrm{sharp}}|^2 = |\mathbf{F}_{\mathbf{h}}|^2 / \bar{f}^2,$$

where $\bar{f}$, the average scattering factor per electron, is given by

$$\bar{f} = \sum_{i=1}^{N} f_i \Big/ \sum_{i=1}^{N} Z_i.$$

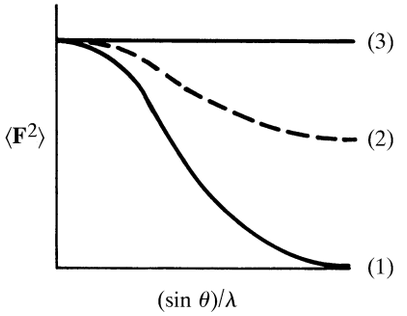

Fig. 2.3.1.1. Effect of 'sharpening' Patterson coefficients. (1) shows a mean distribution of $|\mathbf{F}|^2$ values with resolution, $(\sin\theta)/\lambda$. The normal decline of this curve is due to increasing destructive interference between different portions within diffuse atoms at larger Bragg angles. (2) shows the distribution of 'sharpened' coefficients. (3) shows the theoretical distribution of $|\mathbf{F}|^2$ produced by a point-atom structure. To represent such a structure with a Fourier series would require an infinite series in order to avoid large errors caused by truncation.

A common formulation for this type of sharpening expresses the atomic scattering factors at a given angle in terms of an overall isotropic thermal parameter B as

$$f(s) = f_0 \exp(-Bs^2).$$

The Patterson coefficients then become

$$\mathbf{F}_{\mathbf{h},\,\mathrm{sharp}} = \frac{Z_{\mathrm{total}}}{\sum_{i=l}^{N} f(s)} \mathbf{F}_{\mathbf{h}}.$$

The normalized structure factors, E (see Chapter 2.2), which are used in crystallographic direct methods, are also a common source of sharpened Patterson coefficients $(E^2 - 1)$. Although the centre positions and total contents of Patterson peaks are unaltered by sharpening, the resolution of individual peaks may be enhanced. The degree of sharpening can be controlled by adjusting the size of the assumed B factor; Lipson & Cochran (1966, pp. 165–170) analysed the effect of such a choice on Patterson peak shape.

All methods of sharpening Patterson coefficients aim at producing a point atomic representation of the unit cell. In this quest, the high-resolution terms are enhanced (Fig. 2.3.1.1). Unfortunately, this procedure must also produce a serious Fourier truncation error which will be seen as large ripples about each Patterson peak (Gibbs, 1898). Consequently, various techniques have been used (mostly unsuccessfully) in an attempt to balance the advantages of sharpening with the disadvantages of truncation errors.

Schomaker and Shoemaker [unpublished; see Lipson & Cochran (1966, p. 168)] used a function

$$|\mathbf{F}_{\mathbf{h},\,\mathrm{sharp}}|^2 = \frac{|\mathbf{F}_{\mathbf{h}}|^2}{\bar{f}^2} s^2 \exp\left[-\frac{\pi^2}{p} s^2\right],$$

in which s is the length of the scattering vector, to produce a Patterson synthesis which is less sensitive to errors in the low-order terms. Jacobson *et al.* (1961) used a similar function,

$$|\mathbf{F}_{\mathbf{h},\,\mathrm{sharp}}|^2 = \frac{|\mathbf{F}_{\mathbf{h}}|^2}{\bar{f}^2} (k + s^2) \exp\left[-\frac{\pi}{p} s^2\right],$$

which they rationalize as the sum of a scaled exponentially sharpened Patterson and a gradient Patterson function (the value of k was empirically chosen as $\frac{2}{3}$). This approach was subsequently further developed and generalized by Wunderlich (1965).

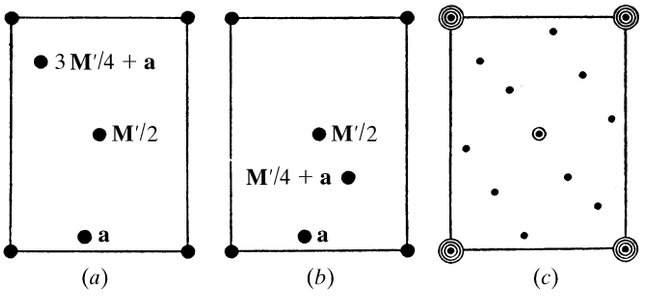

Fig. 2.3.1.2. (*c*) The point Patterson of the two homometric structures in (*a*) and (*b*). The latter are constructed by taking points at $\mathbf{a}$ and $\frac{1}{2}\mathbf{M}'$, where $\mathbf{M}'$ is a cell diagonal, and adding a third point which is (*a*) at $\frac{3}{4}\mathbf{M}' + \mathbf{a}$ or (*b*) at $\frac{1}{4}\mathbf{M}' + \mathbf{a}$. [Reprinted with permission from Patterson (1944).]

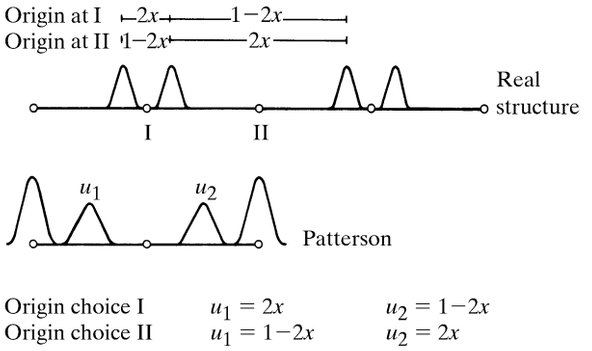
2.3.1.4. Homometric structures and the uniqueness of structure solutions; enantiomorphic solutions

Interpretation of any Patterson requires some assumption, such as the existence of discrete atoms. A complete interpretation might also require an assumption of the number of atoms and may require other external information (*e.g.* bond lengths, bond angles, van der Waals separations, hydrogen bonding, positive density *etc.*). To what extent is the solution of a Patterson function unique? Clearly the greater is the supply of external information, the fewer will be the number of possible solutions. Other constraints on the significance of a Patterson include the error involved in measuring the observed coefficients and the resolution limit to which they have been observed. The larger the error, the larger the number of solutions. When the error on the amplitudes is infinite, it is only the other physical constraints, such as packing, which limit the structural solutions. Alternative solutions of the same Patterson are known as homometric structures.

During their investigation of the mineral bixbyite, Pauling & Shappell (1930) made the disturbing observation that there were two solutions to the structure, with different arrangements of atoms, which yielded the same set of calculated intensities. Specifically, atoms occupying equipoint set 24*d* in space group $I(2_1/a)\bar{3}$ can be placed at either $x, 0, \frac{1}{4}$ or $-x, 0, \frac{1}{4}$ without changing the calculated intensities. Yet the two structures were not chemically equivalent. These authors resolved the ambiguity by placing the oxygen atoms in question at positions which gave the most acceptable bonding distances with the rest of the structure.

Patterson interpreted the above ambiguity in terms of the F^2 series: the distance vector sets or Patterson functions of the two structures were the same since each yielded the same calculated intensities (Patterson, 1939). He defined such a pair of structures a homometric pair and called the degenerate vector set which they produced a homometric set. Patterson went on to investigate the likelihood of occurrence of homometric structures and, indeed, devoted a great deal of his time to this matter. He also developed algebraic formalisms for examining the occurrence of homometric pairs and multiplets in selected one-dimensional sets of points, such as cyclotomic sets, and also sets of points along a line (Patterson, 1944). Some simple homometric pairs are illustrated in Fig. 2.3.1.2.

Drawing heavily from Patterson's inquiries into the structural uniqueness allowed by the diffraction data, Hosemann, Bagchi and others have given formal definitions of the different types of homometric structures (Hosemann & Bagchi, 1954). They suggested a classification divided into pseudohomometric structures and homomorphs, and used an integral equation representing a convolution operation to express their examples of finite homometric structures. Other workers have chosen various



Origin choice I	$u_1 = 2x$	$u_2 = 1-2x$
Origin choice II	$u_1 = 1-2x$	$u_2 = 2x$

Fig. 2.3.2.1. Origin selection in the interpretation of a Patterson of a one-dimensional centrosymmetric structure.

means for describing homometric structures [Buerger (1959, pp. 41–50), Menzer (1949), Bullough (1961, 1964), Hoppe (1962)].

Since a Patterson function is centrosymmetric, the Pattersons of a crystal structure and of its mirror image are identical. Thus the enantiomeric ambiguity present in noncentrosymmetric crystal structures cannot be overcome by using the Patterson alone and represents a special case of homometric structures. Assignment of the correct enantiomorph in a crystal structure analysis is generally not possible unless a recognizable fragment of known chirality emerges (*e.g.* L-amino acids in proteins, D-riboses in nucleic acids, the known framework of steroids and other natural products, the right-handed twist of α-helices, the left-handed twist of successive strands in a β-sheet, the fold of a known protein subunit *etc.*) or anomalous-scattering information is available and can be used to resolve the ambiguity (Bijvoet *et al.*, 1951).

It is frequently necessary to select arbitrarily one enantiomorph over another in the early stages of a structure solution. Structure-factor phases calculated from a single heavy atom in space group $P1$, $P2$ or $P2_1$ (for instance) will be centrosymmetric and both enantiomorphs will be present in Fourier calculations based on these phases. In other space groups (*e.g.* $P2_12_12_1$), the selected heavy atom is likely to be near one of the planes containing the 2_1 axes and thus produce a weaker 'ghost' image of the opposite enantiomorph. The mixture of the two overlapped enantiomorphic solutions can cause interpretive difficulties. As the structure solution progresses, the 'ghosts' are exorcized owing to the dominance of the chosen enantiomorph in the phases.

2.3.1.5. The Patterson synthesis of the second kind

Patterson also defined a second, less well known, function (Patterson, 1949) as

$$P_{\pm}(\mathbf{u}) = \int \rho(\mathbf{u}+\mathbf{x}) \cdot \rho(\mathbf{u}-\mathbf{x})\ \mathrm{d}\mathbf{x}$$
$$= \frac{2}{V^2} \sum_{\mathbf{h}}^{\text{hemisphere}} F_{\mathbf{h}}^2 \cos(2\pi 2\mathbf{h}\cdot\mathbf{u} - 2\alpha_{\mathbf{h}}).$$

This function can be computed directly only for centrosymmetric structures. It can be calculated for noncentrosymmetric structures when the phase angles are known or assumed. It will represent the degree to which the known or assumed structure has a centre of symmetry at $\mathbf{u}$. That is, the product of the density at $\mathbf{u}+\mathbf{x}$ and $\mathbf{u}-\mathbf{x}$ is large when integrated over all values $\mathbf{x}$ within the unit cell. Since atoms themselves have a centre of symmetry, the function will contain peaks at each atomic site roughly proportional in height to the square of the number of electrons in each atom plus peaks at the midpoint between atoms proportional in height to the product of the electrons in each atom. Although this function has not been found very useful in practice, it is useful for demonstrating the presence of weak enantiomorphic images in a given tentative structure determination.

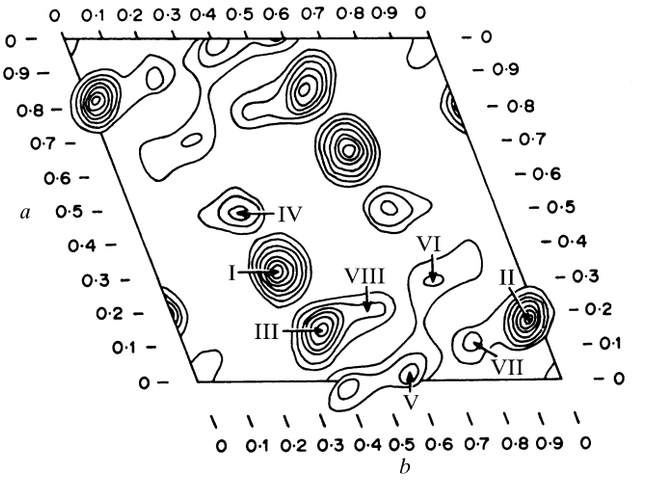


Fig. 2.3.2.2. The *c*-axis projection of cuprous chloride azomethane complex ($C_2H_6Cl_2Cu_2N_2$). The space group is $P\bar{1}$ with one molecule per unit cell. [Adapted from and reprinted with permission from Woolfson (1970, p. 321).]

2.3.2. Interpretation of Patterson maps

2.3.2.1. Simple solutions in the triclinic cell. Selection of the origin

A hypothetical one-dimensional centrosymmetric crystal structure containing an atom at x and at $-x$ and the corresponding Patterson is illustrated in Fig. 2.3.2.1. There are two different centres of symmetry which may be chosen as convenient origins. If the atoms are of equal weight, we expect Patterson vectors at positions $u = \pm 2x$ with weights equal to half the origin peak. There are two symmetry-related peaks, u_1 and u_2 (Fig. 2.3.2.1) in the Patterson. It is an arbitrary choice whether $u_1 = 2x$ or $u_2 = 2x$. This choice is equivalent to selecting the origin at the centre of symmetry I or II in the real structure (Fig. 2.3.2.1). Similarly in a three-dimensional $P\bar{1}$ cell, the Patterson will contain peaks at $\langle uvw\rangle$ which can be used to solve for the atom coordinates $\pm\langle 2x, 2y, 2z\rangle$. Solving for the same coordinates by starting from symmetric representations of the same vector will lead to alternate origin choices. For example, use of $\langle 1+u, 1+v, w\rangle$ will lead to translating the origin by $(+\frac{1}{2}, +\frac{1}{2}, 0)$ relative to the solution based on $\langle uvw\rangle$. There are eight distinct inversion centres in $P\bar{1}$, each one of which represents a valid origin choice. Although any choice of origin would be allowable, an inversion centre is convenient because then the structure factors are all real. Typically, one of the vector peaks closest to the Patterson origin is selected to start the solution, usually in the calculated asymmetric unit of the Patterson. Care must be exercised in selecting the same origin for all atomic positions by considering cross-vectors between atoms.

Examine, for example, the *c*-axis Patterson projection of a cuprous chloride azomethane complex ($C_2H_6Cl_2Cu_2N_2$) in $P\bar{1}$ as shown in Fig. 2.3.2.2. The largest Patterson peaks should correspond to vectors arising from Cu ($Z = 29$) and Cl ($Z = 17$) atoms. There will be copper atoms at $\mathbf{x}_{Cu}(x_{Cu}, y_{Cu})$ and $-\mathbf{x}_{Cu}(-x_{Cu}, -y_{Cu})$ as well as chlorine atoms at analogous positions. The interaction matrix is

	$\mathbf{x}_{Cu}$, 29	$\mathbf{x}_{Cl}$, 17	$-\mathbf{x}_{Cu}$, 29	$-\mathbf{x}_{Cl}$, 17
$\mathbf{x}_{Cu}$, 29	0, 841	$\mathbf{x}_{Cu}-\mathbf{x}_{Cl}$, 493	$2\mathbf{x}_{Cu}$, 841	$\mathbf{x}_{Cu}+\mathbf{x}_{Cl}$, 493
$\mathbf{x}_{Cl}$, 17		0, 289	$\mathbf{x}_{Cl}+\mathbf{x}_{Cu}$, 493	$2\mathbf{x}_{Cl}$, 289
$-\mathbf{x}_{Cu}$, 29			0, 841	$\mathbf{x}_{Cu}-\mathbf{x}_{Cl}$, 493
$-\mathbf{x}_{Cl}$, 17				0, 289

Table 2.3.2.1. *Coordinates of Patterson peaks for $C_2H_6Cl_2Cu_2N_2$ projection*

Height	u	v	Number in diagram (Fig. 2.3.2.2)
7	0.33	0.34	I
7	0.18	0.97	II
6	0.16	0.40	III
3	0.49	0.29	IV
3	0.02	0.59	V
2	0.30	0.75	VI
2	0.12	0.79	VII

which shows that the Patterson should contain the following types of vectors:

Position	Weight	Multiplicity	Total weight
$2\mathbf{x}_{\rm Cu}$	841	1	841
$2\mathbf{x}_{\rm Cl}$	289	1	289
$\mathbf{x}_{\rm Cu}-\mathbf{x}_{\rm Cl}$	493	2	986
$\mathbf{x}_{\rm Cu}+\mathbf{x}_{\rm Cl}$	493	2	986

The coordinates of the largest Patterson peaks are given in Table 2.3.2.1 for an asymmetric half of the cell chosen to span $0 \rightarrow \frac{1}{2}$ in u and $0 \rightarrow 1$ in v. Since the three largest peaks are in the same ratio (7:7:6) as the three largest expected vector types (986:986:841), it is reasonable to assume that peak III corresponds to the copper–copper interaction at $2\mathbf{x}_{\rm Cu}$. Hence, $x_{\rm Cu} = 0.08$ and $y_{\rm Cu} = 0.20$. Peaks I and II should be due to the double-weight Cu–Cl vectors at $\mathbf{x}_{\rm Cu} - \mathbf{x}_{\rm Cl}$ and $\mathbf{x}_{\rm Cu} + \mathbf{x}_{\rm Cl}$. Now suppose that peak I is at position $\mathbf{x}_{\rm Cu} + \mathbf{x}_{\rm Cl}$, then $x_{\rm Cl} = 0.25$ and $y_{\rm Cl} = 0.14$. Peak II should now check out as the remaining double-weight Cu–Cl interaction at $\mathbf{x}_{\rm Cu} - \mathbf{x}_{\rm Cl}$. Indeed, $\mathbf{x}_{\rm Cu} - \mathbf{x}_{\rm Cl} = \langle -0.17, 0.06\rangle = -\langle 0.17, -0.06\rangle$ which agrees tolerably well with the position of peak II. The chlorine position also predicts the position of a peak at $2\mathbf{x}_{\rm Cl}$ with weight 289; peak IV confirms the chlorine assignment. In fact, this Patterson can be solved also for the lighter nitrogen- and carbon-atom positions which account for the remainder of the vectors listed in Table 2.3.2.1. However, the simplest way to complete the structure determination is probably to compute a Fourier synthesis using phases calculated from the heavier copper and chlorine positions.

Consider now a real cell with M crystallographic asymmetric units, each of which contains N atoms. Let us define $\mathbf{x}_{mn}$, the position of the nth atom in the mth crystallographic unit, by

$$\mathbf{x}_{mn} = [\boldsymbol{T}_m]\mathbf{x}_{1n} + \mathbf{t}_m,$$

where $[\boldsymbol{T}_m]$ and $\mathbf{t}_m$ are the rotation matrix and translation vector, respectively, for the mth crystallographic symmetry operator. The Patterson of this crystal will contain vector peaks which arise from atoms interacting with other atoms both in the same and in different crystallographic asymmetric units. The set of $(MN)^2$ Patterson vector interactions for this crystal is represented in a matrix in Table 2.3.2.2. Upon dissection of this diagram we see that there are MN origin vectors, $M[(N-1)N]$ vectors from atom interactions with other atoms in the same crystallographic asymmetric unit and $[M(M-1)]N^2$ vectors involving atoms in separate asymmetric units. Often a number of vectors of special significance relating symmetry-equivalent atoms emerge from this milieu of Patterson vectors and such 'Harker vectors' constitute the subject of the next section.

2.3.2.2. Harker sections

Soon after Patterson introduced the F^2 series, Harker (1936) recognized that many types of crystallographic symmetry result in a concentration of vectors at characteristic locations in the Patterson. Specifically, he showed that atoms related by rotation axes produce vectors in characteristic planes of the Patterson, and that atoms related by mirror planes or reflection glide planes produce vectors on characteristic lines. Similarly, noncrystallographic symmetry operators produce analogous concentrations of vectors. Harker showed how special sections through a three-dimensional function could be computed using one- or two-dimensional summations. With the advent of powerful computers, it is usual to calculate a full three-dimensional Patterson synthesis. Nevertheless, 'Harker' planes or lines are often the starting point for a structure determination. It should, however, be noted that non-Harker vectors (those not due to interactions between symmetry-related atoms) can appear by coincidence in a Harker section. Table 2.3.2.3 shows the position in a Patterson of Harker planes and lines produced by all types of crystallographic symmetry operators.

Buerger (1946) noted that Harker sections can be helpful in space-group determination. Concentrations of vectors in appropriate regions of the Patterson should be diagnostic for the presence of some symmetry elements. This is particularly useful where these elements (such as mirror planes) are not directly detected by systematic absences.

Buerger also developed a systematic method of interpreting Harker peaks which he called implication theory [Buerger (1959, Chapter 7)].

Table 2.3.2.2. *Square matrix representation of vector interactions in a Patterson of a crystal with M crystallographic asymmetric units each containing N atoms*

Peak positions $\mathbf{u}_{m1n1,\,m2n2}$ correspond to vectors between the atoms $\mathbf{x}_{m1n1}$ and $\mathbf{x}_{m2n2}$ where $\mathbf{x}_{mn}$ is the nth atom in the mth crystallographic asymmetric unit. The corresponding weights are $w_{n1}w_{n2}$. The outlined blocks I1 and IM represent vector interactions between atoms in the same crystallographic asymmetric units (there are M such blocks). The off-diagonal blocks IIM1 and II1M represent vector interactions between atoms in crystal asymmetric units 1 and M; there are $M(M-1)$ blocks of this type. The significance of diagonal elements of block IIM1 is that they represent Harker-type interactions between symmetry-equivalent atoms (see Section 2.3.2.2).

(i) 2, 3, $\bar{3}$, 4, $\bar{4}$, 6, $\bar{6}$	$P(x, y, 0)$
(ii) 2_1, 4_2, 6_3	$P(x, y, \frac{1}{2})$
(iii) 3_1, 3_2, 6_2, 6_4	$P(x, y, \frac{1}{3})$
(iv) 4_1, 4_3	$P(x, y, \frac{1}{4})$
(v) 6_1, 6_5	$P(x, y, \frac{1}{6})$
(*b*) Harker lines	
Planes perpendicular to the *b* axis:	
(i) Reflection planes	$P(0, y, 0)$
(ii) Glide plane, glide $= \frac{1}{2}a$	$P(\frac{1}{2}, y, 0)$
(iii) Glide plane, glide $= \frac{1}{2}c$	$P(0, y, \frac{1}{2})$
(iv) Glide plane, glide $= \frac{1}{2}(a + c)$	$P(\frac{1}{2}, y, \frac{1}{2})$
(v) Glide plane, glide $= \frac{1}{4}(a + c)$	$P(\frac{1}{4}, y, \frac{1}{4})$
(vi) Glide plane, glide $= \frac{1}{4}(3a + c)$	$P(\frac{3}{4}, y, \frac{1}{4})$
(*c*) Special Harker planes	
Axes parallel to or containing body diagonal (111), valid for cubic space groups only:	
	Equation of plane $lx + my + nz - p = 0$
(i) 3	$l = m = n = \cos 54.73561^\circ = 0.57735$, $p = 0$
(ii) 3_1	$l = m = n = \cos 54.73561^\circ = 0.57735$, $p = \sqrt{3}/3$
Rhombohedral threefold axes produce analogous Harker planes whose description will depend on the interaxial angle.	

2.3.2.3. *Finding heavy atoms*

The previous two sections have developed some of the useful mechanics for interpreting Pattersons. In this section, we will consider finding heavy-atom positions, in the presence of numerous light atoms, from Patterson maps. The feasibility of structure solution by the heavy-atom method depends on a number of factors which include the relative size of the heavy atom and the extent and quality of the data. A useful rule of thumb is that the ratio

$$r = \frac{\sum_{\text{heavy}} Z^2}{\sum_{\text{light}} Z^2}$$

should be near unity if the heavy atom is to provide useful starting phase information (Z is the atomic number of an atom). The condition that $r > 1$ normally guarantees interpretability of the Patterson function in terms of the heavy-atom positions. This 'rule', arising from the work of Luzzati (1953), Woolfson (1956), Sim (1961) and others, is not inviolable; many ambitious determinations have been accomplished *via* the heavy-atom method for which r was well below 1.0. An outstanding example is vitamin B_{12} with formula $C_{62}H_{88}CoO_{14}P$, which gave an $r = 0.14$ for the cobalt atom alone (Hodgkin *et al.*, 1957). One factor contributing to the success of such a determination is that the relative scattering power of Co is enhanced for higher scattering angles. Thus, the ratio, r, provides a conservative estimate. If the value of r is well above 1.0, the initial easier interpretation of the Patterson will come at the expense of poorly defined parameters of the lighter atoms.

A general strategy for determining heavy atoms from the Patterson usually involves the following steps.

(1) List the number and type of atoms in the cell.

(2) Construct the interaction matrix for the heaviest atoms to predict the positions and weights of the largest Patterson vectors. Group recurrent vectors and notice vectors with special properties, such as Harker vectors.

(3) Compute the Patterson using any desired modifications. Placing the map on an absolute scale [$P(000) = \sum Z^2$] is convenient but not necessary.

(4) Examine Harker sections and derive trial atom coordinates from vector positions.

(5) Check the trial coordinates using other vectors in the predicted set. Correlate enantiomorphic choice and origin choice for independent sites.

(6) Include the next-heaviest atoms in the interpretation if possible. In particular, use the cross-vectors with the heaviest atoms.

(7) Use the best heavy-atom model to initiate phasing.

Detailed and instructive examples of using Pattersons to find heavy-atom positions are found in almost every textbook on crystal structure analysis [see, for example, Buerger (1959), Lipson & Cochran (1966) and Stout & Jensen (1968)].

The determination of the crystal structure of cholesteryl iodide by Carlisle & Crowfoot (1945) provides an example of using the Patterson function to locate heavy atoms. There were two molecules, each of formula $C_{27}H_{45}I$, in the $P2_1$ unit cell. The ratio $r = 2.8$ is clearly well over the optimal value of unity. The $P(x, z)$ Patterson projection showed one dominant peak at $\langle 0.434, 0.084 \rangle$ in the asymmetric unit. The equivalent positions for $P2_1$ require that an iodine atom at x_I, y_I, z_I generates another at $-x_I, \frac{1}{2} + y_I, z_I$ and thus produces a Patterson peak at $\langle 2x_I, \frac{1}{2}, 2z_I \rangle$. The iodine position was therefore determined as 0.217, 0.042. The y coordinate of the iodine is arbitrary for $P2_1$ yet the value of $y_I = 0.25$ is convenient, since an inversion centre in the two-atom iodine structure is then exactly at the origin, making all calculated phases 0 or π. Although the presence of this extra symmetry caused some initial difficulties in the interpretation of the steroid backbone, Carlisle and Crowfoot successfully separated the enantiomorphic images. Owing to the presence of the perhaps *too heavy* iodine atom, however, the structure of the carbon skeleton could not be defined very precisely. Nevertheless, all critical stereochemical details were adequately illuminated by this determination. In the cholesteryl iodide example, a number of different yet equivalent origins could have been selected. Alternative origin choices include all combinations of $x \pm \frac{1}{2}$ and $z \pm \frac{1}{2}$.

A further example of using the Patterson to find heavy atoms will be provided in Section 2.3.5.2 on solving for heavy atoms in the presence of noncrystallographic symmetry.

2.3.2.4. *Superposition methods. Image detection*

As early as 1939, Wrinch (1939) showed that it was possible, in principle, to recover a fundamental set of points from the vector map of that set. Unlike the Harker–Buerger implication theory (Buerger, 1946), the method that Wrinch suggested was capable of using all the vectors in a three-dimensional set, not those restricted to special lines or sections. Wrinch's ideas were developed for vector sets of points, however, and could not be directly applied to real, heavily overlapped Pattersons of a complex structure. These ideas seem to have lain dormant until the early 1950s when a number of independent investigators developed superposition methods (Beevers & Robertson, 1950; Clastre & Gay, 1950; Garrido, 1950*a*; Buerger, 1950*a*).

A Patterson can be considered as a sum of images of a molecule as seen, in turn, for each atom placed on the origin (Fig. 2.3.2.3). Thus, the deconvolution of a Patterson could proceed by superimposing each image of the molecule obtained onto the others by translating the Patterson origin to each imaging atom.

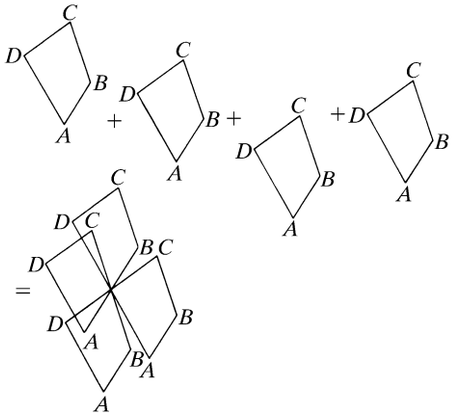

Fig. 2.3.2.3. Atoms *ABCD*, arranged as a quadrilateral, generate a Patterson which is the sum of the images of the quadrilateral when each atom is placed on the origin in turn.

For instance, let us take a molecule consisting of four atoms *ABCD* arranged in the form of a quadrilateral (Fig. 2.3.2.3). Then the Patterson consists of the images of four identical quadrilaterals with atoms *A*, *B*, *C* and *D* placed on the origin in turn. The Pattersons can then be deconvoluted by superimposing two of these Pattersons after translating these (without rotation) by, for instance, the vector **AB**. A further improvement could be obtained by superimposing a third Patterson translated by **AC**. This would have the additional advantage in that *ABC* is a noncentrosymmetric arrangement and, therefore, selects the enantiomorph corresponding to the hand of the atomic arrangement *ABC* [*cf.* Buerger (1951, 1959)].

A basic problem is that knowledge of the vectors **AB** and **AC** also implies some knowledge of the structure at a time when the structure is not yet known. In practice 'good-looking' peaks, estimated to be single peaks by assessing the absolute scale of the structure amplitudes with Wilson statistics, can be assumed to be the result of single interatomic vectors within a molecule. Superposition can then proceed and the result can be inspected for reasonable chemical sense. As many apparently single peaks can be tried systematically using a computer, this technique is useful for selecting and testing a series of reasonable Patterson interpretations (Jacobson *et al.*, 1961).

Three major methods have been used for the detection of molecular images of superimposed Pattersons. These are the sum, product and minimum 'image seeking' functions (Raman & Lipscomb, 1961). The concept of the sum function is to add the images where they superimpose, whereas elsewhere the summed Pattersons will have a lower value owing to lack of image superposition. Therefore, the sum function determines the average Patterson density for superimposed images, and is represented analytically as

$$S(\mathbf{x}) = \sum_{i=1}^{N} P(\mathbf{x} + \mathbf{u}_i),$$

where $S(\mathbf{x})$ is the sum function at $\mathbf{x}$ given by the superposition of the ith Patterson translated by $\mathbf{u}_i$, or

$$S(\mathbf{x}) = \sum_{\mathbf{h}} \left\{ F_{\mathbf{h}}^2 \exp(2\pi i \mathbf{h} \cdot \mathbf{x}) \left[\sum_{i=1}^{N} \exp(2\pi i \mathbf{h} \cdot \mathbf{u}_i) \right] \right\}.$$

Setting

$$m \exp(i\varphi_{\mathbf{h}}) = \sum_{i=1}^{N} \exp(2\pi i \mathbf{h} \cdot \mathbf{u}_i)$$

(m and $\varphi_{\mathbf{h}}$ can be calculated from the translational vectors used for the superposition),

$$S(\mathbf{x}) = \sum_{\mathbf{h}} F_{\mathbf{h}}^2 m \exp(2\pi i \mathbf{h} \cdot \mathbf{x} + \varphi_{\mathbf{h}}).$$

Thus, the sum function is equivalent to a weighted 'heavy atom' method based on the known atoms assumed by the superposition translation vectors.

The product function is somewhat more vigorous in that the images are enhanced by the product. If an image is superimposed on no image, then the product should be zero.

The product function can be expressed as

$$Pr(\mathbf{x}) = \prod_{i=1}^{N} P(\mathbf{x} + \mathbf{u}_i).$$

When $N = 2$ ($\mathbf{h}$ and $\mathbf{p}$ are sets of Miller indices),

$$Pr(\mathbf{x}) = \sum_{\mathbf{h}} \sum_{\mathbf{p}} F_{\mathbf{h}}^2 F_{\mathbf{p}}^2 \exp[2\pi i(\mathbf{h} + \mathbf{p}) \cdot \mathbf{x}] \times \exp[2\pi i(\mathbf{h} \cdot \mathbf{u}_i + \mathbf{p} \cdot \mathbf{u}_i)].$$

Successive superpositions using the product functions will quickly be dominated by a few terms with very large coefficients.

Finally, the minimum function is a clever invention of Buerger (Buerger, 1950*b*, 1951, 1953*a*,*b*,*c*; Taylor, 1953; Rogers, 1951). If a superposition is correct then each Patterson must represent an image of the structure. Whenever there are two or more images that intersect in the Patterson, the Patterson density will be greater than a single image. When two different images are superimposed, it is a reasonable hope that at least one of these is a single image. Thus by taking the value of that Patterson which is the minimum, it should be possible to select a single image and eliminate noise from interfering images as far as possible. Although the minimum function is perhaps the most powerful algorithm for image selection of well sharpened Pattersons, it is not readily amenable to Fourier representation.

The minimum function was conceived on the basis of selecting positive images on a near-zero background. If it were desired to select negative images [*e.g.* the $(\mathbf{F}_1 - \mathbf{F}_2)^2$ correlation function discussed in Section 2.3.3.4], then it would be necessary to use a maximum function. In fact, normally, an image has finite volume with varying density. Thus, some modification of the minimum function is necessary in those cases where the image is large compared to the volume of the unit cell, as in low-resolution protein structures (Rossmann, 1961*b*). Nordman (1966) used the average of the Patterson values of the lowest 10 to 20 per cent of the vectors in comparing Pattersons with hypothetical point Pattersons. A similar criterion was used by High & Kraut (1966).

Image-seeking methods using Patterson superposition have been used extensively (Beevers & Robertson, 1950; Garrido, 1950*b*; Robertson, 1951). For a review the reader is referred to *Vector Space* (Buerger, 1959) and a paper by Fridrichsons & Mathieson (1962). However, with the advent of computerized direct methods (see Chapter 2.2), such techniques are no longer popular. Nevertheless, they provide the conceptual framework for the rotation and translation functions (see Sections 2.3.6 and 2.3.7).

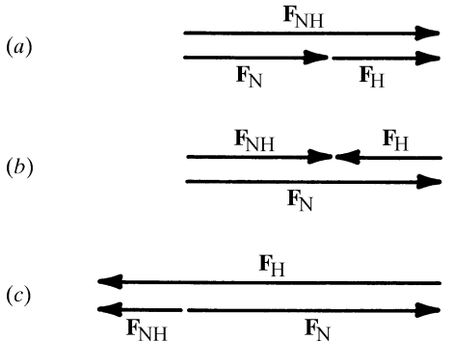

Fig. 2.3.3.1. Three different cases which can occur in the relation of the native, $\mathbf{F}_N$, and heavy-atom derivative, $\mathbf{F}_{NH}$, structure factors for centrosymmetric reflections. $\mathbf{F}_N$ is assumed to have a phase of 0, although analogous diagrams could be drawn when $\mathbf{F}_N$ has a phase of π. The crossover situation in (*c*) is clearly rare if the heavy-atom substitution is small compared to the native molecule, and can in general be neglected.

2.3.2.5. Systematic computerized Patterson vector-search procedures. Looking for rigid bodies

The power of the modern digital computer has enabled rapid access to the large number of Patterson density values which can serve as a lookup table for systematic vector-search procedures. In the late 1950s, investigators began to use systematic searches for the placement of single atoms, of known chemical groups or fragments and of entire known structures. Methods for locating single atoms were developed and called variously: vector verification (Mighell & Jacobson, 1963), symmetry minimum function (Kraut, 1961; Simpson *et al*., 1965; Corfield & Rosenstein, 1966) and consistency functions (Hamilton, 1965). Patterson superposition techniques using stored function values were often used to image the structure from the known portion. In such single-site search procedures, single atoms are placed at all possible positions in a crystal, using a search grid of the same fineness as for the stored Patterson function, preferably about one-third of the resolution of the Patterson map. Solutions are gauged to be acceptable if all expected vectors due to symmetry-related atoms are observed above a specified threshold in the Patterson.

Systematic computerized Patterson search procedures for orienting and positioning known molecular fragments were also developed in the early 1960s. These hierarchical procedures rely on first using the 'self'-vectors which depend only on the orientation of a molecular fragment. A search for the position of the fragment relative to the crystal symmetry elements then uses the cross-vectors between molecules (see Sections 2.3.6 and 2.3.7). Nordman constructed a weighted point representation of the predicted vector set for a fragment (Nordman & Nakatsu, 1963; Nordman, 1966) and successfully solved the structure of a number of complex alkaloids. Huber (1965) used the convolution molecule method of Hoppe (1957*a*) in three dimensions to solve a number of natural-product structures, including steroids. Various program systems have used Patterson search methods operating in real space to solve complex structures (Braun *et al*., 1969; Egert, 1983).

Others have used reciprocal-space procedures for locating known fragments. Tollin & Cochran (1964) developed a procedure for determining the orientation of planar groups by searching for origin-containing planes of high density in the Patterson. General procedures using reciprocal-space representations for determining rotation and translation parameters have been developed and will be described in Sections 2.3.6 and 2.3.7, respectively.

Although as many functions have been used to detect solutions in these Patterson search procedures as there are programs, most rely on some variation of the sum, product and minimum functions (Section 2.3.2.4). The quality of the stored Patterson density representation also varies widely, but it is now common to use 16 or more bits for single density values. Treatment of vector overlap is handled differently by different investigators and the choice will depend on the degree of overlapping (Nordman & Schilling, 1970; Nordman, 1972). General Gaussian multiplicity corrections can be employed to treat coincidental overlap of independent vectors in general positions and overlap which occurs for symmetric peaks in the vicinity of a special position or mirror plane in the Patterson (G. Kamer, S. Ramakumar & P. Argos, unpublished results; Rossmann *et al*., 1972).

2.3.3. Isomorphous replacement difference Pattersons

2.3.3.1. Introduction

One of the initial stages in the application of the isomorphous replacement method is the determination of heavy-atom positions. Indeed, this step of a structure determination can often be the most challenging. Not only may the number of heavy-atom sites be unknown, and have incomplete substitution, but the various isomorphous compounds may also lack isomorphism. To compound these problems, the error in the measurement of the isomorphous difference in structure amplitudes is often comparable to the differences themselves. Clearly, therefore, the ease with which a particular problem can be solved is closely correlated with the quality of the data-measuring procedure.

The isomorphous replacement method was used incidentally by Bragg in the solution of NaCl and KCl. It was later formalized by J. M. Robertson in the analysis of phthalocyanine where the coordination centre could be Pt, Ni and other metals (Robertson, 1935, 1936; Robertson & Woodward, 1937). In this and similar cases, there was no difficulty in finding the heavy-atom positions. Not only were the heavy atoms frequently in special positions, but they dominated the total scattering effect. It was not until Perutz and his colleagues (Green *et al*., 1954; Bragg & Perutz, 1954) applied the technique to the solution of haemoglobin, a protein of 68 000 Da, that it was necessary to consider methods for detecting heavy atoms. The effect of a single heavy atom, even uranium, can only have a very marginal effect on the structure amplitudes of a crystalline macromolecule. Hence, techniques had to be developed which were dependent on the difference of the isomorphous structure amplitudes rather than on the solution of the Patterson of the heavy-atom-derivative compound on its own.

2.3.3.2. Finding heavy atoms with centrosymmetric projections

Phases in a centrosymmetric projection will be 0 or π if the origin is chosen at the centre of symmetry. Hence, the native structure factor, $\mathbf{F}_N$, and the heavy-atom-derivative structure factor, $\mathbf{F}_{NH}$, will be collinear. It follows that the structure amplitude, $|\mathbf{F}_H|$, of the heavy atoms alone in the cell will be given by

$$|\mathbf{F}_H| = |(|\mathbf{F}_{NH}| \pm |\mathbf{F}_N|)| + \varepsilon,$$

where ε is the error on the parenthetic sum or difference. Three different cases may arise (Fig. 2.3.3.1). Since the situation shown in Fig. 2.3.3.1(*c*) is rare, in general

$$|\mathbf{F}_H|^2 \simeq (|\mathbf{F}_{NH}| - |\mathbf{F}_N|)^2. \qquad (2.3.3.1)$$

Thus, a Patterson computed with the square of the differences between the native and derivative structure amplitudes of a centrosymmetric projection will approximate to a Patterson of the heavy atoms alone.

The approximation (2.3.3.1) is valid if the heavy-atom substitution is small enough to make $|\mathbf{F}_H| \ll |\mathbf{F}_{NH}|$ for most reflections, but sufficiently large to make $\varepsilon \ll (|\mathbf{F}_{NH}| - |\mathbf{F}_N|)^2$. It is also

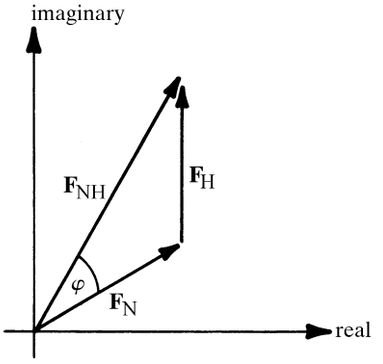

Fig. 2.3.3.2. Vector triangle showing the relationship between $\mathbf{F}_N$, $\mathbf{F}_{NH}$ and $\mathbf{F}_H$, where $\mathbf{F}_{NH} = \mathbf{F}_N + \mathbf{F}_H$.

assumed that the native and heavy-atom-derivative data have been placed on the same relative scale. Hence, the relation (2.3.3.1) should be rewritten as

$$|\mathbf{F}_H|^2 \simeq (|\mathbf{F}_{NH}| - k|\mathbf{F}_N|)^2,$$

where k is an experimentally determined scale factor (see Section 2.3.3.7). Uncertainty in the determination of k will contribute further to ε, albeit in a systematic manner.

Centrosymmetric projections were used extensively for the determination of heavy-atom sites in early work on proteins such as haemoglobin (Green *et al.*, 1954), myoglobin (Bluhm *et al.*, 1958) and lysozyme (Poljak, 1963). However, with the advent of faster data-collecting techniques, low-resolution (*e.g.* a 5 Å limit) three-dimensional data are to be preferred for calculating difference Pattersons. For noncentrosymmetric reflections, the approximation (2.3.3.1) is still valid but less exact (Section 2.3.3.3). However, the larger number of three-dimensional differences compared to projection differences will enhance the signal of the real Patterson peaks relative to the noise. If there are N terms in the Patterson synthesis, then the peak-to-noise ratio will be proportionally $\sqrt{N}$ and $1/\varepsilon$. With the subscripts 2 and 3 representing two- and three-dimensional syntheses, respectively, the latter will be more powerful than the former whenever

$$\frac{\sqrt{N_3}}{\varepsilon_3} > \frac{\sqrt{N_2}}{\varepsilon_2}.$$

Now, as $\varepsilon_3 \simeq \sqrt{2}\varepsilon_2$, it follows that N_3 must be greater than $2N_2$ if the three-dimensional noncentrosymmetric computation is to be more powerful. This condition must almost invariably be true.

2.3.3.3. Finding heavy atoms with three-dimensional methods

A Patterson of a native biomacromolecular structure (coefficients F_N^2) can be considered as being, at least approximately, a vector map of all the light atoms (carbons, nitrogens, oxygens, some sulfurs, and also phosphorus for nucleic acids) other than hydrogen atoms. These interactions will be designated as LL. Similarly, a Patterson of the heavy-atom derivative will contain $HH + HL + LL$ interactions, where H represents the heavy atoms. Thus, a true difference Patterson, with coefficients $F_{NH}^2 - F_N^2$, will contain only the interactions $HH + HL$. In general, the carpet of HL vectors completely dominates the HH vectors except for very small proteins such as insulin (Adams *et al.*, 1969). Therefore, it would be preferable to compute a Patterson containing only HH interactions in order to interpret the map in terms of specific heavy-atom sites.

Blow (1958) and Rossmann (1960) showed that a Patterson with $(|\mathbf{F}_{NH}| - |\mathbf{F}_N|)^2$ coefficients approximated to a Patterson containing only HH vectors. If the phase angle between $\mathbf{F}_N$ and $\mathbf{F}_{NH}$ is φ (Fig. 2.3.3.2), then

$$|\mathbf{F}_H|^2 = |\mathbf{F}_N|^2 + |\mathbf{F}_{NH}|^2 - 2|\mathbf{F}_N||\mathbf{F}_{NH}|\cos\varphi.$$

In general, however, $|\mathbf{F}_H| \ll |\mathbf{F}_N|$. Hence, φ is small and

$$|\mathbf{F}_H|^2 \simeq (|\mathbf{F}_{NH}| - |\mathbf{F}_N|)^2,$$

which is the same relation as (2.3.3.1) for centrosymmetric approximations. Since the direction of $\mathbf{F}_H$ is random compared to $\mathbf{F}_N$, the root-mean-square projected length of $\mathbf{F}_H$ onto $\mathbf{F}_N$ will be $\mathbf{F}_H/\sqrt{2}$. Thus it follows that a better approximation is

$$|\mathbf{F}_H|^2 \simeq \sqrt{2}(|\mathbf{F}_{NH}| - |\mathbf{F}_N|)^2, \qquad (2.3.3.2)$$

which accounts for the assumption (Section 2.3.3.2) that $\varepsilon_3 = \sqrt{2}\varepsilon_2$. The almost universal method for the initial determination of major heavy-atom sites in an isomorphous derivative utilizes a Patterson with $(|\mathbf{F}_{NH}| - |\mathbf{F}_N|)^2$ coefficients. Approximation (2.3.3.2) is also the basis for the refinement of heavy-atom parameters in a single isomorphous replacement pair (Rossmann, 1960; Cullis *et al.*, 1962; Terwilliger & Eisenberg, 1983).

2.3.3.4. Correlation functions

In the most general case of a triclinic space group, it will be necessary to select an origin arbitrarily, usually coincident with a heavy atom. All other heavy atoms (and subsequently also the macromolecular atoms) will be referred to this reference atom. However, the choice of an origin will be independent in the interpretation of each derivative's difference Patterson. It will then be necessary to correlate the various, arbitrarily chosen, origins. The same problem occurs in space groups lacking symmetry axes perpendicular to the primary rotation axis (*e.g.* $P2_1$, $P6$ *etc.*), although only one coordinate, namely parallel to the unique rotation axis, will require correlation. This problem gave rise to some concern in the 1950s. Bragg (1958), Blow (1958), Perutz (1956), Hoppe (1959) and Bodo *et al.* (1959) developed a variety of techniques, none of which were entirely satisfactory. Rossmann (1960) proposed the $(\mathbf{F}_{NH1} - \mathbf{F}_{NH2})^2$ synthesis and applied it successfully to the heavy-atom determination of horse haemoglobin. This function gives positive peaks ($H1 \cdot H1$) at the end of vectors between the heavy-atom sites in the first compound, positive peaks ($H2 \cdot H2$) between the sites in the second compound, and negative peaks between sites in the first and second compound (Fig. 2.3.3.3). It is thus the negative peaks which provide the necessary correlation. The function is unique in that it is a Patterson containing significant information in both positive and negative peaks. Steinrauf (1963) suggested using the coefficients $(|\mathbf{F}_{NH1}| - |\mathbf{F}_N|) \cdot (|\mathbf{F}_{NH2}| - |\mathbf{F}_N|)$ in order to eliminate the positive $H1 \cdot H1$ and $H2 \cdot H2$ vectors.

Although the problem of correlation was a serious concern in the early structural determination of proteins during the late 1950s and early 1960s, the problem has now been bypassed. Blow & Rossmann (1961) and Kartha (1961) independently showed that it was possible to compute usable phases from a single isomorphous replacement (SIR) derivative. This contradicted the previously accepted notion that it was necessary to have at least two isomorphous derivatives to be able to determine a noncentrosymmetric reflection's phase (Harker, 1956). Hence, currently, the procedure used to correlate origins in different derivatives is to compute SIR phases from the first compound and apply them to a difference electron-density map of the second heavy-atom derivative. Thus, the origin of the second

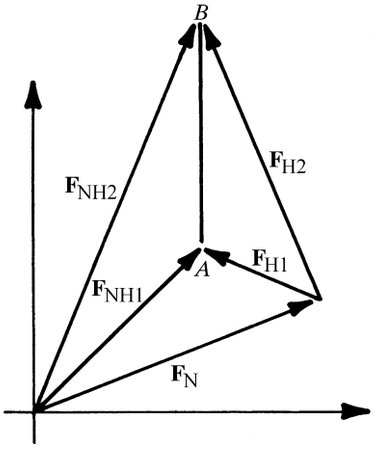

Fig. 2.3.3.3. A Patterson with coefficients $(\mathbf{F}_{NH1} - \mathbf{F}_{NH2})^2$ will be equivalent to a Patterson whose coefficients are $(AB)^2$. However, $AB = -\mathbf{F}_{H1} + \mathbf{F}_{H2}$. Thus, a Patterson with $(AB)^2$ coefficients is equivalent to having negative atomic substitutions in compound 1 and positive substitutions in compound 2, or *vice versa*. Therefore, the Patterson will contain positive peaks for vectors of the type $H1 \cdot H1$ and $H2 \cdot H2$, but negative vector peaks for vectors of type $H1 \cdot H2$.

derivative will be referred to the arbitrarily chosen origin of the first compound. More important, however, the interpretation of such a 'feedback' difference Fourier is easier than that of a difference Patterson. Hence, once one heavy-atom derivative has been solved for its heavy-atom sites, the solution of other derivatives is almost assured. This concept is examined more closely in the following section.

2.3.3.5. Interpretation of isomorphous difference Pattersons

Difference Pattersons have usually been manually interpreted in terms of point atoms. In more complex situations, such as crystalline viruses, a systematic approach may be necessary to analyse the Patterson. That is especially true when the structure contains noncrystallographic symmetry (Argos & Rossmann, 1976). Such methods are in principle dependent on the comparison of the observed Patterson, $P_1(\mathbf{x})$, with a calculated Patterson, $P_2(\mathbf{x})$. A criterion, C_P, based on the sum of the Patterson densities at all test vectors within the unit-cell volume V, would be

$$C_P = \int_V P_1(\mathbf{x}) \cdot P_2(\mathbf{x})\, d\mathbf{x}.$$

C_P can be evaluated for all reasonable heavy-atom distributions. Each different set of trial sites corresponds to a different P_2 Patterson. It is then easily shown that

$$C_P = \sum_{\mathbf{h}} \Delta_{\mathbf{h}}^2 E_{\mathbf{h}}^2,$$

where the sum is taken over all $\mathbf{h}$ reflections in reciprocal space, $\Delta_{\mathbf{h}}^2$ are the observed differences and $E_{\mathbf{h}}$ are the structure factors of the trial point Patterson. (The symbol E is used here because of its close relation to normalized structure factors.)

Let there be n noncrystallographic asymmetric units within the crystallographic asymmetric unit and m crystallographic asymmetric units within the crystal unit cell. Then there are L symmetry-related heavy-atom sites where $L = nm$. Let the scattering contribution of the ith site have a_i and b_i real and imaginary structure-factor components with respect to an arbitrary origin. Hence, for reflection $\mathbf{h}$

$$E_{\mathbf{h}}^2 \left(\sum_L a_{\mathbf{h}i}\right)^2 + \left(\sum_L b_{\mathbf{h}i}\right)^2 = L + \sum_{i\neq j}^{N}\sum^{N} (a_{\mathbf{h}i}a_{\mathbf{h}j} + b_{\mathbf{h}i}b_{\mathbf{h}j}).$$

Therefore,

$$C_P = \sum_{\mathbf{h}} \Delta_{\mathbf{h}}^2 \left[L + 2 \sum_{i\neq j}\sum (a_{\mathbf{h}i}a_{\mathbf{h}j} + b_{\mathbf{h}i}b_{\mathbf{h}j}) \right].$$

But $\sum_{\mathbf{h}} \Delta_{\mathbf{h}}^2$ must be independent of the number, L, of heavy-atom sites per cell. Thus the criterion can be rewritten as

$$C'_P = \sum_{\mathbf{h}} \Delta_{\mathbf{h}}^2 \left[\sum_{i\neq j}\sum (a_{\mathbf{h}i}a_{\mathbf{h}j} + b_{\mathbf{h}i}b_{\mathbf{h}j}) \right]. \quad (2.3.3.3)$$

More generally, if some sites have already been tentatively determined, and if these sites give rise to the structure-factor components $A_{\mathbf{h}}$ and $B_{\mathbf{h}}$, then

$$E_{\mathbf{h}}^2 = \left(A_{\mathbf{h}} + \sum_N a_{\mathbf{h}i}\right)^2 + \left(B_{\mathbf{h}} + \sum_N b_{\mathbf{h}i}\right)^2. \quad (2.3.3.4)$$

Following the same procedure as above, it follows that

$$C'_P = \sum_{\mathbf{h}} \Delta_{\mathbf{h}}^2 \left[(A_{\mathbf{h}}a_{\mathbf{h}} + B_{\mathbf{h}}b_{\mathbf{h}}) + \sum_{i\neq j}\sum (a_{\mathbf{h}i}a_{\mathbf{h}j} + b_{\mathbf{h}i}b_{\mathbf{h}j}) \right], \quad (2.3.3.5)$$

where $a_{\mathbf{h}} = \sum_{i=1}^{L} a_{\mathbf{h}i}$ and $b_{\mathbf{h}} = \sum_{i=1}^{L} b_{\mathbf{h}i}$.

Expression (2.3.3.5) will now be compared with the 'feedback' method (Dickerson *et al.*, 1967, 1968) of verifying heavy-atom sites using SIR phasing. Inspection of Fig. 2.3.3.4 shows that the native phase, α, will be determined as $\alpha = \varphi + \pi$ (φ is the structure-factor phase corresponding to the presumed heavy-atom positions) when $|\mathbf{F}_N| > |\mathbf{F}_H|$ and $\alpha = \varphi$ when $|\mathbf{F}_N| \ll |\mathbf{F}_H|$. Thus, an SIR difference electron density, $\Delta\rho(\mathbf{x})$, can be synthesized by the Fourier summation

$$\begin{aligned}\Delta\rho(\mathbf{x}) =& \frac{1}{V}\sum m(|\mathbf{F}_{NH}| - |\mathbf{F}_N|)\cos(2\pi\mathbf{h}\cdot\mathbf{x} - \varphi_{\mathbf{h}}) \\ & \text{from terms with } \Delta_{\mathbf{h}} = |\mathbf{F}_{NH}| - |\mathbf{F}_N| > 0 \\ & + \frac{1}{V}\sum m(|\mathbf{F}_{NH}| - |\mathbf{F}_N|)\cos(2\pi\mathbf{h}\cdot\mathbf{x} - \varphi_{\mathbf{h}} - \pi) \\ & \text{from terms with } \Delta_{\mathbf{h}} < 0 \\ =& \frac{1}{V}\sum m|\Delta_{\mathbf{h}}|\cos(2\pi\mathbf{h}\cdot\mathbf{x} - \varphi_{\mathbf{h}}),\end{aligned}$$

where m is a figure of merit of the phase reliability (Blow & Crick, 1959; Dickerson *et al.*, 1961). Now,

$$\mathbf{F}_{\mathbf{h}} = A_{\mathbf{h}} + iB_{\mathbf{h}} = F_H \cos\varphi_{\mathbf{h}} + iF_H \sin\varphi_{\mathbf{h}},$$

where $A_{\mathbf{h}}$ and $B_{\mathbf{h}}$ are the real and imaginary components of the presumed heavy-atom sites. Therefore,

$$\Delta\rho(\mathbf{x}) = \frac{1}{V}\sum \frac{m|\Delta_{\mathbf{h}}|}{|\mathbf{F}_H|}(A_{\mathbf{h}}\cos 2\pi\mathbf{h}\cdot\mathbf{x} + B_{\mathbf{h}}\sin 2\pi\mathbf{h}\cdot\mathbf{x}).$$

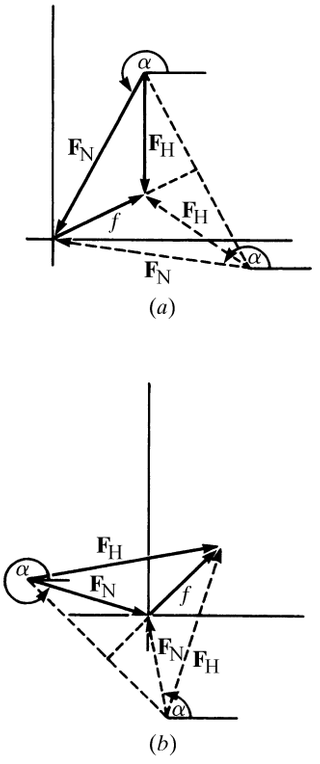

Fig. 2.3.3.4. The phase α of the native compound (structure factor $\mathbf{F}_N$) is determined either as being equal to, or 180° out of phase with, the presumed heavy-atom contribution when only a single isomorphous compound is available. In (*a*) is shown the case when $|\mathbf{F}_N| > |\mathbf{F}_{NH}|$ and $\alpha \simeq \varphi + \pi$. In (*b*) is shown the case when $|\mathbf{F}_N| < |\mathbf{F}_{NH}|$ and $\alpha = \varphi$, where φ is the phase of the heavy-atom structure factor $\mathbf{F}_H$.

If this SIR difference electron-density map shows significant peaks at sites related by noncrystallographic symmetry, then those sites will be at the position of a further set of heavy atoms. Hence, a suitable criterion for finding heavy-atom sites is

$$C_{\rm SIR} = \sum_{j=1}^{n} \Delta\rho(\mathbf{x}_j),$$

or by substitution

$$C_{\rm SIR} = \sum_{j=1}^{n} \frac{1}{V} \sum_{\mathbf{h}} \frac{m|\Delta_{\mathbf{h}}|}{|\mathbf{F}_H|} (A_{\mathbf{h}} \cos 2\pi\mathbf{h}\cdot\mathbf{x}_j + B_{\mathbf{h}} \sin 2\pi\mathbf{h}\cdot\mathbf{x}_j).$$

But

$$a_{\mathbf{h}} = \sum_{j=1}^{n} \cos 2\pi\mathbf{h}\cdot\mathbf{x}_j \quad \text{and} \quad b_{\mathbf{h}} = \sum_{j=1}^{n} \sin 2\pi\mathbf{h}\cdot\mathbf{x}_j.$$

Therefore,

$$C_{\rm SIR} = \frac{1}{V} \sum_{\mathbf{h}} \frac{m|\Delta_{\mathbf{h}}|}{|\mathbf{F}_H|} (A_{\mathbf{h}} a_{\mathbf{h}} + B_{\mathbf{h}} b_{\mathbf{h}}). \qquad (2.3.3.6)$$

This expression is similar to (2.3.3.5) derived by consideration of a Patterson search. It differs from (2.3.3.5) in two respects: the Fourier coefficients are different and expression (2.3.3.6) is lacking a second term. Now the figure of merit m will be small whenever $|\mathbf{F}_H|$ is small as the SIR phase cannot be determined well under those conditions. Hence, effectively, the coefficients are a function of $|\Delta_{\mathbf{h}}|$, and the coefficients of the functions

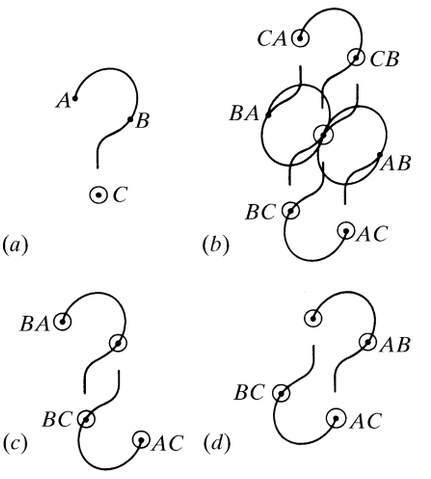

Fig. 2.3.3.5. Let (*a*) be the original structure which contains three heavy atoms *ABC* in a noncentrosymmetric configuration. Then a Fourier summation, with $(F_{NH}^2 - F_N^2)$ coefficients, will give the Patterson shown in (*b*). Displacement of the Patterson by the vector *BC* and selecting the common patterns yields (*c*). Similarly, displacement by *AC* gives (*d*). Finally, superposition of (*c*) on (*d*) gives the original figure or its enantiomorph. This series of steps demonstrates that, in principle, complete structural information is contained in an SIR derivative.

(2.3.3.5) and (2.3.3.6) are indeed rather similar. The second term in (2.3.3.5) relates to the use of the search atoms in phasing and could be included in (2.3.3.6), provided the actual feedback sites in each of the n electron-density functions tested by $C_{\rm SIR}$ are omitted in turn. Thus, a systematic Patterson search and an SIR difference Fourier search are very similar in character and power.

2.3.3.6. Direct structure determination from difference Pattersons

The difference Patterson computed with coefficients $F_{HN}^2 - F_N^2$ contains information on the heavy atoms (*HH* vectors) and the macromolecular structure (*HL* vectors) (Section 2.3.3.3). If the scaling between the $|\mathbf{F}_{HN}|$ and $|\mathbf{F}_N|$ data sets is not perfect there will also be noise. Rossmann (1961*b*) was partially successful in determining the low-resolution horse haemoglobin structure by using a series of superpositions based on the known heavy-atom sites. Nevertheless, Patterson superposition methods have not been used for the structure determination of proteins owing to the successful error treatment of the isomorphous replacement method in reciprocal space. However, it is of some interest here for it gives an alternative insight into SIR phasing.

The deconvolution of an arbitrary molecule, represented as '?', from an $(F_{HN}^2 - F_N^2)$ Patterson, is demonstrated in Fig. 2.3.3.5. The original structure is shown in Fig. 2.3.3.5(*a*) and the corresponding Patterson in Fig. 2.3.3.5(*b*). Superposition with respect to one of the heavy-atom sites is shown in Fig. 2.3.3.5(*c*) and the other in Fig. 2.3.3.5(*d*). Both Figs. 2.3.3.5(*c*) and (*d*) contain a centre of symmetry because the use of only a single *HH* vector implies a centre of symmetry half way between the two sites. The centre is broken on combining information from all three sites (which together lack a centre of symmetry) by superimposing Figs. 2.3.3.5(*c*) and (*d*) to obtain either the original structure (Fig. 2.3.3.5*a*) or its enantiomorph. Thus it is clear, in principle, that there is sufficient information in a single isomorphous derivative data set, when used in conjunction with a native data set, to solve a structure completely. However, the procedure shown in Fig. 2.3.3.5 does not consider the accumulation of error in the selection of individual images when these intersect with another image. In this sense the reciprocal-space isomorphous replacement technique has greater elegance and provides more insight, whereas the alternative view given by the Patterson method was the original stimulus for the discovery of the SIR phasing technique (Blow & Rossmann, 1961).

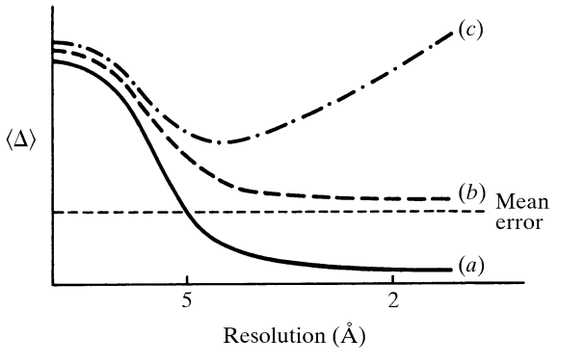

Fig. 2.3.3.6. A plot of mean isomorphous differences as a function of resolution. (*a*) The theoretical size of mean differences following roughly a Gaussian distribution. (*b*) The observed size of differences for a good isomorphous derivative where the smaller higher-order differences have been largely masked by the error of measurement. (*c*) Observed differences where 'lack of isomorphism' dominates beyond approximately 5 Å resolution.

Other Patterson functions for the deconvolution of SIR data have been proposed by Ramachandran & Raman (1959), as well as others. The principles are similar but the coefficients of the functions are optimized to emphasize various aspects of the signal representing the molecular structure.

2.3.3.7. Isomorphism and size of the heavy-atom substitution

It is insufficient to discuss Patterson techniques for locating heavy-atom substitutions without also considering errors of all kinds. First, it must be recognized that most heavy-atom labels are not a single atom but a small compound containing one or more heavy atoms. The compound itself will displace water or ions and locally alter the conformation of the protein or nucleic acid. Hence, a simple Gaussian approximation will suffice to represent individual heavy-atom scatterers responsible for the difference between native and heavy-atom derivatives. Furthermore, the heavy-atom compound often introduces small global structural changes which can be detected only at higher resolution. These problems were considered with some rigour by Crick & Magdoff (1956). In general, lack of isomorphism is exhibited by an increase in the size of the isomorphous differences with increasing resolution (Fig. 2.3.3.6).

Crick & Magdoff (1956) also derived the approximate expression

$$\sqrt{\frac{2N_{\rm H}}{N_{\rm P}}}\cdot\frac{f_{\rm H}}{f_{\rm P}}$$

to estimate the r.m.s. fractional change in intensity as a function of heavy-atom substitution. Here, $N_{\rm H}$ represents the number of heavy atoms attached to a protein (or other large molecule) which contains $N_{\rm P}$ light atoms. $f_{\rm H}$ and $f_{\rm P}$ are the scattering powers of the average heavy and protein atom, respectively. This function was tabulated by Eisenberg (1970) as a function of molecular weight (proportional to $N_{\rm P}$). For instance, for a single, fully substituted, Hg atom the formula predicts an r.m.s. intensity change of around 25% in a molecule of 100 000 Da. However, the error of measurement of a reflection intensity is likely to be arround 10% of I, implying perhaps an error of around 14% of I on a difference measurement. Thus, the isomorphous replacement difference measurement for almost half the reflections will be buried in error for this case.

Scaling of the different heavy-atom-derivative data sets onto a common relative scale is clearly important if error is to be reduced. Blundell & Johnson (1976, pp. 333–336) give a careful discussion of this subject. Suffice it to say here only that a linear scale factor is seldom acceptable as the heavy-atom-derivative crystals frequently suffer from greater disorder than the native crystals. The heavy-atom derivative should, in general, have a slightly larger mean value for the structure factors on account of the additional heavy atoms (Green *et al.*, 1954). The usual effect is to make $\sum|\mathbf{F}_{\rm NH}|^2/\sum|\mathbf{F}_{\rm N}|^2 \simeq 1.05$ (Phillips, 1966).

As the amount of heavy atom is usually unknown in a yet unsolved heavy-atom derivative, it is usual practice either to apply a scale factor of the form $k\exp[-B(\sin\theta/\lambda)^2]$ or, more generally, to use local scaling (Matthews & Czerwinski, 1975). The latter has the advantage of not making any assumption about the physical nature of the relative intensity decay with resolution.

2.3.4. Anomalous dispersion

2.3.4.1. Introduction

The physical basis for anomalous dispersion has been well reviewed by Ramaseshan & Abrahams (1975), James (1965), Cromer (1974) and Bijvoet (1954). As the wavelength of radiation approaches the absorption edge of a particular element, then an atom will disperse X-rays in a manner that can be defined by the complex scattering factor

$$f_0 + \Delta f' + i\Delta f'',$$

where f_0 is the scattering factor of the atom without the anomalous absorption and rescattering effect, $\Delta f'$ is the real correction term (usually negative), and $\Delta f''$ is the imaginary component. The real term $f_0 + \Delta f'$ is often written as f', so that the total scattering factor will be $f' + i\Delta f''$. Values of $\Delta f'$ and $\Delta f''$ are tabulated in *IT* IV (Cromer, 1974), although their precise values are dependent on the environment of the anomalous scatterer. Unlike f_0, $\Delta f'$ and $\Delta f''$ are almost independent of scattering angle as they are caused by absorption of energy in the innermost electron shells. Thus, the anomalous effect resembles scattering from a point atom.

The structure factor of index **h** can now be written as

$$\mathbf{F}_{\mathbf{h}} = \sum_{j=1}^{N} f_j' \exp(2\pi i\mathbf{h}\cdot\mathbf{x}_j) + i\sum_{j=1}^{N}\Delta f_j'' \exp(2\pi i\mathbf{h}\cdot\mathbf{x}_j). \qquad (2.3.4.1)$$

(Note that the only significant contributions to the second term are from those atoms that have a measurable anomalous effect at the chosen wavelength.)

Let us now write the first term as $A + iB$ and the second as $a + ib$. Then, from (2.3.4.1),

$$\mathbf{F} = (A + iB) + i(a + ib) = (A - b) + i(B + a). \qquad (2.3.4.2)$$

Therefore,

$$|\mathbf{F}_{\mathbf{h}}|^2 = (A - b)^2 + (B + a)^2$$

and similarly

$$|\mathbf{F}_{\bar{\mathbf{h}}}|^2 = (A + b)^2 + (-B + a)^2,$$

demonstrating that Friedel's law breaks down in the presence of anomalous dispersion. However, it is only for noncentrosymmetric reflections that $|\mathbf{F}_{\mathbf{h}}| \neq |\mathbf{F}_{\bar{\mathbf{h}}}|$.

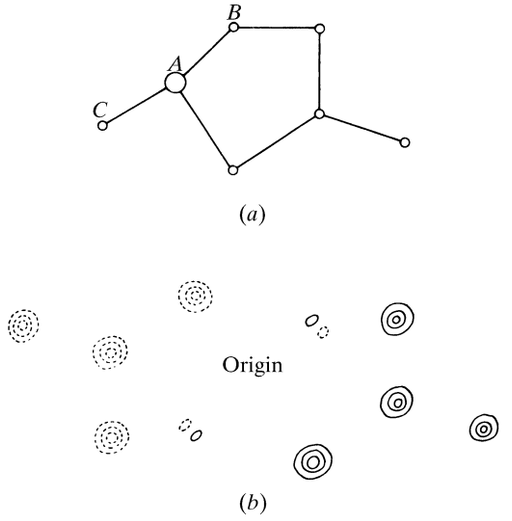

Fig. 2.3.4.1. (*a*) A model structure with an anomalous scatterer at *A*. (*b*) The corresponding $P_s(\mathbf{u})$ function showing positive peaks (full lines) and negative peaks (dashed lines). [Reprinted with permission from Woolfson (1970, p. 293).]

Now,

$$\rho(\mathbf{x}) = \frac{1}{V}\sum_{\mathbf{h}}^{\text{sphere}} \mathbf{F}_{\mathbf{h}} \exp(2\pi i \mathbf{h}\cdot\mathbf{x}).$$

Hence, by using (2.3.4.2) and simplifying,

$$\rho(\mathbf{x}) = \frac{2}{V}\sum_{\mathbf{h}}^{\text{hemisphere}} [(A\cos 2\pi\mathbf{h}\cdot\mathbf{x} - B\sin 2\pi\mathbf{h}\cdot\mathbf{x}) + i(a\cos 2\pi\mathbf{h}\cdot\mathbf{x} - b\sin 2\pi\mathbf{h}\cdot\mathbf{x})]. \quad (2.3.4.3)$$

The first term in (2.3.4.3) is the usual real Fourier expression for electron density, while the second term is an imaginary component due to the anomalous scattering of a few atoms in the cell.

2.3.4.2. The $P_s(\mathbf{u})$ function

Expression (2.3.4.3) gives the complex electron density expression in the presence of anomalous scatterers. A variety of Patterson-type functions can be derived from (2.3.4.3) for the determination of a structure. For instance, the $P_s(\mathbf{u})$ function gives vectors between the anomalous atoms and the 'normal' atoms.

From (2.3.4.1) it is easy to show that

$$\begin{aligned}\mathbf{F}_{\mathbf{h}}\mathbf{F}_{\mathbf{h}}^* &= |\mathbf{F}_{\mathbf{h}}|^2 \\ &= \sum_{i,j}(f_i' f_j' + f_i'' f_j'')\cos 2\pi\mathbf{h}\cdot(\mathbf{x}_i - \mathbf{x}_j) \\ &\quad + \sum_{i,j}(f_i' f_j'' - f_i'' f_j')\sin 2\pi\mathbf{h}\cdot(\mathbf{x}_i - \mathbf{x}_j).\end{aligned}$$

Therefore,

$$|\mathbf{F}_{\mathbf{h}}|^2 + |\mathbf{F}_{\bar{\mathbf{h}}}|^2 = 2\sum_{i,j}(f_i' f_j' + f_i'' f_j'')\cos 2\pi\mathbf{h}\cdot(\mathbf{x}_i - \mathbf{x}_j)$$

and

$$|\mathbf{F}_{\mathbf{h}}|^2 - |\mathbf{F}_{\bar{\mathbf{h}}}|^2 = 2\sum_{i,j}(f_i' f_j'' - f_i'' f_j')\sin 2\pi\mathbf{h}\cdot(\mathbf{x}_i - \mathbf{x}_j).$$

Let us now consider the significance of a Patterson in the presence of anomalous dispersion. The normal Patterson definition is given by

$$\begin{aligned}P(\mathbf{u}) &= \int_V \rho^*(\mathbf{x})\rho(\mathbf{x}+\mathbf{u})\,\mathrm{d}\mathbf{x} \\ &= \frac{1}{V^2}\sum_{\mathbf{h}}^{\text{sphere}} |\mathbf{F}_{\mathbf{h}}|^2 \exp(-2\pi i\mathbf{h}\cdot\mathbf{u}) \\ &\equiv P_c(\mathbf{u}) - iP_s(\mathbf{u}),\end{aligned}$$

where

$$P_c(\mathbf{u}) = \frac{2}{V}\sum_{\mathbf{h}}^{\text{hemisphere}} (|\mathbf{F}_{\mathbf{h}}|^2 + |\mathbf{F}_{\bar{\mathbf{h}}}|^2)\cos 2\pi\mathbf{h}\cdot\mathbf{u}$$

and

$$P_s(\mathbf{u}) = \frac{2}{V}\sum_{\mathbf{h}}^{\text{hemisphere}} (|\mathbf{F}_{\mathbf{h}}|^2 - |\mathbf{F}_{\bar{\mathbf{h}}}|^2)\sin 2\pi\mathbf{h}\cdot\mathbf{u}.$$

The $P_c(\mathbf{u})$ component is essentially the normal Patterson, in which the peak heights have been very slightly modified by the anomalous-scattering effect. That is, the peaks of $P_c(\mathbf{u})$ are proportional in height to $(f_i' f_j' + f_i'' f_j'')$.

The $P_s(\mathbf{u})$ component is more interesting. It represents vectors between the normal atoms in the unit cell and the anomalous scatterers, proportional in height to $(f_i' f_j'' - f_i'' f_j')$ (Okaya *et al.*, 1955). This function is antisymmetric with respect to the change of the direction of the diffraction vector. An illustration of the function is given in Fig. 2.3.4.1. In a unit cell containing N atoms, n of which are anomalous scatterers, the $P_s(\mathbf{u})$ function contains only $n(N-n)$ positive peaks and an equal number of negative peaks related to the former by anticentrosymmetry. The analysis of a $P_s(\mathbf{u})$ synthesis presents problems somewhat similar to those posed by a normal Patterson. The procedure has been used only rarely [*cf.* Moncrief & Lipscomb (1966) and Pepinsky *et al.* (1957)], probably because alternative procedures are available for small compounds and the solution of $P_s(\mathbf{u})$ is too complex for large biological molecules.

2.3.4.3. The position of anomalous scatterers

Anomalous scatterers can be used as an aid to phasing, when their positions are known. But the anomalous-dispersion differences (Bijvoet differences) can also be used to determine or confirm the heavy atoms which scatter anomalously (Rossmann, 1961*a*). Furthermore, the use of anomalous-dispersion information obviates the lack of isomorphism but, on the other hand, the differences are normally far smaller than those produced by a heavy-atom isomorphous replacement.

Consider a structure of many light atoms giving rise to the structure factor $\mathbf{F}_{\mathbf{h}}(N)$. In addition, it contains a few heavy atoms which have a significant anomalous-scattering effect. The non-anomalous component will be $\mathbf{F}_{\mathbf{h}}(H)$ and the anomalous component is $\mathbf{F}_{\mathbf{h}}''(H) = i(\Delta f''/f')\mathbf{F}_{\mathbf{h}}(H)$ (Fig. 2.3.4.2*a*). The total structure factor will be $\mathbf{F}_{\mathbf{h}}$. The Friedel opposite is constructed appropriately (Fig. 2.3.4.2*a*). Now reflect the Friedel opposite construction across the real axis of the Argand diagram (Fig.

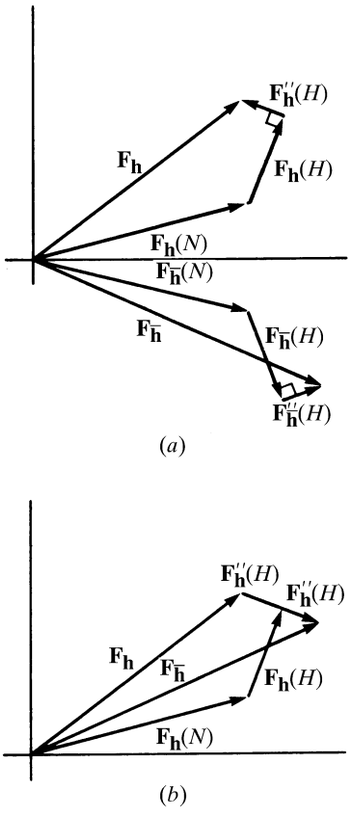

Fig. 2.3.4.2. Anomalous-dispersion effect for a molecule whose light atoms contribute $\mathbf{F}_{\mathbf{h}}(N)$ and heavy atom $\mathbf{F}_{\mathbf{h}}(H)$ with a small anomalous component of $\mathbf{F}_{\mathbf{h}}''(H)$, 90° ahead of the non-anomalous $\mathbf{F}_{\mathbf{h}}(H)$ component. In (*a*) is seen the construction for $\mathbf{F}_{\mathbf{h}}$ and $\mathbf{F}_{\bar{\mathbf{h}}}$. In (*b*) $\mathbf{F}_{\bar{\mathbf{h}}}$ has been reflected across the real axis.

2.3.4.2*b*). Let the difference in phase between $\mathbf{F}_{\mathbf{h}}$ and $\mathbf{F}_{\bar{\mathbf{h}}}$ be φ. Thus

$$4|\mathbf{F}_{\mathbf{h}}''(H)|^2 = |\mathbf{F}_{\mathbf{h}}|^2 + |\mathbf{F}_{\bar{\mathbf{h}}}|^2 - 2|\mathbf{F}_{\mathbf{h}}||\mathbf{F}_{\bar{\mathbf{h}}}|\cos\varphi,$$

but since φ is very small

$$|\mathbf{F}_{\mathbf{h}}''(H)|^2 \simeq \tfrac{1}{4}(|\mathbf{F}_{\mathbf{h}}| - |\mathbf{F}_{\bar{\mathbf{h}}}|)^2.$$

Hence, a Patterson with coefficients $(|\mathbf{F}_{\mathbf{h}}| - |\mathbf{F}_{\bar{\mathbf{h}}}|)^2$ will be equivalent to a Patterson with coefficients $|\mathbf{F}_{\mathbf{h}}''(H)|^2$ which is proportional to $|\mathbf{F}_{\mathbf{h}}(H)|^2$. Such a Patterson (Rossmann, 1961*a*) will have vectors between all anomalous scatterers with heights proportional to the number of anomalous electrons $\Delta f''$. This 'anomalous dispersion' Patterson function has been used to find anomalous scatterers such as iron (Smith *et al.*, 1983; Strahs & Kraut, 1968) and sulfur atoms (Hendrickson & Teeter, 1981). The anomalous signal from Se atoms in selenomethionine-substituted proteins has been found to be extremely powerful and is now routinely used for protein structure determinations (Hendrickson, 1991). Anomalous signals from halide ions or xenon atoms have also been used to solve protein structures (Dauter *et al.*, 2000; Nagem *et al.*, 2003; Schiltz *et al.*, 2003). The anomalous signal from sulfur atoms, though very small (Hendrickson & Teeter, 1981), has recently been applied successfully to solve several protein structures (Debreczeni *et al.*, 2003; Ramagopal *et al.*, 2003; Yang *et al.*, 2003).

It is then apparent that a Patterson with coefficients

$$\Delta F_{\mathrm{ANO}}^2 = (|\mathbf{F}_{\mathbf{h}}| - |\mathbf{F}_{\bar{\mathbf{h}}}|)^2$$

(Rossmann, 1961*a*), as well as a Patterson with coefficients

$$\Delta F_{\mathrm{ISO}}^2 = (|\mathbf{F}_{\mathrm{NH}}| - |\mathbf{F}_{\mathrm{H}}|)^2$$

(Rossmann, 1960; Blow, 1958), represent Pattersons of the heavy atoms. The $\Delta F_{\mathrm{ANO}}^2$ Patterson suffers from errors which may be larger than the size of the Bijvoet differences, while the $\Delta F_{\mathrm{ISO}}^2$ Patterson may suffer from partial lack of isomorphism. Hence, Kartha & Parthasarathy (1965) have suggested the use of the sum of these two Pattersons, which would then have coefficients $(\Delta F_{\mathrm{ANO}}^2 + \Delta F_{\mathrm{ISO}}^2)$.

However, given both SIR and anomalous-dispersion data, it is possible to make an accurate estimate of the $|\mathbf{F}_{\mathrm{H}}|^2$ magnitudes for use in a Patterson calculation [Blundell & Johnson (1976, p. 340), Matthews (1966), Singh & Ramaseshan (1966)]. In essence, the Harker phase diagram can be constructed out of three circles: the native amplitude and each of the two isomorphous Bijvoet differences, giving three circles in all (Blow & Rossmann, 1961) which should intersect at a single point thus resolving the ambiguity in the SIR data and the anomalous-dispersion data. Furthermore, the phase ambiguities are orthogonal; thus the two data sets are cooperative. It can be shown (Matthews, 1966; North, 1965) that

$$F_{\mathrm{N}}^2 = F_{\mathrm{NH}}^2 + F_{\mathrm{N}}^2 \mp \frac{2}{k}(16k^2F_{\mathrm{P}}^2F_{\mathrm{H}}^2 - \Delta I^2)^{1/2},$$

where $\Delta I = F_{\mathrm{NH}}^{+\,2} - F_{\mathrm{NH}}^{-\,2}$ and $k = \Delta f''/f'$. The sign in the third-term expression is $-$ when $|(\alpha_{\mathrm{NH}} - \alpha_{\mathrm{H}})| < \pi/2$ or $+$ otherwise. Since, in general, $|\mathbf{F}_{\mathrm{H}}|$ is small compared to $|\mathbf{F}_{\mathrm{N}}|$, it is reasonable to assume that the sign above is usually negative. Hence, the heavy-atom lower estimate (HLE) is usually written as

$$F_{\mathrm{HLE}}^2 = F_{\mathrm{NH}}^2 + F_{\mathrm{H}}^2 - \frac{2}{k}(16k^2F_{\mathrm{P}}^2F_{\mathrm{H}}^2 - \Delta I^2)^{1/2},$$

which is an expression frequently used to derive Patterson coefficients useful in the determination of heavy-atom positions when both SIR and anomalous-dispersion data are available.

2.3.4.4. Computer programs for automated location of atomic positions from Patterson maps

Several programs are currently used for automated systematic interpretation of (difference) Patterson maps to locate the positions of heavy atoms and/or anomalous scatterers from isomorphous replacement and anomalous-dispersion data (Weeks *et al.*, 2003). These include *Solve* (Terwilliger & Berendzen, 1999), *CNS* (Brünger *et al.*, 1998), *CCP4* (Collaborative Computational Project, Number 4, 1994) and *Patsol* (Tong & Rossmann, 1993). In these programs, sets of trial atomic positions (seeds) are produced based on one- and two-atom solutions to the Patterson map (see Section 2.3.2.5) (Grosse-Kunstleve & Brunger, 1999; Terwilliger *et al.*, 1987; Tong & Rossmann, 1993). Information from a translation search with a single atom can also be used in this process (Grosse-Kunstleve & Brunger, 1999). Scoring functions have been devised to identify the likely correct solutions, based on agreements with the Patterson map or the observed isomorphous or anomalous differences, as well as the quality of the resulting electron-density map (Terwilliger, 2003*b*; Terwilliger & Berendzen, 1999). The power of modern computers allows the rapid screening of a large collection of trial structures, and the correct solution is found automatically in many cases, even when there is a large number of atomic positions (Weeks *et al.*, 2003).

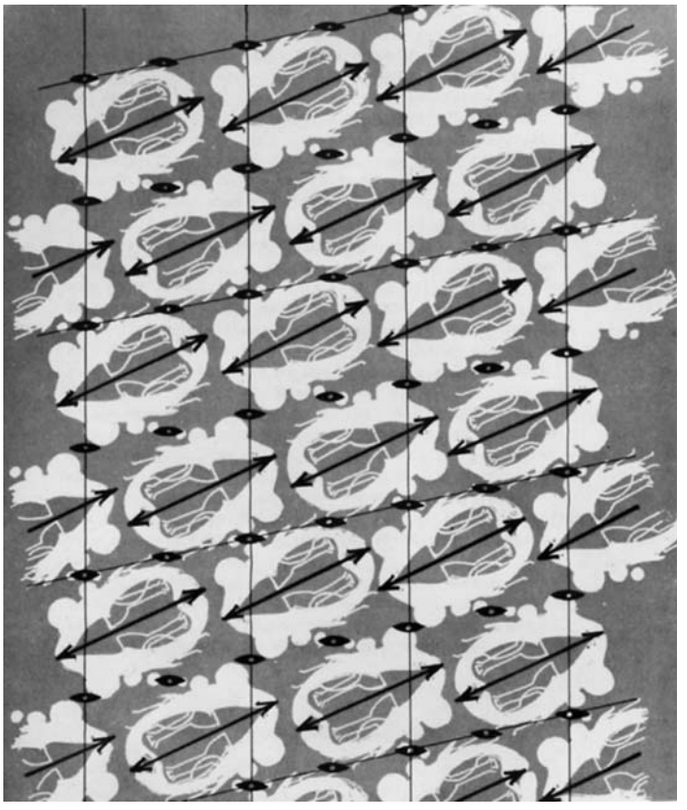

Fig. 2.3.5.1. The two-dimensional periodic design shows crystallographic twofold axes perpendicular to the page and local noncrystallographic rotation axes in the plane of the paper (design by Audrey Rossmann). [Reprinted with permission from Rossmann (1972, p. 8).]

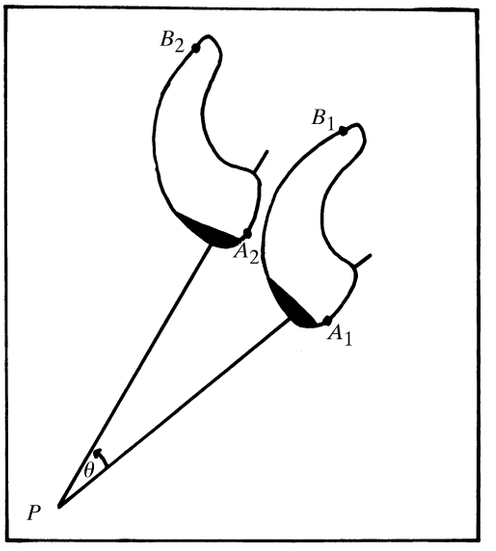

Fig. 2.3.5.2. The objects A_1B_1 and A_2B_2 are related by an improper rotation θ, since it is necessary to consider the sense of rotation to achieve superposition of the two objects. [Reprinted with permission from Rossmann (1972, p. 9).]

2.3.5. Noncrystallographic symmetry

2.3.5.1. Definitions

The interpretation of Pattersons can be helped by using various types of chemical or physical information. An obvious example is the knowledge that one or two heavy atoms per crystallographic asymmetric unit are present. Another example is the exploitation of a rigid chemical framework in a portion of a molecule (Nordman & Nakatsu, 1963; Burnett & Rossmann, 1971). One extremely useful constraint on the interpretation of Pattersons is noncrystallographic symmetry. Indeed, the structural solution of large biological assemblies such as viruses is only possible because of the natural occurrence of this phenomenon. The term 'molecular replacement' is used for methods that utilize noncrystallographic symmetry in the solution of structures [for earlier reviews see Rossmann (1972); Argos & Rossmann (1980); and Rossmann (1990, 2001)]. These methods, which are only partially dependent on Patterson concepts, are discussed in Sections 2.3.6–2.3.8.

Crystallographic symmetry applies to the whole of the three-dimensional crystal lattice. Hence, the symmetry must be expressed both in the lattice and in the repeating pattern within the lattice. In contrast, noncrystallographic symmetry is valid only within a limited volume about the noncrystallographic symmetry element. For instance, the noncrystallographic twofold axes in the plane of the paper of Fig. 2.3.5.1 are true only in the immediate vicinity of each local dyad. In contrast, the crystallographic twofold axes perpendicular to the plane of the paper (Fig. 2.3.5.1) apply to every point within the lattice. Two types of noncrystallographic symmetry can be recognized: proper and improper rotations. A proper symmetry element is independent of the sense of rotation, as, for example, a fivefold axis in an icosahedral virus; a rotation either left or right by one-fifth of a revolution will leave all parts of a given icosahedral shell (but not the whole crystal) in equivalent positions. Proper noncrystallographic symmetry can also be recognized by the existence of a closed point group within a defined volume of the lattice. Improper rotation axes are found when two molecules are arbitrarily oriented relative to each other in the same asymmetric unit or when they occur in two entirely different crystal lattices. For instance, in Fig. 2.3.5.2, the object A_1B_1 can be rotated by $+\theta$ about the axis at P to orient it identically with A_2B_2. However, the two objects will not be coincident after a rotation of A_1B_1 by $-\theta$ or of A_2B_2 by $+\theta$. The envelope around each noncrystallographic object must be known in order to define an improper rotation. In contrast, only the volume about the closed point group need be defined for proper noncrystallographic operations. Hence, the boundaries of the repeating unit need not correspond to chemically covalently linked units in the presence of proper rotations.

Translational components of noncrystallographic rotation elements are said to be 'precise' in a direction parallel to the axis and 'imprecise' perpendicular to the axis (Rossmann *et al.*, 1964). The position, but not direction, of a rotation axis is arbitrary. However, a convenient choice is one that leaves the translation perpendicular to the axis at zero after rotation (Fig. 2.3.5.3).

Noncrystallographic symmetry has been used as a tool in structural analysis primarily in the study of biological molecules. This is due to the propensity of proteins to form aggregates with closed point groups, as, for instance, viruses with 532 symmetry. At best, only part of such a point group can be incorporated into the crystal lattice. Since biological materials cannot contain inversion elements, all studies of noncrystallographic symmetries have been limited to rotational axes. Reflection planes and inversion centres could also be considered in the application of molecular replacement to nonbiological materials.

In this chapter, the relationship

$$\mathbf{x}' = [\boldsymbol{C}]\mathbf{x} + \mathbf{d}$$

will be used to describe noncrystallographic symmetry, where $\mathbf{x}$ and $\mathbf{x}'$ are position vectors, expressed as fractional coordinates, with respect to the crystallographic origin, $[\boldsymbol{C}]$ is a rotation matrix, and $\mathbf{d}$ is a translation vector. Crystallographic symmetry will be described as

$$\mathbf{x}' = [\boldsymbol{T}]\mathbf{x} + \mathbf{t},$$

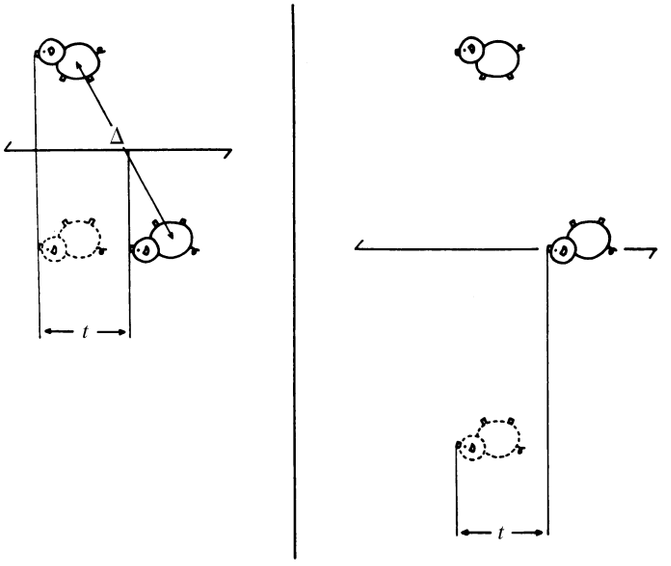

Fig. 2.3.5.3. The position of the twofold rotation axis which relates the two piglets is completely arbitrary. The diagram on the left shows the situation when the translation is parallel to the rotation axis. The diagram on the right has an additional component of translation perpendicular to the rotation axis, but the component parallel to the axis remains unchanged. [Reprinted from Rossmann *et al.* (1964).]

where $[\boldsymbol{T}]$ and $\mathbf{t}$ are the crystallographic rotation matrix and translation vector, respectively. The noncrystallographic asymmetric unit will be defined as having n copies within the crystallographic asymmetric unit, and the unit cell will be defined as having m crystallographic asymmetric units. Hence, there are $L = nm$ noncrystallographic asymmetric units within the unit cell. Clearly, the n noncrystallographic asymmetric units cannot completely fill the volume of one crystallographic asymmetric unit. The remaining space must be assumed to be empty or to be occupied by solvent molecules which disobey the noncrystallographic symmetry.

2.3.5.2. Interpretation of Pattersons in the presence of noncrystallographic symmetry

If noncrystallographic symmetry is present, an atom at a general position within the relevant volume will imply the presence of others within the same crystallographic asymmetric unit. If the noncrystallographic symmetry is known, then the positions of equivalent atoms may be generated from a single atomic position. The additional vector interactions which arise from crystallographically and noncrystallographically equivalent atoms in a crystal may be predicted and exploited in an interpretation of the Patterson function.

An object in real space which has a closed point group may incorporate some of its symmetry in the crystallographic symmetry. If there are l such objects in the cell, then there will be mn/l equivalent positions within each object. The 'self-vectors' formed between these positions within the object will be independent of the position of the objects. This distinction is important in that the self-vectors arising from atoms interacting with other atoms within a single particle may be correctly predicted without the knowledge of the particle centre position. In fact, this distinction may be exploited in a two-stage procedure in which an atom may be first located relative to the particle centre by use of the self-vectors and subsequently the particle may be positioned relative to crystallographic symmetry elements by use of the 'cross-vectors' (Table 2.3.5.1).

The interpretation of a heavy-atom difference Patterson for the holo-enzyme of lobster glyceraldehyde-3-phosphate dehydrogenase (GAPDH) provides an illustration of how the known noncrystallographic symmetry can aid the solution (Rossmann *et al.*, 1972; Buehner *et al.*, 1974). The GAPDH enzyme crystallized in a $P2_12_12_1$ cell (a = 149.0, b = 139.1, c = 80.7 Å) containing one tetramer per asymmetric unit. A rotation-function analysis had indicated the presence of three mutually perpendicular molecular twofold axes which suggested that the tetramer had 222 symmetry, and a locked rotation function determined the precise orientation of the tetramer relative to the crystal axes (see Table 2.3.5.2). Packing considerations led to assignment of a tentative particle centre near $\frac{1}{2}, \frac{1}{4}, Z$.

Table 2.3.5.1. *Possible types of vector searches*

Self-vectors	Cross-vectors	Dimension of search, n
(1) Locate single site relative to particle centre		$n = 3$
(2)	Use information from (1) to locate particle centre	$n \leq 3$
(3) Simultaneous search for both (1) and (2). In general this is a six-dimensional search but may be simplified when particle is on a crystallographic symmetry axis		$3 \leq n \leq 6$
(4) Given (1) for more than one site, find all vectors within particle		$n = 3$
(5) Given information from (3), locate additional site using complete vector set		$n = 3$

An isomorphous difference Patterson was calculated for the K_2HgI_4 derivative of GAPDH using data to a resolution of 6.8 Å. From an analysis of the three Harker sections, a tentative first heavy-atom position was assigned (atom A_2 at x, y, z). At this juncture, the known noncrystallographic symmetry was used to obtain a full interpretation. From Table 2.3.5.2 we see that molecular axis 2 will generate a second heavy atom with coordinates roughly $\frac{1}{4} + y, -\frac{1}{4} + x, 2Z - z$ (if the molecular centre was assumed to be at $\frac{1}{2}, \frac{1}{4}, Z$). Starting from the tentative coordinates of site A_2, the site A_1 related by molecular axis 1 was detected at about the predicted position and the second site A_1 generated acceptable cross-vectors with the earlier determined site A_2. Further examination enabled the completion of the set of four noncrystallographically related heavy-atom sites, such that all predicted Patterson vectors were acceptable and all four sites placed the molecular centre in the same position. Following refinement of these four sites, the corresponding SIR phases were used to find an additional set of four sites in this compound as well as in a number of other derivatives. The multiple isomorphous replacement phases, in conjunction with real-space electron-density averaging of the noncrystallographically related units, were then sufficient to solve the GAPDH structure.

When investigators studied larger macromolecular aggregates such as the icosahedral viruses, which have 532 point symmetry, systematic methods were developed for utilizing the noncrystallographic symmetry to aid in locating heavy-atom sites in isomorphous heavy-atom derivatives. Argos & Rossmann (1974, 1976) introduced an exhaustive Patterson search procedure for a single heavy-atom site within the noncrystallographic asymmetric unit which has been successfully applied to the interpretation of both virus [satellite tobacco necrosis virus (STNV) (Lentz *et al.*, 1976), southern bean mosaic virus (Rayment *et al.*, 1978), alfalfa mosaic virus (Fukuyama *et al.*, 1983), cowpea mosaic virus

Table 2.3.5.2. *Orientation of the glyceraldehyde-3-phosphate dehydrogenase molecular twofold axis in the orthorhombic cell*

Rotation axes	Polar coordinates (°)		Cartesian coordinates (direction cosines)		
	ψ	φ	u	v	w
1	45.0	−7.0	0.7018	0.7071	−0.0862
2	180.0–55.0	38.6	0.6402	−0.5736	0.5111
3	180.0–66.0	−70.6	0.3035	−0.4067	−0.8616

Table 2.3.6.1. *Different types of uses for the rotation function*

Type of rotation function	Pattersons to be compared		Purpose
	P_1	P_2	
Self	Unknown structure	Unknown structure, same cell	Finds orientation of noncrystallographic axes
Cross	Unknown structure	Unknown structure in different cell	Finds relative orientation of unknown molecules
Cross	Unknown structure	Known structure in large cell to avoid overlap of self-Patterson vectors	Determines orientation of unknown structure as preliminary to positioning and subsequent phasing with known molecule

(Stauffacher *et al.*, 1987)] and enzyme [catalase (Murthy *et al.*, 1981)] heavy-atom difference Pattersons. This procedure has also been implemented in the program *Patsol* (Tong & Rossmann, 1993). A heavy atom is placed in turn at all plausible positions within the volume of the noncrystallographic asymmetric unit and the corresponding vector set is constructed from the resulting constellation of heavy atoms. Argos & Rossmann (1976) found a spherical polar coordinate search grid to be convenient for spherical viruses. After all vectors for the current search position are predicted, the vectors are allocated to the nearest grid point and the list is sorted to eliminate recurring ones. The criterion used by Argos & Rossmann for selecting a solution is that the sum

$$S = \sum_{i=1}^{N} P_i - NP_{\rm av}$$

of the lookup Patterson density values P_i achieves a high value for a correct heavy-atom position. The sum is corrected for the carpet of cross-vectors by the second term in the sum.

An additional criterion, which has been found useful for discriminating correct solutions, is a unit vector density criterion (Arnold *et al.*, 1987)

$$U = \sum_{i=1}^{N} (P_i/n_i) \Big/ N,$$

where n_i is the number of vectors expected to contribute to the Patterson density value P_i (Arnold *et al.*, 1987). This criterion can be especially valuable for detecting correct solutions at special search positions, such as an icosahedral fivefold axis, where the number of vector lookup positions may be drastically reduced owing to the higher symmetry. An alternative, but equivalent, method for locating heavy-atom positions from isomorphous difference data is discussed in Section 2.3.3.5.

Even for a single heavy-atom site at a general position in the simplest icosahedral or ($T = 1$) virus, there are 60 equivalent heavy atoms in one virus particle. The number of unique vectors corresponding to this self-particle vector set will depend on the crystal symmetry but may be as many as $(60)(59)/2 = 1770$ for a virus particle at a general crystallographic position. Such was the case for the STNV crystals which were in space group $C2$ containing four virus particles at general positions. The method of Argos & Rossmann was applied successfully to a solution of the K_2HgI_4 derivative of STNV using a 10 Å resolution difference Patterson. Application of the noncrystallographic symmetry vector search procedure to a $K_2Au(CN)_2$ derivative of human rhinovirus 14 (HRV14) crystals (space group $P2_13$, $Z = 4$) has succeeded in establishing both the relative positions of heavy atoms within one particle and the positions of the virus particles relative to the crystal symmetry elements (Arnold *et al.*, 1987). The particle position was established by incorporating inter-particle vectors in the search and varying the particle position along the crystallographic threefold axis until the best fit for the predicted vector set was achieved.

Conversely, the knowledge that the heavy-atom positions, especially the Se atoms in a selenomethionyl protein, should obey the noncrystallographic symmetry can be used to deduce the nature, orientation and position of the noncrystallographic symmetry in the crystal unit cell, with either manual or automated procedures (Buehner *et al.*, 1974; Lu, 1999; Terwilliger, 2002*a*). The noncrystallographic symmetry can also serve as a powerful tool for refining the phase information derived from the heavy-atom positions (Buehner *et al.*, 1974).

2.3.6. Rotation functions

2.3.6.1. Introduction

The rotation function is designed to detect noncrystallographic rotational symmetry (see Table 2.3.6.1). The normal rotation function definition is given as (Rossmann & Blow, 1962)

$$R = \int_U P_1(\mathbf{u}) \cdot P_2(\mathbf{u}')\, {\rm d}\mathbf{u}, \qquad (2.3.6.1)$$

where P_1 and P_2 are two Pattersons and U is an envelope centred at the superimposed origins. This convolution therefore measures the degree of similarity, or 'overlap', between the two Pattersons when P_2 has been rotated relative to P_1 by an amount defined by

$$\mathbf{u}' = [\boldsymbol{C}]\mathbf{u}. \qquad (2.3.6.2)$$

The elements of $[\boldsymbol{C}]$ will depend on three rotation angles $(\theta_1, \theta_2, \theta_3)$. Thus, R is a function of these three angles. Alternatively, the matrix $[\boldsymbol{C}]$ could be used to express mirror symmetry, permitting searches for noncrystallographic mirror or glide planes.

The basic concepts were first clearly stated by Rossmann & Blow (1962), although intuitive uses of the rotation function had been considered earlier. Hoppe (1957*b*) had also hinted at a convolution of the type given by (2.3.6.1) to find the orientation of known molecular fragments and these ideas were implemented by Huber (1965).

Consider a structure of two identical units which are in different orientations. The Patterson function of such a structure consists of three parts. There will be the self-Patterson vectors of one unit, being the set of interatomic vectors which can be formed within that unit, with appropriate weights. The set of self-Patterson vectors of the other unit will be identical, but they will be rotated away from the first due to the different orientation. Finally, there will be the cross-Patterson vectors, or set of interatomic vectors which can be formed from one unit to another. The self-Patterson vectors of the two units will all lie in a volume centred at the origin and limited by the overall dimensions of the units. Some or all of the cross-Patterson vectors will lie outside this volume. Suppose the Patterson function is now superposed on a rotated version of itself. There will be no particular agreement except when one set of self-Patterson vectors of one unit has the same orientation as the self-Patterson vectors from the other unit. In this position, we would expect a maximum of agreement or 'overlap' between the two. Similarly,

the superposition of the molecular self-Patterson derived from different crystal forms can provide the relative orientation of the two crystals when the molecules are aligned.

While it would be possible to evaluate R by interpolating in P_2 and forming the point-by-point product with P_1 within the volume U for every combination of θ_1, θ_2 and θ_3, such a process is tedious and requires large computer storage for the Pattersons. Instead, the process is usually performed in reciprocal space where the number of independent structure amplitudes which form the Pattersons is about one-thirtieth of the number of Patterson grid points. Thus, the computation of a rotation function is carried out directly on the structure amplitudes, while the overlap definition (2.3.6.1) simply serves as a physical basis for the technique.

The derivation of the reciprocal-space expression depends on the expansion of each Patterson either as a Fourier summation, the conventional approach of Rossmann & Blow (1962), or as a sum of spherical harmonics in Crowther's (1972) analysis. The conventional and mathematically easier treatment is discussed presently, but the reader is referred also to Section 2.3.6.5 for Crowther's elegant approach. The latter leads to a rapid technique for performing the computations, about one hundred times faster than conventional methods.

Let, omitting constant coefficients,

$$P_1(\mathbf{u}) = \sum_{\mathbf{h}} |\mathbf{F}_{\mathbf{h}}|^2 \exp(2\pi i \mathbf{h} \cdot \mathbf{u})$$

and

$$P_2(\mathbf{u}') = \sum_{\mathbf{p}} |\mathbf{F}_{\mathbf{p}}|^2 \exp(2\pi i \mathbf{p} \cdot \mathbf{u}').$$

From (2.3.6.2) it follows that

$$P_2(\mathbf{u}') = \sum_{\mathbf{p}} |\mathbf{F}_{\mathbf{p}}|^2 \exp(2\pi i \mathbf{p}[\boldsymbol{C}] \cdot \mathbf{u}),$$

and, hence, by substitution in (2.3.6.1)

$$\begin{aligned} R(\theta_1, \theta_2, \theta_3) = \int_U & \left[\sum_{\mathbf{h}} |\mathbf{F}_{\mathbf{h}}|^2 \exp(2\pi i \mathbf{h} \cdot \mathbf{u}) \right] \\ & \times \left[\sum_{\mathbf{p}} |\mathbf{F}_{\mathbf{p}}|^2 \exp(2\pi i \mathbf{p}[\boldsymbol{C}] \cdot \mathbf{u}) \right] \mathrm{d}\mathbf{u} \\ = U \sum_{\mathbf{h}} |\mathbf{F}_{\mathbf{h}}|^2 & \left(\sum_{\mathbf{p}} |\mathbf{F}_{\mathbf{p}}|^2 G_{\mathbf{hp}} \right), \end{aligned} \tag{2.3.6.3}$$

where

$$U G_{\mathbf{hp}} = \int_U \exp\{2\pi i (\mathbf{h} + \mathbf{p}[\boldsymbol{C}]) \cdot \mathbf{u}\} \, \mathrm{d}\mathbf{u}.$$

When the volume U is a sphere, $G_{\mathbf{hp}}$ has the analytical form

$$G_{\mathbf{hp}} = \frac{3(\sin\theta - \theta\cos\theta)}{\theta^3}, \tag{2.3.6.4}$$

where $\theta = 2\pi HR$ and $H = \mathbf{h} + \mathbf{p}[\boldsymbol{C}]$. G is a spherical interference function whose form is shown in Fig. 2.3.6.1.

The expression (2.3.6.3) represents the rotation function in reciprocal space. If $\mathbf{h}' = [\boldsymbol{C}^T]\mathbf{p}$ in the argument of $G_{\mathbf{hp}}$, then $\mathbf{h}'$ can be seen as the point in reciprocal space to which $\mathbf{p}$ is rotated by

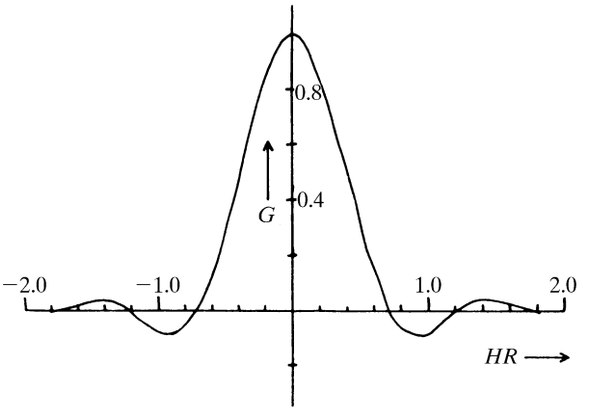

Fig. 2.3.6.1. Shape of the interference function G for a spherical envelope of radius R at a distance H from the reciprocal-space origin. [Reprinted from Rossmann & Blow (1962).]

$[\boldsymbol{C}]$. Only for those integral reciprocal-lattice points which are close to $-\mathbf{h}'$ will $G_{\mathbf{hp}}$ be of an appreciable size (Fig. 2.3.6.1). Thus, the number of significant terms is greatly reduced in the summation over $\mathbf{p}$ for every value of $\mathbf{h}$, making the computation of the rotation function manageable.

The radius of integration R should be approximately equal to or a little smaller than the molecular diameter. If R were roughly equal to the length of a lattice translation, then the separation of reciprocal-lattice points would be about $1/R$. Hence, when H is equal to one reciprocal-lattice separation, $HR \simeq 1$, and G is thus quite small. Indeed, all terms with $HR > 1$ might well be neglected. Thus, in general, the only terms that need be considered are those where $-\mathbf{h}'$ is within one lattice point of $\mathbf{h}$. However, in dealing with a small molecular fragment for which R is small compared to the unit-cell dimensions, more reciprocal-lattice points must be included for the summation over $\mathbf{p}$ in the rotation-function expression (2.3.6.3).

In practice, the equation

$$\mathbf{h} + \mathbf{h}' = 0,$$

that is

$$[\boldsymbol{C}^T]\mathbf{p} = -\mathbf{h}$$

or

$$\mathbf{p} = [\boldsymbol{C}^T]^{-1}(-\mathbf{h}), \tag{2.3.6.5}$$

determines $\mathbf{p}$, given a set of Miller indices $\mathbf{h}$. This will give a non-integral set of Miller indices. The terms included in the inner summation of (2.3.6.3) will be integral values of $\mathbf{p}$ around the non-integral lattice point found by solving (2.3.6.5).

Details of the conventional program were given by Tollin & Rossmann (1966) and follow the principles outlined above. They discussed various strategies as to which crystal should be used to calculate the first ($\mathbf{h}$) and second ($\mathbf{p}$) Patterson. Rossmann & Blow (1962) noted that the factor $\sum_{\mathbf{p}} |\mathbf{F}_{\mathbf{p}}|^2 G_{\mathbf{hp}}$ in expression (2.3.6.3) represents an interpolation of the squared transform of the self-Patterson of the second ($\mathbf{p}$) crystal. Thus, the rotation function is a sum of the products of the two molecular transforms taken over all the $\mathbf{h}$ reciprocal-lattice points. Lattman & Love (1970) therefore computed the molecular transform explicitly and stored it in the computer, sampling it as required by the rotation operation. A discussion on the suitable choice of variables in the computation of rotation functions has been given by Lifchitz (1983).

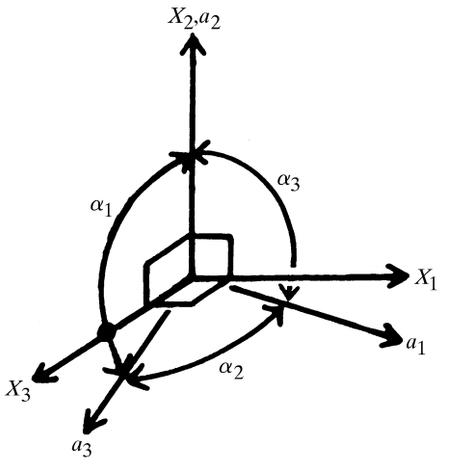

Fig. 2.3.6.2. Relationships of the orthogonal axes X_1, X_2, X_3 to the crystallographic axes a_1, a_2, a_3. [Reprinted from Rossmann & Blow (1962).]

2.3.6.2. Matrix algebra

The initial step in the rotation-function procedure involves the orthogonalization of both crystal systems. Thus, if fractional coordinates in the first crystal system are represented by **x**, these can be orthogonalized by a matrix $[\boldsymbol{\beta}]$ to give the coordinates **X** in units of length (Fig. 2.3.6.2); that is,

$$\mathbf{X} = [\boldsymbol{\beta}]\mathbf{x}.$$

If the point **X** is rotated to the point $\mathbf{X}'$, then

$$\mathbf{X}' = [\boldsymbol{\rho}]\mathbf{X}, \qquad (2.3.6.6)$$

where $\boldsymbol{\rho}$ represents the rotation matrix relating the two vectors in the orthogonal system. Finally, $\mathbf{X}'$ is converted back to fractional coordinates measured along the oblique cell dimension in the second crystal by

$$\mathbf{x}' = [\boldsymbol{\alpha}]\mathbf{X}'.$$

Thus, by substitution,

$$\mathbf{x}' = [\boldsymbol{\alpha}][\boldsymbol{\rho}]\mathbf{X} = [\boldsymbol{\alpha}][\boldsymbol{\rho}][\boldsymbol{\beta}]\mathbf{x}, \qquad (2.3.6.7)$$

and by comparison with (2.3.6.2) it follows that

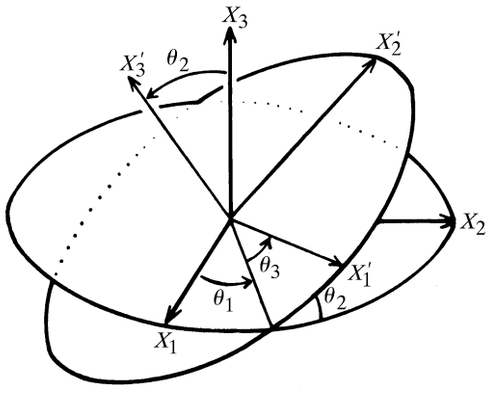

Fig. 2.3.6.3. Eulerian angles $\theta_1, \theta_2, \theta_3$ relating the rotated axes X_1', X_2', X_3' to the original unrotated orthogonal axes X_1, X_2, X_3. [Reprinted from Rossmann & Blow (1962).]

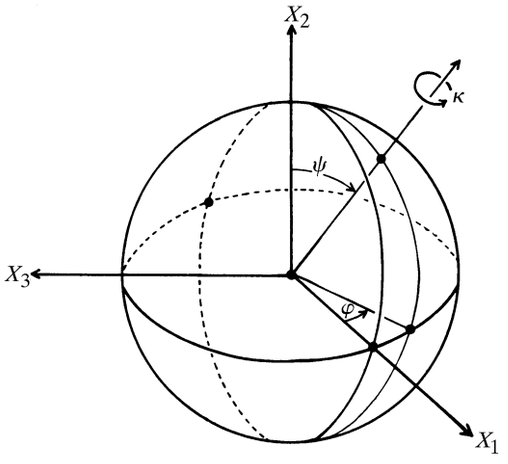

Fig. 2.3.6.4. Variables ψ and φ are polar coordinates which specify a direction about which the axes may be rotated through an angle κ. [Reprinted from Rossmann & Blow (1962).]

$$[\boldsymbol{C}] = [\boldsymbol{\alpha}][\boldsymbol{\rho}][\boldsymbol{\beta}].$$

Fig. 2.3.6.2 shows the mode of orthogonalization used by Rossmann & Blow (1962). With their definition it can be shown that

$$[\boldsymbol{\alpha}] = \begin{pmatrix} 1/(a_1 \sin\alpha_3 \sin\omega) & 0 & 0 \\ 1/(a_2 \tan\alpha_1 \tan\omega) & 1/a_2 & -1/(a_2 \tan\alpha_1) \\ -1/(a_2 \tan\alpha_3 \sin\omega) & & \\ -1/(a_3 \sin\alpha_1 \tan\omega) & 0 & 1/(a_3 \sin\alpha_1) \end{pmatrix}$$

and

$$[\boldsymbol{\beta}] = \begin{pmatrix} a_1 \sin\alpha_3 \sin\omega & 0 & 0 \\ a_1 \cos\alpha_3 & a_2 & a_3 \cos\alpha_1 \\ a_1 \sin\alpha_3 \cos\omega & 0 & a_3 \sin\alpha_1 \end{pmatrix},$$

where $\cos\omega = (\cos\alpha_2 - \cos\alpha_1 \cos\alpha_3)/(\sin\alpha_1 \sin\alpha_3)$ with $0 \le \omega < \pi$. For a Patterson compared with itself, $[\boldsymbol{\alpha}] = [\boldsymbol{\beta}]^{-1}$.

An alternative mode of orthogonalization, used by the Protein Data Bank and most programs, is to align the a_1 axis of the unit cell with the Cartesian X_1 axis, and to align the a_3^* axis with the Cartesian X_3 axis. With this definition, the orthogonalization matrix is

$$[\boldsymbol{\beta}] = \begin{pmatrix} a_1 & a_2 \cos\alpha_3 & a_3 \cos\alpha_2 \\ 0 & a_2 \sin\alpha_3 & -a_3 \sin\alpha_2 \cos\alpha_1^* \\ 0 & 0 & a_3 \sin\alpha_2 \sin\alpha_1^* \end{pmatrix}.$$

Other modes of orthogonalization are also possible, some of which are supported in the program *GLRF* (Tong & Rossmann, 1990, 1997).

Both spherical (κ, ψ, φ) and Eulerian $(\theta_1, \theta_2, \theta_3)$ angles are used in evaluating the rotation function. The usual definitions employed are given diagrammatically in Figs. 2.3.6.3 and 2.3.6.4. They give rise to the following rotation matrices.

(*a*) Matrix $[\boldsymbol{\rho}]$ in terms of Eulerian angles $\theta_1, \theta_2, \theta_3$:

$$\begin{pmatrix} -\sin\theta_1\cos\theta_2\sin\theta_3 + \cos\theta_1\cos\theta_3 & \cos\theta_1\cos\theta_2\sin\theta_3 + \sin\theta_1\cos\theta_3 & \sin\theta_2\sin\theta_3 \\ -\sin\theta_1\cos\theta_2\cos\theta_3 - \cos\theta_1\sin\theta_3 & \cos\theta_1\cos\theta_2\cos\theta_3 - \sin\theta_1\sin\theta_3 & \sin\theta_2\cos\theta_3 \\ \sin\theta_1\sin\theta_2 & -\cos\theta_1\sin\theta_2 & \cos\theta_2 \end{pmatrix}$$

and (b) matrix $[\boldsymbol{\rho}]$ in terms of rotation angle κ and the spherical polar coordinates ψ, φ:

$$\begin{pmatrix} \cos\kappa + \sin^2\psi\cos^2\varphi(1-\cos\kappa) & \sin\psi\cos\psi\cos\varphi(1-\cos\kappa) + \sin\psi\sin\varphi\sin\kappa & -\sin^2\psi\cos\varphi\sin\varphi(1-\cos\kappa) + \cos\psi\sin\kappa \\ \sin\psi\cos\psi\cos\varphi(1-\cos\kappa) - \sin\psi\sin\varphi\sin\kappa & \cos\kappa + \cos^2\psi(1-\cos\kappa) & -\sin\psi\cos\psi\sin\varphi(1-\cos\kappa) - \sin\psi\cos\varphi\sin\kappa \\ -\sin^2\psi\sin\varphi\cos\varphi(1-\cos\kappa) - \cos\psi\sin\kappa & -\sin\psi\cos\psi\sin\varphi(1-\cos\kappa) + \sin\psi\cos\varphi\sin\kappa & \cos\kappa + \sin^2\psi\sin^2\varphi(1-\cos\kappa) \end{pmatrix}$$

Alternatively, (b) can be expressed as

$$\begin{pmatrix} \cos\kappa + u^2(1-\cos\kappa) & uv(1-\cos\kappa) - w\sin\kappa & uw(1-\cos\kappa) + v\sin\kappa \\ vu(1-\cos\kappa) + w\sin\kappa & \cos\kappa + v^2(1-\cos\kappa) & uw(1-\cos\kappa) - u\sin\kappa \\ wu(1-\cos\kappa) - v\sin\kappa & wv(1-\cos\kappa) + u\sin\kappa & \cos\kappa + w^2(1-\cos\kappa) \end{pmatrix},$$

where u, v and w are the direction cosines of the rotation axis given by

$$\begin{aligned} u &= \sin\psi\cos\varphi, \\ v &= \cos\psi, \\ w &= -\sin\psi\sin\varphi. \end{aligned}$$

This latter form also demonstrates that the trace of a rotation matrix is $2\cos\kappa + 1$.

The relationship between the two sets of variables established by comparison of the elements of the two matrices yields

$$\begin{aligned} \cos(\kappa/2) &= \cos(\theta_2/2)\cos\left(\frac{\theta_1+\theta_3}{2}\right), \\ \tan\varphi &= -\cot(\theta_2/2)\sin\left(\frac{\theta_1+\theta_3}{2}\right)\sec\left(\frac{\theta_1-\theta_3}{2}\right), \\ \cos\varphi\tan\psi &= \cot\left(\frac{\theta_1-\theta_3}{2}\right). \end{aligned}$$

Since φ and ψ can always be chosen in the range 0 to π, these equations suffice to find (κ, ψ, φ) from any set $(\theta_1, \theta_2, \theta_3)$.

Another definition for the polar angles is also commonly used. In this definition, the angle ψ is measured from the Cartesian Z (X_3) axis, instead of the Y (X_2) axis. As most space groups have the unique axis along a_3, the ψ angle will define the inclination relative to the unique axis of the space group with this definition.

2.3.6.3. Symmetry

In analogy with crystal lattices, the rotation function is periodic and contains symmetry. The rotation function has a cell whose periodicity is 2π in each of its three angles. This may be written as

$$R(\theta_1, \theta_2, \theta_3) \equiv R(\theta_1 + 2\pi n_1, \theta_2 + 2\pi n_2, \theta_3 + 2\pi n_3)$$

or

$$R(\kappa, \psi, \varphi) \equiv R(\kappa + 2\pi n_1, \psi + 2\pi n_2, \varphi + 2\pi n_3),$$

where n_1, n_2 and n_3 are integers. A redundancy in the definition of either set of angles leads to the equivalence of the following points:

$$R(\theta_1, \theta_2, \theta_3) \equiv R(\theta_1 + \pi, -\theta_2, \theta_3 + \pi) \quad \text{in Eulerian space}$$

or

$$R(\kappa, \psi, \varphi) \equiv R(\kappa, 2\pi - \psi, \varphi + \pi) \quad \text{in polar space.}$$

These relationships imply an n glide plane perpendicular to θ_2 for Eulerian space or a φ glide plane perpendicular to ψ in polar space.

In addition, the Laue symmetry of the two Pattersons themselves must be considered. This problem was first discussed by Rossmann & Blow (1962) and later systematized by Tollin *et al.* (1966), Burdina (1970, 1971, 1973) and Rao *et al.* (1980). A closely related problem was considered by Hirshfeld (1968). The rotation function will have the same value whether the Patterson density at $\mathbf{X}$ or $[\boldsymbol{T}_i]\mathbf{X}$ in the first crystal is multiplied by the Patterson density at $\mathbf{X}'$ or $[\boldsymbol{T}_j]\mathbf{X}'$ in the second crystal. $[\boldsymbol{T}_i]$ and $[\boldsymbol{T}_j]$ refer to the ith and jth crystallographic rotations in the orthogonalized coordinate systems of the first and second crystal, respectively. Hence, from (2.3.6.6)

$$([\boldsymbol{T}_j]\mathbf{X}') = [\boldsymbol{\rho}]([\boldsymbol{T}_i]\mathbf{X})$$

or

$$\mathbf{X}' = [\boldsymbol{T}_j^T][\boldsymbol{\rho}][\boldsymbol{T}_i]\mathbf{X}.$$

Thus, it is necessary to find angular relationships which satisfy the relation

$$[\boldsymbol{\rho}] = [\boldsymbol{T}_j^T][\boldsymbol{\rho}][\boldsymbol{T}_i]$$

for given Patterson symmetries. Tollin *et al.* (1966) show that the Eulerian angular equivalences can be expressed in terms of the Laue symmetries of each Patterson (Table 2.3.6.2).

The example given by Tollin *et al.* (1966) is instructive in the use of Table 2.3.6.2. They consider the determination of the Eulerian space group when P_1 has symmetry *Pmmm* and P_2 has symmetry $P2/m$. These Pattersons contain the proper rotation groups 222 and 2 (parallel to **b**), respectively. Inspection of Table 2.3.6.2 shows that these symmetries produce the following Eulerian relationships:

Table 2.3.6.2. *Eulerian symmetry elements for all possible types of space-group rotations*

Axis	Direction	First crystal	Second crystal
1		$(\pi+\theta_1, -\theta_2, \pi+\theta_3)$	$(\pi+\theta_1, -\theta_2, \pi+\theta_3)$
2	[010]	$(\pi-\theta_1, \pi+\theta_2, \theta_3)$	$(\theta_1, \pi+\theta_2, \pi-\theta_3)$
2	[001]	$(\pi+\theta_1, \theta_2, \theta_3)$	$(\theta_1, \theta_2, \pi+\theta_3)$
4	[001]	$(-\pi/2+\theta_1, \theta_2, \theta_3)$	$(\theta_1, \theta_2, \pi/2+\theta_3)$
3	[001]	$(-2\pi/3+\theta_1, \theta_2, \theta_3)$	$(\theta_1, \theta_2, 2\pi/3+\theta_3)$
6	[001]	$(-\pi/3+\theta_1, \theta_2, \theta_3)$	$(\theta_1, \theta_2, \pi/3+\theta_3)$
2†	[110]	$(3\pi/2-\theta_1, \pi-\theta_2, \pi+\theta_3)$	$(\pi+\theta_1, \pi-\theta_2, -3\pi/2-\theta_3)$

† This axis is not unique (that is, it can always be generated by two other unique axes), but is included for completeness.

Table 2.3.6.3. *Numbering of the rotation-function space groups*

The Laue group of the rotated Patterson map P_1 is chosen from the left column and the Laue group of P_2 is chosen from the upper row.

(*a*) In the first crystal (*Pmmm*):

$\theta_1\theta_2\theta_3 \rightarrow \pi+\theta_1, -\theta_2, \pi+\theta_3$ (onefold axis)
$\theta_1\theta_2\theta_3 \rightarrow \pi-\theta_1, \pi+\theta_2, \theta_3$ (twofold axis parallel to **b**)
$\theta_1\theta_2\theta_3 \rightarrow \pi+\theta_1, \theta_2, \theta_3$ (twofold axis parallel to **c**).

(*b*) In the second crystal (*P*2/*m*):

$\theta_1\theta_2\theta_3 \rightarrow \pi+\theta_1, -\theta_2, \pi+\theta_3$ (onefold axis)
$\theta_1\theta_2\theta_3 \rightarrow \theta_1, \pi+\theta_2, \pi-\theta_3$ (twofold axis parallel to **b**).

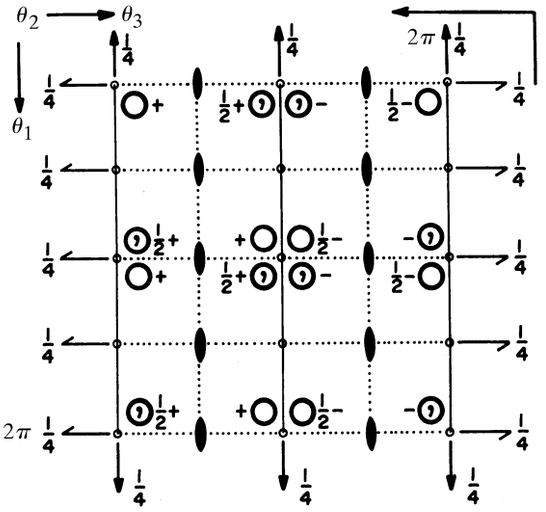

Fig. 2.3.6.5. Rotation space group diagram for the rotation function of a *Pmmm* Patterson function (P_1) against a *P*2/*m* Patterson function (P_2). The Eulerian angles $\theta_1, \theta_2, \theta_3$ repeat themselves after an interval of 2π. Heights above the plane are given in fractions of a revolution. [Reprinted from Tollin *et al.* (1966).]

When these symmetry operators are combined two cells result, each of which has the space group *Pbcb* (Fig. 2.3.6.5). The asymmetric unit within which the rotation function need be evaluated is found from a knowledge of the Eulerian space group. In the above example, the limits of the asymmetric unit are $0 \le \theta_1 \le \pi/2$, $0 \le \theta_2 \le \pi$ and $0 \le \theta_3 \le \pi/2$.

Nonlinear transformations occur when using Eulerian symmetries for threefold axes along [111] (as in the cubic system) or when using polar coordinates. Hence, Eulerian angles are far more suitable for a derivation of the limits of the rotation-function asymmetric unit. However, when searching for given molecular axes, where some plane of κ need be explored, polar angles are more useful.

Rao *et al.* (1980) have determined all possible rotation-function Eulerian space groups, except for combinations with Pattersons of cubic space groups. They numbered these rotation groups 1 through 100 (Table 2.3.6.3) according to the combination of the Patterson Laue groups. The characteristics of each of the 100 groups are given in Table 2.3.6.4, including the limits of the asymmetric unit. In the 100 unique combinations of noncubic Laue groups, there are only 16 basic rotation-function space groups.

2.3.6.4. Sampling, background and interpretation

If the origins are retained in the Pattersons, their product will form a high but constant plateau on which the rotation-function peaks are superimposed; this leads to a small apparent peak-to-noise ratio. The effect can be eliminated by removal of the origins through a modification of the Patterson coefficients. Irrespective of origin removal, a significant peak is one which is more than three r.m.s. deviations from the mean background.

As in all continuous functions sampled at discrete points, a convenient grid size must be chosen. Small intervals result in an excessive computing burden, while large intervals might miss peaks. Furthermore, equal increments of angles do not represent equal changes in rotation, which can result in distorted peaks (Lattman, 1972). In general, a crude idea of a useful sampling

Table 2.3.6.4. *Rotation-function Eulerian space groups*

The rotation space groups are given in Table 2.3.6.3.

Notes: (*a*) This is the number of equivalent positions in the rotation unit cell. (*b*) Each symbol retains the order $\theta_1, \theta_2, \theta_3$. The monoclinic space groups have the *b* axis unique setting. (*c*) This is a translation symmetry: *e.g.* for the case of $\pi/2$ translation along the θ_1 axis, $\theta_1, \theta_2, \theta_3$ goes to $\pi/2 + \theta_1, \theta_2, \theta_3$ and $\pi + \theta_1, \theta_2, \theta_3$, and $3\pi/2 + \theta_1, \theta_2, \theta_3$. All other equivalent positions in the basic rotation space group are similarly translated. (*d*) Several consistent sets of ranges exist but the one with the minimum range of θ_2 is listed.

interval can be obtained by considering the angle necessary to move one reciprocal-lattice point onto its neighbour (separated by a^*) at the extremity of the resolution limit, R. This interval is given by

$$\Delta\theta = a^*/2(1/R) = \tfrac{1}{2}Ra^*.$$

Simple sharpening of the rotation function can be useful. This can be achieved by restricting the computations to a shell in reciprocal space or by using normalized structure factors. Useful limits are frequently 10 to 6, 10 to 4 or 10 to 3.5 Å for an average protein or 6 to 5 Å for a virus structure determination. In addition, use of restricted resolution ranges, such as 6 to 5 Å or 3.5 to 3.0 Å, has been found in numerous cases to give especially well defined results (Arnold *et al.*, 1984).

When exploring the rotation function in polar coordinates, there is no significance to the latitude φ (Fig. 2.3.6.4) when $\psi = 0$. For small values of ψ, the rotation function will be quite insensitive to φ, which therefore needs to be explored only at coarse intervals (say 45°). As ψ approaches the equator at 90°, optimal increments of ψ and φ will be about equal. A similar situation exists with Eulerian angles. When $\theta_2 = 0$, the rotation function will be determined by $\theta_1 + \theta_3$, corresponding to $\psi = 0$ and

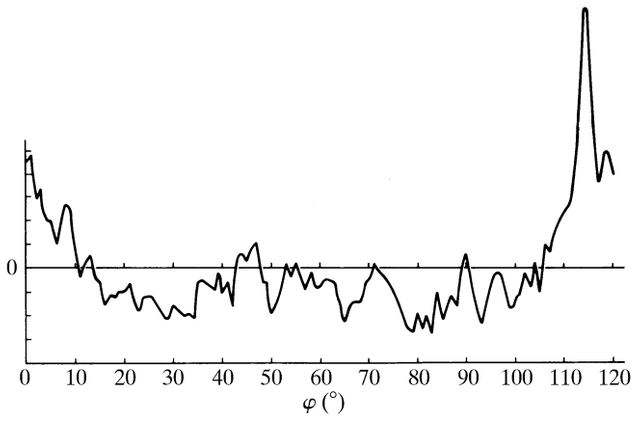

Fig. 2.3.6.6. The locked rotation function, L, applied to the determination of the orientation of the common cold virus (Arnold *et al.*, 1984). There are four virus particles per cubic cell with each particle sitting on a threefold axis. The locked rotation function explores all positions of rotation about this axis and, hence, repeats itself after 120°. The locked rotation function is determined from the individual rotation-function values of the noncrystallographic symmetry directions of a 532 icosahedron. [Reprinted with permission from Arnold *et al.* (1984).]

varying κ in polar coordinates. There will be no dependence on $(\theta_1 - \theta_3)$. Thus Eulerian searches can often be performed more economically in terms of the variables $\eta = \theta_1 + \theta_3$ and $\Delta = \theta_1 - \theta_3$, where

$$[\boldsymbol{\rho}] = \begin{pmatrix} \left[\cos\eta\cos^2\left(\frac{\theta_2}{2}\right) + \cos\Delta\sin^2\left(\frac{\theta_2}{2}\right)\right] & \left[\sin\eta\cos^2\left(\frac{\theta_2}{2}\right) + \sin\Delta\sin^2\left(\frac{\theta_2}{2}\right)\right] & \sin\theta_2\sin(\eta-\Delta) \\ \left[-\sin\eta\cos^2\left(\frac{\theta_2}{2}\right) + \sin\Delta\sin^2\left(\frac{\theta_2}{2}\right)\right] & \left[\cos\eta\cos^2\left(\frac{\theta_2}{2}\right) - \cos\Delta\sin^2\left(\frac{\theta_2}{2}\right)\right] & \sin\theta_2\cos(\eta-\Delta) \\ \sin\theta_2\sin(\eta+\Delta) & -\sin\theta_2\cos(\eta+\Delta) & \cos\theta_2 \end{pmatrix},$$

which reduces to the simple rotation matrix

$$[\boldsymbol{\rho}] = \begin{pmatrix} \cos\eta & \sin\eta & 0 \\ -\sin\eta & \cos\eta & 0 \\ 0 & 0 & 1 \end{pmatrix}$$

when $\theta_2 = 0$.

The computational effort to explore carefully a complete asymmetric unit of the rotation-function Eulerian group can be considerable. However, unless improper rotations are under investigation (as, for example, cross-rotation functions between different crystal forms of the same molecule), it is not generally necessary to perform such a global search. The number of molecules per crystallographic asymmetric unit, or the number of subunits per molecule, are often good indicators as to the possible types of noncrystallographic symmetry element. For instance, in the early investigation of insulin, the rotation function was used to explore only the $\kappa = 180°$ plane in polar coordinates as there were only two molecules per crystallographic asymmetric unit (Dodson *et al.*, 1966). Rotation functions of viruses, containing 532 icosahedral symmetry, are usually limited to exploration of the κ = 180, 120, 72 and 144° planes [*e.g.* Rayment *et al.* (1978) and Arnold *et al.* (1984)].

In general, the interpretation of the rotation function is straightforward. However, noise often builds up relative to the signal in high-symmetry space groups or if the data are limited or poor. One aid to a systematic interpretation is the locked rotation function (Rossmann *et al.*, 1972) for use when a molecule has more than one noncrystallographic symmetry axis. It is then possible to determine the rotation-function values for each molecular axis for a chosen molecular orientation (Fig. 2.3.6.6) (see Section 2.3.6.6).

Another problem in the interpretation of rotation functions is the appearance of apparent noncrystallographic symmetry that relates the self-Patterson of one molecule to the self-Patterson of a crystallographically related molecule. For example, take the case of α-chymotrypsin (Blow *et al.*, 1964). The space group is $P2_1$ with a molecular dimer in each of the two crystallographic asymmetric units. The noncrystallographic dimer axis was found to be perpendicular to the crystallographic 2_1 axis. The product of the crystallographic twofold in the Patterson with the orthogonal twofold in the self-Patterson vectors around the origin creates a third twofold, orthogonal to both of the other twofolds. In real space this represents a twofold screw direction relating the two dimers in the cell. In other cases, the product of the crystallographic and noncrystallographic symmetry results in symmetry which only has meaning in terms of all the vectors in the vicinity of the Patterson origin, but not in real space. Rotation-function peaks arising from such products are called Klug peaks (Johnson *et al.*, 1975). Such peaks normally refer to the total symmetry of all the vectors around the Patterson origin and may, therefore, be much larger than the peaks due to noncrystallographic symmetry within one molecule alone. Hence the Klug peaks, if not correctly recognized, can lead to erroneous conclusions (Åkervall *et al.*, 1972). Litvin (1975) has shown how Klug peaks can be predicted. These usually occur only for special orientations of a particle with a given symmetry relative to the crystallographic symmetry axes. Prediction of Klug peaks requires the simultaneous consideration of the noncrystallographic point group, the crystallographic point group and their relative orientations.

A special, but frequently occurring, situation arises when an evenfold noncrystallographic symmetry operator (*e.g.* 2-, 4-, 6-, 8-*etc.* fold axes) is parallel, or nearly parallel, to a crystallographic evenfold axis or screw axis. If the crystallographic evenfold axis is, say, parallel to Z, then if the centre of molecule I is at (X_0, Y_0, Z_0), the centre of molecule II will be at $(-X_0, -Y_0, Z_0)$. If molecule I has an evenfold axis parallel to Z, then for every atom (a) at $(x + X_0, y + Y_0, z + Z_0)$, there will be an atom (b) at $(-x + X_0, -y + Y_0, z + Z_0)$. The crystallographic symmetry-equivalent positions of these two atoms in molecule II will be at (c) $(-x - X_0, -y - Y_0, z + Z_0)$ and (d) $(x - X_0, y - Y_0, z + Z_0)$. The vectors between atoms (a) and (d) and also between atoms (b) and (c) will both have component lengths of $(2X_0, 2Y_0, 0)$. The position of this vector in a Patterson map is independent of the actual atoms in the molecule and depends only on the position of the molecular noncrystallographic symmetry axis.

Every atom will produce two vectors of this type, all of which will accumulate in a Patterson map to produce a large peak, which establishes the exact position of the noncrystallographic symmetry evenfold axis relative to the crystallographic axis. The position of the special peak is on the Harker section, namely at w = 0 for a crystallographic twofold axis and at $w = \frac{1}{2}$ for a crystallographic 2_1 screw axis. If there are N atoms in the structure of the two crystallographically related dimers, then the height of the origin is proportional to N (the number of zero-length vectors). The number of vectors with length $(2X_0, 2Y_0, 0)$ will be twice the number of atoms in each monomer, or $2 \times (N/4)$, which is $N/2$. Thus the special peak should be about half the height of the Patterson map's origin peak. In practice, the peak is often somewhat lower because the noncrystallographic symmetry and crystallographic axes might not be exactly parallel. This situation can be mitigated by computing the Patterson map with lower-resolution reflections only, as the difference in orientation between the axes is less significant when viewed at lower resolution (McKenna *et al.*, 1992).

2.3.6.5. The fast rotation function

Unfortunately, the rotation-function computations can be extremely time-consuming by conventional methods. Sasada (1964) developed a technique for rapidly finding the maximum of a given peak by looking at the slope of the rotation function. A major breakthrough came when Crowther (1972) recast the rotation function in a manner suitable for rapid computation. Only a brief outline of Crowther's fast rotation function is given here. Details are found in the original text (Crowther, 1972) and his computer program description.

Since the rotation function correlates spherical volumes of a given Patterson density with rotated versions of either itself or another Patterson density, it is likely that a more natural form for the rotation function will involve spherical harmonics rather than the Fourier components $|\mathbf{F_h}|^2$ of the crystal representation. Thus, if the two Patterson densities $P_1(r, \psi, \varphi)$ and $P_2(r, \psi, \varphi)$ are expanded within the spherical volume of radius less than a limiting value of a, then

$$P_1(r, \psi, \varphi) = \sum_{lmn} a^*_{lmn} \hat{j}_l(k_{ln} r) \hat{Y}_l^{m^*}(\psi, \varphi)$$

and

$$P_2(r, \psi, \varphi) = \sum_{l'm'n'} b_{l'm'n'} \hat{j}_{l'}(k_{l'n'} r) \hat{Y}_{l'}^{m'}(\psi, \varphi),$$

and the rotation function would then be defined as

$$R = \int_{\text{sphere}} P_1(r, \psi, \varphi) \mathscr{R} P_2(r, \psi, \varphi) r^2 \sin\psi \, \mathrm{d}r \, \mathrm{d}\psi \, \mathrm{d}\varphi.$$

Here $\hat{Y}_l^m(\psi, \varphi)$ is the normalized spherical harmonic of order l; $\hat{j}_l(k_{ln} r)$ is the normalized spherical Bessel function of order l; a_{lmn}, b_{lmn} are complex coefficients; and $\mathscr{R}P_2(r, \psi, \varphi)$ represents the rotated second Patterson. The rotated spherical harmonic can then be expressed in terms of the Eulerian angles $\theta_1, \theta_2, \theta_3$ as

$$\mathscr{R}(\theta_1, \theta_2, \theta_3) \hat{Y}_l^m(\psi, \varphi) = \sum_{q=-l}^{l} D^l_{qm}(\theta_1, \theta_2, \theta_3) \hat{Y}_l^q(\psi, \varphi),$$

where

$$D^l_{qm}(\theta_1, \theta_2, \theta_3) = \exp(iq\theta_3) d^l_{qm}(\theta_2) \exp(im\theta_1)$$

and $d^l_{qm}(\theta_2)$ are the matrix elements of the three-dimensional rotation group. It can then be shown that

$$R(\theta_1, \theta_2, \theta_3) = \sum_{lmm'n} a^*_{lmn} b_{lm'n} D^l_{m'm}(\theta_1, \theta_2, \theta_3).$$

Since the radial summation over n is independent of the rotation,

$$c_{lmm'} = \sum_n a^*_{lmn} b_{lmn},$$

and hence

$$R(\theta_1, \theta_2, \theta_3) = \sum_{lmm'} c_{lmm'} D^l_{m'm}(\theta_1, \theta_2, \theta_3)$$

or

$$R(\theta_1, \theta_2, \theta_3) = \sum_{mm'} \left[\sum_l c_{lmm'} d^l_{m'm}(\theta_2) \right] \exp[i(m'\theta_3 + m\theta_1)].$$

The coefficients $c_{lmm'}$ refer to a particular pair of Patterson densities and are independent of the rotation. The coefficients $D^l_{m'm}$, containing the whole rotational part, refer to rotations of spherical harmonics and are independent of the particular Patterson densities. Since the summations over m and m' represent a Fourier synthesis, rapid calculation is possible.

As polar coordinates rather than Eulerian angles provide a more graphic interpretation of the rotation function, Tanaka (1977) has recast the initial definition as

$$\begin{aligned} R(\theta_1, \theta_2, \theta_3) = & \int_{\text{sphere}} [\mathscr{R}(\theta_1, \theta_2, \theta_3 = 0) P_1(r, \psi, \varphi)] \\ & \times [\mathscr{R}(\theta_1, \theta_2, \theta_3) P_2(r, \psi, \varphi)] \, \mathrm{d}V \\ = & \int_{\text{sphere}} [P_1(r, \psi, \varphi)][\mathscr{R}^{-1}(\theta_1, \theta_2, \theta_3 = 0) \\ & \times \mathscr{R}(\theta_1, \theta_2, \theta_3) P_2(r, \psi, \varphi)] \, \mathrm{d}V. \end{aligned}$$

He showed that the polar coordinates are now equivalent to $\kappa = \theta_3$, $\psi = \theta_2$ and $\varphi = \theta_1 - \pi/2$. The rotation function can then be expressed as

$$\begin{aligned} R(\kappa, \psi, \varphi) = \sum_{lmm'} \left(\sum_n a^*_{lmn} b_{lm'n} \right) \sum_q \{ & d^l_{qm}(\psi) d^l_{qm'}(\psi) (-1)^{(m'-m)} \\ & \times \exp[i(\kappa q)] \exp[i(m' - m)\varphi] \}, \end{aligned}$$

permitting rapid calculation of the fast rotation function in polar coordinates.

Crowther (1972) uses the Eulerian angles α, β, γ which are related to those defined by Rossmann & Blow (1962) according to $\theta_1 = \alpha + \pi/2$, $\theta_2 = \beta$ and $\theta_3 = \gamma - \pi/2$.

An alternative formulation of the fast rotation function, which reduces the errors in the calculation, is implemented in *AMoRe* (Navaza, 1987, 1993, 1994, 2001*a*). New target functions derived from the principle of maximum likelihood have been implemented in conjunction with fast rotation functions in the program *Phaser*, which can also take advantage of partial model information in orienting unknown fragments (Storoni *et al.*, 2004).

2.3.6.6. Locked rotation functions

Many oligomers of macromolecules obey simple point-group symmetry, which is maintained as noncrystallographic symmetry when they are crystallized. For example, a homo-tetramer often obeys 222 point-group symmetry, and icosahedral viruses obey 532 point-group symmetry. The locked rotation function takes advantage of this information and can greatly simplify the calculation and the interpretation of rotation functions (Fig. 2.3.6.6) (Arnold *et al.*, 1984; Rossmann *et al.*, 1972; Tong, 2001*a*; Tong & Rossmann, 1990, 1997). During the rotation-function calculation, the noncrystallographic symmetry of the crystal is *locked* to the presumed point group, hence the name locked rotation function.

Given the noncrystallographic symmetry point group, a standard orientation can be defined which serves as a reference orientation for this point group. For example, for 222 point-group symmetry, the standard orientation can be defined such that the three twofold axes are parallel to the three Cartesian coordinate axes that are defined with respect to the crystal unit cell. Once the standard orientation is defined, any orientation of the noncrystallographic symmetry point group can be related to the standard

orientation by a single set of three rotation angles that determine the rotation matrix [**E**].

Assume $[\mathbf{I}_n]$ ($n = 1, \ldots, N$) is the collection of noncrystallographic symmetry point-group rotation matrices in the standard orientation. Then the operation [**E**] will bring the noncrystallographic symmetry point group to a new orientation and the noncrystallographic symmetry rotation matrices in this new orientation, $[\boldsymbol{\rho}_n]$, are given by (Tong & Rossmann, 1990)

$$[\boldsymbol{\rho}_n] = [\mathbf{E}][\mathbf{I}_n][\mathbf{E}]^{-1}. \qquad (2.3.6.8)$$

For each rotation [**E**], the ordinary self-rotation-function value (R_n) for each of the noncrystallographic symmetry rotation matrices in the new orientation ($[\boldsymbol{\rho}_n]$) is calculated. The locked self-rotation-function value ($R_{\rm L}$) for this rotation is defined as the average of the ordinary rotation-function values over the noncrystallographic symmetry elements

$$R_{\rm L}([\mathbf{E}]) = \frac{1}{N-1}\sum_{n=2}^{N} R_n,$$

where the summation starts from 2 as it is assumed that $[\mathbf{I}_1]$ is the identity matrix.

The locked self rotation function simplifies the task of interpreting the self rotation function for the orientation of an noncrystallographic symmetry assembly. Instead of searching for $N-1$ peaks in the ordinary self rotation function, a single peak is sought in the locked self rotation function. It must be emphasized that this rotation ([**E**]) in the locked self rotation function is most often a general rotation. The locked self rotation function also reduces the noise in the rotation-function calculation by a factor of $(N-1)^{1/2}$ due to the averaging of the ordinary rotation-function values (Tong & Rossmann, 1990).

The symmetry of the locked self rotation function is generally rather complex and an analytical solution is often impossible (Tong & Rossmann, 1990). It depends not only on the crystallographic symmetry and the noncrystallographic symmetry, but also on the definition of the standard orientation of the noncrystallographic symmetry. For example, if the standard orientation is defined such that the twofold axes are parallel to the Cartesian coordinate axes for the 222 point group, a 90° rotation around the X, Y or Z axis, or a 120° rotation around the 111 direction, does not cause a net change to the standard orientation. Such rotations will appear as symmetry in the locked self rotation function (Tong & Rossmann, 1997). In practice, the locked self rotation function can be calculated rather quickly, especially if the fast rotation function is used. A large region of rotation space can be explored in the calculation of the locked rotation function and the solutions can then be clustered based on the resulting orientation of the noncrystallographic symmetry. For example, two rotations $[\mathbf{E}_1]$ and $[\mathbf{E}_2]$ that produce the same set of noncrystallographic symmetry matrices based on (2.3.6.8) are likely to be related by the symmetry of the locked self rotation function.

A locked cross rotation function can also be defined to determine the orientation, [**F**], of the known monomer structure relative to the noncrystallographic symmetry of the molecular assembly (Navaza *et al.*, 1998; Tong, 2001*a*; Tong & Rossmann, 1990, 1997). With the knowledge of [**F**] and the orientation of the noncrystallographic symmetry in the crystal [**E**], which can be determined from the locked self rotation function, the orientation of all the monomers in the crystal cell is given by

$$[\boldsymbol{\rho}_n] = [\mathbf{E}][\mathbf{I}_n][\mathbf{F}].$$

Therefore, $[\boldsymbol{\rho}_n]$ represents the rotational relationship between the monomer search model and the monomers of the assembly in the crystal. An ordinary cross-rotation-function value R_n can be calculated for each of the rotations $[\boldsymbol{\rho}_n]$, and the locked cross-rotation-function value is defined as the average

$$R_{\rm L} = (1/N)\sum_n R_n.$$

Like the locked self rotation function, the locked cross rotation function can determine the orientation of all the monomers of the noncrystallographic symmetry assembly with a single rotation.

2.3.7. Translation functions

2.3.7.1. Introduction

The problem of determining the position of a noncrystallographic symmetry element in space, or the position of a molecule of known orientation in a unit cell, has been reviewed by Rossmann (1972), Colman *et al.* (1976), Karle (1976), Argos & Rossmann (1980), Harada *et al.* (1981) and Beurskens (1981). All methods depend on the prior knowledge of the object's orientation implied by the rotation matrix [***C***]. The various translation functions, T, derived below, can only be computed given this information.

The general translation function can be defined as

$$T(\mathbf{S}_x, \mathbf{S}_{x'}) = \int_U \rho_1(\mathbf{x}) \cdot \rho_2(\mathbf{x}')\, {\rm d}\mathbf{x},$$

where T is a six-variable function given by each of the three components that define $\mathbf{S}_x$ and $\mathbf{S}_{x'}$. Here $\mathbf{S}_x$ and $\mathbf{S}_{x'}$ are equivalent reference positions of the objects, whose densities are $\rho_1(\mathbf{x})$ and $\rho_2(\mathbf{x}')$. The translation function searches for the optimal overlap of the two objects after they have been similarly oriented. Following the same procedure used for the rotation-function derivation, Fourier summations are substituted for $\rho_1(\mathbf{x})$ and $\rho_2(\mathbf{x}')$. It can then be shown that

$$T(\mathbf{S}_x, \mathbf{S}_{x'}) = \int_U \left\{\frac{1}{V_{\mathbf{h}}}\sum_{\mathbf{h}} |\mathbf{F}_{\mathbf{h}}| \exp[i(\alpha_{\mathbf{h}} - 2\pi\mathbf{h}\cdot\mathbf{x})]\right\} \times \left\{\frac{1}{V_{\mathbf{p}}}\sum_{\mathbf{p}} |\mathbf{F}_{\mathbf{p}}| \exp[i(\alpha_{\mathbf{p}} - 2\pi\mathbf{p}\cdot\mathbf{x}')]\right\} {\rm d}\mathbf{x}.$$

Using the substitution $\mathbf{x}' = [\boldsymbol{C}]\mathbf{x} + \mathbf{d}$ and simplifying leads to

$$T(\mathbf{S}_x, \mathbf{S}'_x) = \frac{1}{V_{\mathbf{h}}V_{\mathbf{p}}}\sum_{\mathbf{h}}\sum_{\mathbf{p}} |\mathbf{F}_{\mathbf{h}}||\mathbf{F}_{\mathbf{p}}| \times \exp[i(\alpha_{\mathbf{h}} + \alpha_{\mathbf{p}} - 2\pi\mathbf{p}\cdot\mathbf{d})] \times \int_U \exp\{-2\pi i(\mathbf{h} + [\boldsymbol{C}]^T\mathbf{p})\cdot\mathbf{x}\}\, {\rm d}\mathbf{x}.$$

The integral is the diffraction function $G_{\mathbf{hp}}$ (2.3.6.4). If the integration is taken over the volume U, centred at $\mathbf{S}_x$ and $\mathbf{S}_{x'}$, it follows that

$$T(\mathbf{S}_x, \mathbf{S}_{x'}) = \frac{2}{V_{\mathbf{h}}V_{\mathbf{p}}}\sum_{\mathbf{h}}\sum_{\mathbf{p}} |\mathbf{F}_{\mathbf{h}}||\mathbf{F}_{\mathbf{p}}| G_{\mathbf{hp}} \times \cos[\alpha_{\mathbf{h}} + \alpha_{\mathbf{p}} - 2\pi(\mathbf{h}\cdot\mathbf{S}_x + \mathbf{p}\cdot\mathbf{S}_{x'})]. \qquad (2.3.7.1)$$

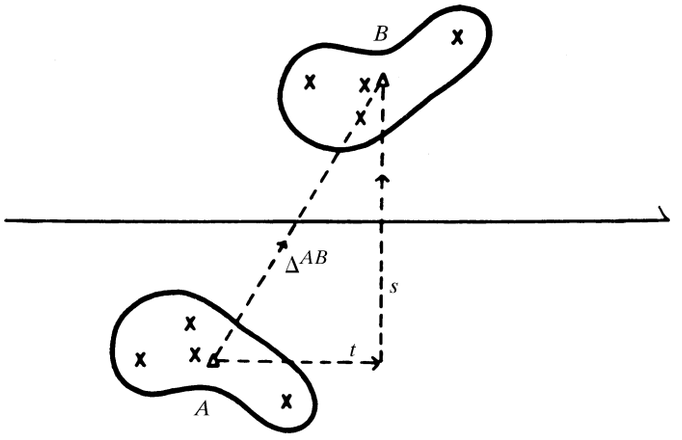

Fig. 2.3.7.1. Crosses represent atoms in a two-dimensional model structure. The triangles are the points chosen as approximate centres of molecules A and B. Δ^{AB} has components t and s parallel and perpendicular, respectively, to the screw rotation axis. [Reprinted from Rossmann *et al.* (1964).]

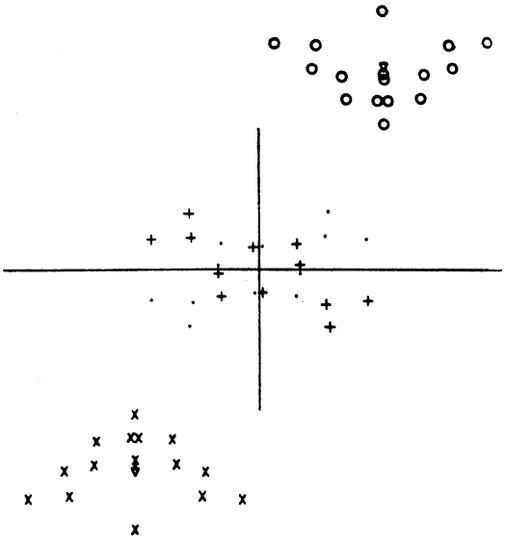

Fig. 2.3.7.2. Vectors arising from the structure in Fig. 2.3.7.1. The self-vectors of molecules A and B are represented by + and ·; the cross-vectors from molecules A to B and B to A by × and ○. Triangles mark the position of $+\Delta^{AB}$ and $-\Delta^{AB}$. [Reprinted from Rossmann *et al.* (1964).]

2.3.7.2. Position of a noncrystallographic element relating two unknown structures

The function (2.3.7.1) is quite general. For instance, the rotation function corresponds to a comparison of Patterson functions P_1 and P_2 at their origins. That is, the coefficients are F^2, phases are zero and $\mathbf{S}_x = \mathbf{S}_{x'} = 0$. However, the determination of the translation between two objects requires the comparison of cross-vectors away from the origin.

Consider, for instance, the determination of the precise translation vector parallel to a rotation axis between two identical molecules of unknown structure. For simplicity, let the noncrystallographic axis be a dyad (Fig. 2.3.7.1). Fig. 2.3.7.2 shows the corresponding Patterson of the hypothetical point-atom structure. Opposite sets of cross-Patterson vectors in Fig. 2.3.7.2 are related by a twofold rotation and a translation equal to twice the precise vector in the original structure. A suitable translation function would then compare a Patterson at $\mathbf{S}$ with the rotated Patterson at $-\mathbf{S}$. Hence, substituting $\mathbf{S}_x = \mathbf{S}$ and $\mathbf{S}_{x'} = -\mathbf{S}$ in (2.3.7.1),

$$T(\mathbf{S}) = \frac{2}{V^2}\sum_{\mathbf{h}}\sum_{\mathbf{p}}|\mathbf{F}_\mathbf{h}|^2|\mathbf{F}_\mathbf{p}|^2 G_{\mathbf{hp}}\cos[2\pi(\mathbf{h}-\mathbf{p})\cdot\mathbf{S}]. \qquad (2.3.7.2)$$

The opposite cross-vectors can be superimposed only if an evenfold rotation between the unknown molecules exists. The translation function (2.3.7.2) is thus applicable only in this special situation. There is no published translation method to determine the interrelation of two unknown structures in a crystallographic asymmetric unit or in two different crystal forms. However, another special situation exists if a molecular evenfold axis is parallel to a crystallographic evenfold axis. In this case, the position of the noncrystallographic symmetry element can be easily determined from the large peak in the corresponding Harker section of the Patterson.

In general, it is difficult or impossible to determine the positions of noncrystallographic axes (or their intersection at a molecular centre). However, the position of heavy atoms in isomorphous derivatives, which usually obey the noncrystallographic symmetry, can often determine this information.

2.3.7.3. Position of a known molecular structure in an unknown unit cell

The most common type of translation function occurs when looking for the position of a known molecular structure in an unknown crystal. For instance, if the structure of an enzyme has previously been determined by the isomorphous replacement method, then the structure of the same enzyme from another species can often be solved by molecular replacement [*e.g.* Grau *et al.* (1981)]. However, there are some severe pitfalls when, for instance, there are gross conformational changes [*e.g.* Moras *et al.* (1980)]. This type of translation function could also be useful in the interpolation of E maps produced by direct methods. Here there may often be confusion as a consequence of a number of molecular images related by translations (Karle, 1976; Beurskens, 1981; Egert & Sheldrick, 1985).

Tollin's (1966) Q function and Crowther & Blow's (1967) translation function are essentially identical (Tollin, 1969) and depend on a prior knowledge of the search molecule as well as its orientation in the unknown cell. The derivation given here, however, is somewhat more general and follows the derivation of Argos & Rossmann (1980), and should be compared with the method of Harada *et al.* (1981).

If the known molecular structure is correctly oriented into a cell (**p**) of an unknown structure and placed at **S** with respect to a defined origin, then a suitable translation function is

$$T(\mathbf{S}) = \sum_{\mathbf{p}}|\mathbf{F}_{\mathbf{p},\,\mathrm{obs}}|^2|\mathbf{F}_\mathbf{p}(\mathbf{S})|^2. \qquad (2.3.7.3)$$

This definition is preferable to one based on an R-factor calculation as it is more amenable to computation and is independent of a relative scale factor.

The structure factor $\mathbf{F}_\mathbf{p}(\mathbf{S})$ can be calculated by modifying expression (2.3.8.9) (see below). That is,

$$\mathbf{F}_\mathbf{p}(\mathbf{S}) = \frac{U}{V_\mathbf{h}}\sum_{n=1}^{N}\exp(2\pi i\mathbf{p}\cdot\mathbf{S}_n)\left[\sum_{\mathbf{h}}\mathbf{F}_\mathbf{h}G_{\mathbf{hp}_n}\exp(-2\pi i\mathbf{h}\cdot\mathbf{S})\right],$$

where $V_\mathbf{h}$ is the volume of cell (**h**) and $\mathbf{S}_n$ is the position, in the nth crystallographic asymmetric unit, of cell (**p**) corresponding to **S** in known cell (**h**). Let

$$A_{\mathbf{p},\,n}\exp(i\gamma_n) = \sum_{\mathbf{h}}\mathbf{F}_\mathbf{h}G_{\mathbf{hp}_n}\exp(-2\pi i\mathbf{h}\cdot\mathbf{S}),$$

which are the coefficients of the molecular transform for the known molecule placed into the nth asymmetric unit of the **p** cell. Thus

$$\mathbf{F}_{\mathbf{p}}(\mathbf{S}) = \frac{U}{V_{\mathbf{h}}} \sum_{n=1}^{N} A_{\mathbf{p},n} \exp[i(\gamma + 2\pi \mathbf{p} \cdot \mathbf{S}_n)]$$

or

$$\mathbf{F}_{\mathbf{p}}(\mathbf{S}) = \frac{U}{V_{\mathbf{h}}} \sum_{n=1}^{N} A_{\mathbf{p},n} \exp[i(\gamma_n + 2\pi \mathbf{p}_n \cdot \mathbf{S})],$$

where $\mathbf{p}_n = [\boldsymbol{C}_n^T]\mathbf{p}$ and $\mathbf{S} = \mathbf{S}_1$. Hence

$$|\mathbf{F}_{\mathbf{p}}(\mathbf{S})|^2 = \left(\frac{U}{V_{\mathbf{h}}}\right)^2 \sum_n \sum_m \big(A_{\mathbf{p},n} A_{\mathbf{p},m} \times \exp\{i[2\pi(\mathbf{p}_n - \mathbf{p}_m) \cdot \mathbf{S} + (\gamma_n - \gamma_m)]\}\big),$$

and then from (2.3.7.3)

$$T(\mathbf{S}) = \left(\frac{U}{V_{\mathbf{h}}}\right)^2 \sum_{\mathbf{p}} \sum_n \sum_m \Big(|\mathbf{F}_{\mathbf{p},\,\mathrm{obs}}|^2 A_{\mathbf{p},n} A_{\mathbf{p},m} \times \exp\{i[2\pi(\mathbf{p}_n - \mathbf{p}_m) \cdot \mathbf{S} + (\gamma_n - \gamma_m)]\}\Big), \qquad (2.3.7.4)$$

which is a Fourier summation with known coefficients $\{|\mathbf{F}_{\mathbf{p},\,\mathrm{obs}}|^2 A_{\mathbf{p},n} A_{\mathbf{p},m} \times \exp[i(\gamma_n - \gamma_m)]\}$ such that $T(\mathbf{S})$ will be a maximum at the correct molecular position.

Terms with $n = m$ in expression (2.3.7.4) can be omitted as they are independent of **S** and only contribute a constant to the value of $T(\mathbf{S})$. For terms with $n \neq m$, the indices take on special values. For instance, if the **p** cell is monoclinic with its unique axis parallel to **b** such that $\mathbf{p}_1 = (p, q, r)$ and $\mathbf{p}_2 = (\bar{p}, q, \bar{r})$, then $\mathbf{p}_1 - \mathbf{p}_2$ would be $(2p, 0, 2r)$. Hence, $T(\mathbf{S})$ would be a two-dimensional function consistent with the physical requirement that the translation component, parallel to the twofold monoclinic axis, is arbitrary.

Crowther & Blow (1967) show that if $\mathbf{F}_{\mathrm{M}}$ are the structure factors of a known molecule correctly oriented within the cell of the unknown structure at an arbitrary molecular origin, then (altering the notation very slightly from above)

$$T(\mathbf{S}) = \sum_{\mathbf{p}} |\mathbf{F}_{\mathrm{obs}}(\mathbf{p})|^2 \mathbf{F}_{\mathrm{M}}(\mathbf{p}) \mathbf{F}_{\mathrm{M}}^*(\mathbf{p}[\boldsymbol{C}]) \exp(-2\pi i \mathbf{p} \cdot \mathbf{S}),$$

where $[\boldsymbol{C}]$ is a crystallographic symmetry operator relative to which the molecular origin is to be determined. This is of the same form as (2.3.7.4) but concerns the special case where the **h** cell, into which the known molecule was placed, has the same dimensions as the **p** cell.

The translation function as defined by (2.3.7.4) is on an arbitrary scale, which makes it difficult to compare results from different calculations. Translation functions can also be defined based on the crystallographic R factor or a correlation coefficient (CC). In particular, CCs based on reflection intensities can be evaluated by Fourier methods (Navaza & Vernoslova, 1995), although it is still computationally more expensive than the evaluation of (2.3.7.4). Alternatively, the translation function can be calculated first with (2.3.7.4), and then the R factor and CC can be calculated for the resulting top solutions.

A correct solution should also produce satisfactory packing arrangements of the molecular models in the crystal. Packing functions have been derived that estimate the amount of overlap among the models (Harada *et al.*, 1981; Hendrickson & Ward, 1976; Rabinovich & Shakked, 1984; Simpson *et al.*, 2001), and such considerations can frequently limit the search volume very considerably. Alternatively, a simple enumeration of the actual close contacts among different molecules in the crystal (for example, Cα–Cα distances less than 3 Å) has also been found to be an effective way of eliminating those solutions that produce unreasonable crystal packing (Jogl *et al.*, 2001; Tong, 1993). If conformational differences are expected between the search atomic model and the actual structure, care must be taken when applying this packing check.

2.3.7.4. Position of a noncrystallographic symmetry element in a poorly defined electron-density map

If an initial set of poor phases, for example from an SIR derivative, are available and the rotation function has given the orientation of a noncrystallographic rotation axis, it is possible to search the electron-density map systematically to determine the translation axis position. The translation function must, therefore, measure the quality of superposition of the poor electron-density map on itself. Hence $\mathbf{S}_x = \mathbf{S}_{x'} = \mathbf{S}$ and the function (2.3.7.1) now becomes

$$T(\mathbf{S}) = \frac{2}{V_{\mathbf{h}}^2} \sum_{\mathbf{h}} \sum_{\mathbf{p}} |\mathbf{F}_{\mathbf{h}}||\mathbf{F}_{\mathbf{p}}| G_{\mathbf{hp}} \cos[\alpha_{\mathbf{h}} + \alpha_{\mathbf{p}} - 2\pi(\mathbf{h} + \mathbf{p}) \cdot \mathbf{S}].$$

This real-space translation function has been used successfully to determine the intermolecular dyad axis for α-chymotrypsin (Blow *et al.*, 1964) and to verify the position of immunoglobulin domains (Colman & Fehlhammer, 1976).

2.3.7.5. Locked translation function

In a translation search, an atomic model with a given orientation is moved systematically through the unit cell. In such a situation, the structure-factor equation takes on the special form (Harada *et al.*, 1981; Rae, 1977; Tong, 1993)

$$\mathbf{F}_{\mathbf{h}}^{\mathrm{c}} = \sum_n \mathbf{F}_{\mathbf{h},n} \exp(2\pi i \mathbf{h}^T [\mathbf{T}_n] \mathbf{S}),$$

where **S** is the translation vector and the summation goes over the crystallographic symmetry operators. $\mathbf{F}_{\mathbf{h},n}$ is the structure factor calculated based only on the nth symmetry-related molecule,

$$\mathbf{F}_{\mathbf{h},n} = \sum_j f_j \exp\{2\pi i \mathbf{h}^T ([\mathbf{T}_n] \mathbf{x}_j^0 + \mathbf{t}_n)\},$$

where $\mathbf{x}_j^0$ represents the atomic position of the model at the reference position and the summation goes over all the atoms.

Noting equation (2.3.7.3), the translation function is given by

$$T(\mathbf{S}) = \sum_{\mathbf{h}} \sum_n |\mathbf{F}_{\mathbf{h}}^{\mathrm{o}}|^2 |\mathbf{F}_{\mathbf{h},n}|^2 + \sum_{\mathbf{h}} \sum_n \sum_{m \neq n} |\mathbf{F}_{\mathbf{h}}^{\mathrm{o}}|^2 |\mathbf{F}_{\mathbf{h},n} \mathbf{F}_{\mathbf{h},m}^*| \exp\{-2\pi i \mathbf{h}^T ([\mathbf{T}_m] - [\mathbf{T}_n]) \mathbf{S}\}, \qquad (2.3.7.5)$$

where the second term is the ordinary translation function, analogous to (2.3.7.4). The first term of (2.3.7.5) depends on the orientation of the model. Maximization of this term, or its correlation coefficient equivalent, is the basis behind the Patterson-correlation refinement (Brünger, 1990; Tong, 1996*b*) and the direct rotation function (DeLano & Brünger, 1995). It is

also related to the intensity-based domain refinement (Yeates & Rini, 1990).

In the presence of noncrystallographic symmetry, the locked self rotation function can be used to define the orientation of the noncrystallographic symmetry point group in the crystal. If an atomic model is available for the monomer but not for the entire oligomer, the locked cross rotation function can be used to determine the orientation of this monomer in the oligomer. The locked translation function can then be used to determine the position of this monomer relative to the centre of the noncrystallographic symmetry point group (Tong, 1996*b*, 2001*a*), which will produce a model for the entire oligomer. The centre of this oligomer in the crystal can be defined by a simple translation search.

With the knowledge of the orientation of one monomer of the oligomer, the first term of (2.3.7.5) is dependent on the position of this monomer relative to the centre of the noncrystallographic symmetry oligomer (Tong, 1996*b*). The atomic positions of the entire noncrystallographic symmetry oligomer in the standard orientation are given by

$$\mathbf{X}_{n,j} = [\mathbf{I}_n]\big([\mathbf{F}]\mathbf{X}_j^0 + \mathbf{V}_0\big),$$

where $\mathbf{X}_j^0$ are the atomic positions of the monomer model, centred at (0, 0, 0); [**F**] is the orientation of this model in the oligomer in the standard orientation; $\mathbf{V}_0$ is the position of this monomer relative to the centre of the oligomer; and $[\mathbf{I}_n]$ is the nth noncrystallographic symmetry rotation matrix in the standard orientation. The atomic positions of the noncrystallographic symmetry oligomer in the crystal unit cell, centred at the origin, are given by

$$\mathbf{x}_{n,j} = [\boldsymbol{\alpha}][\mathbf{E}]\mathbf{X}_{n,j} = [\boldsymbol{\alpha}][\mathbf{E}][\mathbf{I}_n]\big([\mathbf{F}]\mathbf{X}_j^0 + \mathbf{V}_0\big),$$

where [**E**] is the orientation of the noncrystallographic symmetry in the crystal unit cell and [$\boldsymbol{\alpha}$] is the deorthogonalization matrix.

By incorporating the calculated structure factors based on this noncrystallographic symmetry oligomer into the first term of (2.3.7.5), the locked translation function is given by

$$\begin{aligned} T_{\rm L}(\mathbf{V}_0) &= \sum_{\mathbf{h}} |\mathbf{F}_{\mathbf{h}}^{\rm o}|^2 |\mathbf{F}_{\mathbf{h}}|^2 \\ &= \sum_{\mathbf{h}} \sum_{n} \sum_{m \neq n} |\mathbf{F}_{\mathbf{h}}^{\rm o}|^2 \mathbf{F}_{\mathbf{h},n} \mathbf{F}_{\mathbf{h},m}^{*} \exp\{-2\pi i \mathbf{h}([\boldsymbol{\theta}_m] - [\boldsymbol{\theta}_n])\mathbf{V}_0\}, \end{aligned} \tag{2.3.7.6}$$

where $[\boldsymbol{\theta}_n] = [\boldsymbol{\alpha}][\mathbf{E}][\mathbf{I}_n]$ and $\mathbf{F}_{\mathbf{h},n_o} = \sum_j f_j \exp(2\pi i \mathbf{h}[\boldsymbol{\theta}_n][\mathbf{F}]\mathbf{X}_j^0)$. A constant term $\sum_{\mathbf{h}} \sum_n |\mathbf{F}_{\mathbf{h}}^{\rm o}|^2 |\mathbf{F}_{\mathbf{h},n}|^2$ has been omitted from this equation.

Conceptually, the locked translation function is based on the overlap of intermolecular vectors within the noncrystallographic symmetry oligomer and the observed Patterson map (Tong, 1996*b*). The equation for the locked translation function, (2.3.7.6), bears remarkable resemblance to that for the ordinary Patterson-correlation translation function, (2.3.7.5), with the interchange of the crystallographic ([$\mathbf{T}_n$]) and noncrystallographic symmetry ([$\boldsymbol{\theta}_n$]) parameters.

2.3.7.6. Computer programs for rotation and translation function calculations

Several programs are currently in popular use for the calculation of rotation and translation functions. These include *AMoRe* (Navaza, 1994, 2001*a*), *BEAST* (Read, 2001*b*), *CCP4* (Collaborative Computational Project, Number 4, 1994), *CNS* (Brünger *et al.*, 1998), *COMO* (Jogl *et al.*, 2001), *EPMR* (Kissinger *et al.*, 1999), *GLRF* (part of the *Replace* package) (Tong, 1993, 2001*a*; Tong & Rossmann, 1990, 1997), *Molrep* (Vagin & Teplyakov, 2000) and *Phaser* (Storoni *et al.*, 2004).

The correct placement of an atomic model in a crystal unit cell is generally a six-dimensional problem, with three degrees of rotational freedom and three degrees of translational freedom. Systematic examination of all six degrees of freedom at the same time is computationally expensive and cannot be used routinely (Fujinaga & Read, 1987; Rabinovich & Shakked, 1984; Sheriff *et al.*, 1999). On the other hand, directed sampling of the six degrees of freedom, driven by a stochastic or genetic algorithm (Chang & Lewis, 1997; Glykos & Kokkinidis, 2000; Kissinger *et al.*, 1999), has been successful in solving structures.

Traditionally, the calculations are divided into a rotational component (the rotation function) and a translational component (the translation function). Only a few rotation angles (for example the top few peaks of the rotation function) are manually passed to the translation function for examination (Fitzgerald, 1988). With the power of modern computers, it is now possible to perform limited six-dimensional searches, with the sampling of the rotational degrees of freedom guided by the rotation function. For example, the top peaks of the rotation function (Navaza, 1994) and their neighbours (Urzhumtsev & Podjarny, 1995) can be automatically examined by the translation function. A more general approach is to examine all rotation-function grid points with values greater than a certain threshold (Tong, 1996*a*). Such combined molecular replacement protocols have been found to be very powerful in solving new structures.

2.3.8. Molecular replacement

2.3.8.1. Using a known molecular fragment

The most straightforward application of the molecular replacement method occurs when the orientation and position of a known molecular fragment in an unknown cell have been previously determined. The simple procedure is to apply the rotation and translation operations to the known fragment. This will place it into one 'standard' asymmetric unit of the unknown cell. Then the crystal operators (assuming no further noncrystallographic operators are present in the unknown cell) are applied to generate the complete unit cell of the unknown structure. Structure factors can then be calculated from the rotated and translated known molecule into the unknown cell. The resultant model can be refined in numerous ways.

More generally, consider a molecule placed in any crystal cell (**h**), within which coordinate positions shall be designated by **x**. Let the corresponding structure factors be $\mathbf{F}_{\mathbf{h}}$. It is then possible to compute the structure factors $\mathbf{F}_{\mathbf{p}}$ for another cell (**p**) into which the same molecule has been placed N times related by the crystallographic symmetry operators $[\boldsymbol{C}_1], \mathbf{d}_1; [\boldsymbol{C}_2], \mathbf{d}_2; \ldots; [\boldsymbol{C}_N], \mathbf{d}_N$. Let the electron density at a point $\mathbf{y}_1$ in the first crystallographic asymmetric unit be spatially related to the point $\mathbf{y}_n$ in the nth asymmetric unit of the **p** crystal such that

$$\rho(\mathbf{y}_n) = \rho(\mathbf{y}_1), \tag{2.3.8.1}$$

where

$$\mathbf{y}_n = [\boldsymbol{C}_n]\mathbf{y}_1 + \mathbf{d}_n. \tag{2.3.8.2}$$

From the definition of a structure factor,

$$\mathbf{F}_{\mathbf{p}} = \sum_{n=1}^{N} \int_U \rho(\mathbf{y}_n) \exp(2\pi i \mathbf{p} \cdot \mathbf{y}_n)\, {\rm d}\mathbf{y}_n, \tag{2.3.8.3}$$

where the integral is taken over the volume U of one molecule. But since each molecule is identical as expressed in equation (2.3.8.1) and since (2.3.8.2) can be substituted in equation (2.3.8.3), we have

$$\mathbf{F}_\mathbf{p} = \sum_{n=1}^{N} \int_U \rho(\mathbf{y}_1) \exp[2\pi i \mathbf{p} \cdot ([\boldsymbol{C}_n]\mathbf{y}_1 + \mathbf{d}_n)] \, \mathrm{d}\mathbf{y}_1. \quad (2.3.8.4)$$

Now let the molecule in the **h** crystal be related to the molecule in the first asymmetric unit of the **p** crystal by the noncrystallographic symmetry operation

$$\mathbf{x} = [\boldsymbol{C}]\mathbf{y} + \mathbf{d}, \quad (2.3.8.5)$$

which implies

$$\rho(\mathbf{x}) = \rho(\mathbf{y}_1) = \rho(\mathbf{y}_2) = \ldots. \quad (2.3.8.6)$$

Furthermore, in the **h** cell

$$\rho(\mathbf{x}) = \frac{1}{V_\mathbf{h}} \sum_\mathbf{h} \mathbf{F}_\mathbf{h} \exp(-2\pi i \mathbf{h} \cdot \mathbf{x}), \quad (2.3.8.7)$$

and thus, by combining with (2.3.8.5), (2.3.8.6) and (2.3.8.7),

$$\rho(\mathbf{y}_1) = \frac{1}{V_\mathbf{h}} \sum_\mathbf{h} \mathbf{F}_\mathbf{h} \exp[-2\pi i(\mathbf{h}[\boldsymbol{C}] \cdot \mathbf{y}_1 + \mathbf{h} \cdot \mathbf{d})]. \quad (2.3.8.8)$$

Now using (2.3.8.4) and (2.3.8.8) it can be shown that

$$\mathbf{F}_\mathbf{p} = \frac{U}{V_\mathbf{h}} \sum_\mathbf{h} \mathbf{F}_\mathbf{h} \sum_{n=1}^{N} G_{\mathbf{hp}_n} \exp[2\pi i(\mathbf{p} \cdot \mathbf{S}_n - \mathbf{h} \cdot \mathbf{S})], \quad (2.3.8.9)$$

where

$$UG_{\mathbf{hp}_n} = \int_U \exp[2\pi i(p[\boldsymbol{C}_n] - \mathbf{h}[\boldsymbol{C}]) \cdot \mathbf{u}] \, \mathrm{d}\mathbf{u}. \quad (2.3.8.10)$$

S is a chosen molecular origin in the **h** crystal and $\mathbf{S}_n$ is the corresponding molecular position in the nth asymmetric unit of the **p** crystal.

2.3.8.2. Using noncrystallographic symmetry for phase improvement

The use of noncrystallographic symmetry for phase determination was proposed by Rossmann & Blow (1962, 1963) and subsequently explored by Crowther (1967, 1969) and Main & Rossmann (1966). These methods were developed in reciprocal space and were primarily concerned with *ab initio* phase determination. Real-space averaging of electron density between noncrystallographically related molecules was used in the structure determination of deoxyhaemoglobin (Muirhead *et al*., 1967) and of α-chymotrypsin (Matthews *et al*., 1967). The improvement derived from the averaging between the two noncrystallographic units was, however, not clear in either case. The first obviously successful application was in the structure determination of lobster glyceraldehyde-3-phosphate dehydrogenase (Buehner *et al*., 1974; Argos *et al*., 1975), where the tetrameric molecule of symmetry 222 occupied one crystallographic asymmetric unit. The improvement in the essentially SIR electron-density map was considerable and the results changed from uninterpretable to interpretable. The uniqueness and validity of the solution lay in the obvious chemical correctness of the polypeptide fold and its agreement with known amino-acid-sequence data. In contrast to the earlier reciprocal-space methods, noncrystallographic symmetry was used as a method to improve poor phases rather than to determine phases *ab initio*.

Table 2.3.8.1. *Molecular replacement: phase refinement as an iterative process*

(*A*)	$\mathbf{F}_\mathrm{obs}, \alpha'_n, m'_n \rightarrow \rho_n$
(*B*)	$\rho_n \rightarrow \rho_n$(modified) (i) Use of noncrystallographic symmetry operators (ii) Definition of envelope limiting volume within which noncrystallographic symmetry is valid (iii) Adjustment of solvent density† (iv) Use of crystallographic operators to reconstruct modified density into a complete cell
(*C*)	ρ_n(modified) $\rightarrow \mathbf{F}_{\mathrm{calc},\,n+1}; \alpha_{\mathrm{calc},\,n+1}$
(*D*)	$(\mathbf{F}_{\mathrm{calc},\,n+1}, \alpha_{\mathrm{calc},\,n+1}) + (\mathbf{F}_\mathrm{obs}, \alpha_0) \rightarrow \mathbf{F}_\mathrm{obs}, \alpha'_{n+1}, m'_{n+1}$ (i) Assessment of reliability of new phasing set α_{n+1} in relation to original phasing set $\alpha_0(w)$ (ii) Use of figures of merit m_0, m_{n+1} and reliability w to determine modified phasing set α'_{n+1}, m'_{n+1}‡ (iii) Consideration of α_{n+1} and m_{n+1} where there was no prior knowledge of (*a*) $\mathbf{F}_\mathrm{obs}$ (*e.g.* very low order reflections or uncollected data) (*b*) α_0 (*e.g.* no isomorphous information or phase extension)
(*E*)	Return to step (*A*) with α'_{n+1}, m'_{n+1} and a possibly augmented set of $\mathbf{F}_\mathrm{obs}$.

† Wang (1985); Bhat & Blow (1982); Collins (1975); Schevitz *et al*. (1981); Hoppe & Gassmann (1968). ‡ Rossmann & Blow (1961); Hendrickson & Lattman (1970).

Many other applications followed rapidly, aided greatly by the versatile techniques developed by Bricogne (1976). Of particular interest is the application to the structure determination of hexokinase (Fletterick & Steitz, 1976), where the averaging occurred both between different crystal forms and within the same crystal.

The most widely used procedure for real-space averaging is the 'double sorting' technique developed by Bricogne (1976) and also by Johnson (1978). An alternative method is to maintain the complete map stored in the computer (Nordman, 1980*b*). This avoids the sorting operation, but is only possible given a very large computer or a low-resolution map containing relatively few grid points.

Bricogne's double sorting technique involves generating real-space non-integral points (D_i) which are related to integral grid points (I_i) in the cell asymmetric unit by the noncrystallographic symmetry operators. The elements of the set D_i are then brought back to their equivalent points in the cell asymmetric unit (D'_i) and sorted by their proximity to two adjacent real-space sections. The set I'_i, calculated on a finer grid than I_i and stored in the computer memory two sections at a time, is then used for linear interpolation to determine the density values at D'_i which are successively stored and summed in the related array I_i. A count is kept of the number of densities received at each I_i, resulting in a final averaged aggregate, when all real-space sections have been utilized. The density to be assigned outside the molecular envelope (defined with respect to the set I_i) is determined by averaging the density of all unused points in I_i. The grid interval for the set I'_i should be about one-sixth of the resolution to avoid serious errors from interpolation (Bricogne, 1976). The grid point separation in the set I_i need only be sufficient for representation of electron density, or about one-third of the resolution.

Molecular replacement in real space consists of the following steps (Table 2.3.8.1): (*a*) calculation of electron density based on a starting phase set and observed amplitudes; (*b*) averaging of this density among the noncrystallographic asymmetric units or molecular copies in several crystal forms, a process which defines

a molecular envelope as the averaging is only valid within the range of the noncrystallographic symmetry; (*c*) reconstructing the unit cell based on averaged density in every noncrystallographic asymmetric unit; (*d*) calculating structure factors from the reconstructed cell; (*e*) combining the new phases with others to obtain a weighted best-phase set; and (*f*) returning to step (*a*) at the previous or an extended resolution. Decisions made in steps (*b*) and (*e*) determine the rate of convergence (see Table 2.3.8.1) to a solution (Arnold *et al*., 1987).

The power of the molecular replacement procedure for either phase improvement or phase extension depends on the number of noncrystallographic asymmetric units, the size of the excluded volume expressed in terms of the ratio $(V - UN)/V$ and the magnitude of the measurement error on the structure amplitudes. Crowther (1967, 1969) and Bricogne (1974) have investigated the dependence on the number of noncrystallographic asymmetric units and conclude that three or more copies are sufficient to ensure convergence of an iterative phase improvement procedure in the absence of errors on the structure amplitudes. As with the analogous case of isomorphous replacement in which three data sets ensure reasonable phase determination, additional copies will enhance the power of the method, although their usefulness is subject to the law of diminishing returns. Another example of this principle is the sign determination of the *h*0*l* reflections of horse haemoglobin (Perutz, 1954) in which seven shrinkage stages constituted the sampling of the transform of a single copy.

In an analysis of how phasing errors propagate into errors in calculations of electron density, Arnold & Rossmann (1986) concluded that the 'power' of phase determination could be related to the noncrystallographic redundancy, *N*, the ratio of the molecular envelope volume, *U*, to the unit cell volume, *V*, the fractional error of the structure-factor amplitudes, *R* and the fractional completeness of the data, *f*, by (Arnold & Rossmann, 1986)

$$P = \frac{(Nf)^{1/2}}{RU/V}. \qquad (2.3.8.11)$$

This semiquantitative result makes intuitive sense in that the noncrystallographic redundancy and solvent content terms can be directly related to over-sampling of the molecular transform in reciprocal space, and, thus, are analogous in providing phasing information. The phasing power of solvent flattening/density modification was further analysed and shown to lead to Sayre's equations (Sayre, 1952) at a limit where the molecular envelope is sufficiently detailed and shrunken to cover sharpened and separated atoms (Arnold & Rossmann, 1986). This result suggests that more detailed definitions of molecular envelopes than are traditionally used could be advantageous for phase improvement and extension procedures.

Procedures for real-space averaging have been used extensively with great success. The interesting work of Wilson *et al*. (1981) is noteworthy for the continuous adjustment of molecular envelope with increased map definition. Furthermore, the analysis of complete virus structures has only been possible as a consequence of this technique (Bloomer *et al*., 1978; Harrison *et al*., 1978; Abad-Zapatero *et al*., 1980; Liljas *et al*., 1982). Although the procedure has been used primarily for phase improvement, apparently successful attempts have been made at phase extension (Nordman, 1980*b*; Gaykema *et al*., 1984; Rossmann *et al*., 1985). *Ab initio* phasing of glyceraldehyde-3-phosphate dehydrogenase (Argos *et al*., 1975) was successfully attempted by initially filling the known envelope with uniform density to determine the phases of the innermost reflections and then gradually extending phases to 6.3 Å resolution. Johnson *et al*. (1976) used the same procedure to determine the structure of southern bean mosaic virus to 22.5 Å resolution. Particularly impressive was the work on polyoma virus (Rayment *et al*., 1982; Rayment, 1983; Rayment *et al*., 1983) where crude initial models led to an entirely unexpected breakdown of the Caspar & Klug (1962) concept of quasi-symmetry. *Ab initio* phasing has also been used by combining the electron-diffraction projection data of two different crystal forms of bacterial rhodopsin (Rossmann & Henderson, 1982).

2.3.8.3. Update on noncrystallographic averaging and density-modification methods

Since this article was originally written, molecular replacement has been subject of a number of reviews (Rossmann, 1990), including a historical background of the subject (Rossmann, 2001). A series of chapters pertaining to molecular replacement have been published in *IT* Volume F (Rossmann & Arnold, 2001*a*), reviewing noncrystallographic symmetry (Chapter 13.1; Blow, 2001), rotation (Chapter 13.2; Navaza, 2001*b*) and translation (Chapter 13.3; Tong, 2001*b*) functions, and noncrystallographic symmetry averaging for phase improvement and extension (Chapter 13.4; Rossmann & Arnold, 2001*b*). Chapters on phase improvement by density modification (Chapter 15.1; Zhang *et al.*, 2001), optimal weighting of Fourier terms in map calculations (Chapter 15.2; Read, 2001*a*) and refinement calculations incorporating bulk solvent correction (Chapter 18.4; Dauter *et al.*, 2001) are also recommended reading.

There has been remarkable progress in the general area of density modification, involving improvement of real-space methods for averaging and reconstruction, and treatment of solvent for iterative phase improvement and refinement calculations. The use of real-space averaging between noncrystallographically related electron density within the crystallographic asymmetric unit has become an accepted mode of extending phase information to higher resolution, particularly for complex structures such as viruses [Acharya *et al.*, 1989; Arnold & Rossmann, 1988; Gaykema *et al.*, 1986; Hogle *et al.*, 1985; Luo *et al.*, 1989; Rossmann & Arnold, 2001*b* (*IT* F Chapter 13.4); Rossmann *et al.*, 1985, 1992]. *Ab initio* phase determination based on noncrystallographic redundancy has become fairly common (Chapman *et al.*, 1992; Lunin *et al.*, 2000; Miller *et al.*, 2001; Rossmann, 1990; Tsao *et al.*, 1992). General programs in common use for noncrystallographic symmetry averaging include *BUSTER-TNT* [Blanc *et al.*, 2004; Roversi *et al.*, 2000; Tronrud & Ten Eyck, 2001 (*IT* F Section 25.2.4)], *CNS* [Brünger *et al.*, 1998; Brunger, Adams, DeLano *et al.*, 2001 (*IT* F Section 25.2.3)], *DM*/*DMMULTI* [Cowtan & Main, 1993; Cowtan *et al.*, 2001 (*IT* F Section 25.2.2); Schuller, 1996; Zhang, 1993], *PHASES* [Furey, 2001 (*IT* F Section 25.2.1); Furey & Swaminathan, 1997], *RAVE*/*MAVE* (Jones, 1992; Kleywegt, 1996) and *SOLVE*/*RESOLVE* [Terwilliger, 2002*b*, 2003*c*; Terwilliger & Berendzen, 2001 (*IT* F Section 14.2.2)].

Solvent flattening has been formulated in reciprocal space for greater computational efficiency (Leslie, 1987; Terwilliger, 1999) and solvent 'flipping' is a powerful extension of solvent density modification (Abrahams, 1997; Abrahams & Leslie, 1996). Bulk-solvent corrections are now commonly used in crystallographic refinement, allowing for better modelling and phase determination of low-resolution data [Brünger *et al.*, 1998; Dauter *et al.*, 2001 (*IT* F Chapter 18.4)]. The problem of phase error estimation and analysis and bias removal has been treated extensively (Cowtan, 1999; Cowtan & Main, 1996), including extension of methods to include maximum-likelihood functions and iterative bias removal procedures [Brunger, Adams & Rice, 2001 (*IT* F Chapter 18.2); Hunt & Deisenhofer, 2003; Lamzin *et al.*, 2001 (*IT* F Section 25.2.5); Perrakis *et al.*, 1997; Terwilliger, 2004]. Histogram matching [Cowtan & Main, 1993; Lunin, 1993; Nieh & Zhang, 1999; Refaat *et al.*, 1996; Zhang, 1993; Zhang *et al.*, 2001 (*IT* F Chapter 15.1)] and skeletonization [Baker *et al.*, 1993;

Zhang *et al.*, 2001 (*IT* F Chapter 15.1)], and structural fragment matching procedures (Terwilliger, 2003*a*) have been added to the arsenal of density-modification methods. Automated mask and molecular-envelope definition has helped to remove the tedium and increase the efficiency and quality of density-modification and symmetry-averaging procedures. Noncrystallographic symmetry averaging among different crystal forms (Perutz, 1954) has become increasingly common, and exploitation of the unit-cell variation among flash-cooled and noncooled forms of the same crystal is a broadly applicable method for phase determination (Das *et al.*, 1996; Ding *et al.*, 1995); soaking crystals in a series of different solvents and buffers can produce an analogous effect (Ren *et al.*, 1995; Tong *et al.*, 1997). Phases from noncrystallographic symmetry averaging and other 'experimental' sources have been incorporated into crystallographic refinement procedures using a number of formalisms (Arnold & Rossmann, 1988; Rees & Lewis, 1983) including maximum likelihood (Pannu *et al.*, 1998).

2.3.8.4. Equivalence of real- and reciprocal-space molecular replacement

Let us proceed in reciprocal space doing exactly the same as is done in real-space averaging. Thus

$$\rho_{\rm AV}(\mathbf{x}) = \frac{1}{N}\sum_{n=1}^{N}\rho(\mathbf{x}_n),$$

where

$$\mathbf{x}_n = [\boldsymbol{C}_n]\mathbf{x} + \mathbf{d}_n.$$

Therefore,

$$\rho_{\rm AV}(\mathbf{x}) = \frac{1}{N}\sum_{N}\frac{1}{V}\left[\sum_{\mathbf{h}}\mathbf{F}_{\mathbf{h}}\exp(2\pi i\mathbf{h}\cdot\mathbf{x}_n)\right].$$

The next step is to perform the back-transform of the averaged electron density. Hence,

$$\mathbf{F}_{\mathbf{p}} = \int_U \rho_{\rm AV}(\mathbf{x})\exp(-2\pi i\mathbf{p}\cdot\mathbf{x})\,{\rm d}\mathbf{x},$$

where U is the volume within the averaged part of the cell. Hence, substituting for $\rho_{\rm AV}$,

$$\mathbf{F}_{\mathbf{p}} = \int_U\left[\frac{1}{NV}\sum_{N}\sum_{\mathbf{h}}\mathbf{F}_{\mathbf{h}}\exp(2\pi i\mathbf{h}\cdot\mathbf{x}_n)\right]\exp(-2\pi i\mathbf{p}\cdot\mathbf{x})\,{\rm d}\mathbf{x},$$

which is readily simplified to

$$\mathbf{F}_{\mathbf{p}} = \frac{U}{NV}\sum_{\mathbf{h}}\mathbf{F}_{\mathbf{h}}\sum_{N}G_{\mathbf{hp}n}\exp(2\pi i\mathbf{h}\cdot\mathbf{d}_n).$$

Setting

$$\mathbf{B}_{\mathbf{hp}} = \frac{U}{NV}\sum_{N}G_{\mathbf{hp}n}\exp(2\pi i\mathbf{h}\cdot\mathbf{d}_n),$$

the molecular replacement equations can be written as

$$\mathbf{F}_{\mathbf{p}} = \sum_{\mathbf{h}}\mathbf{B}_{\mathbf{hp}}\mathbf{F}_{\mathbf{h}} \qquad (2.3.8.12)$$

(Main & Rossmann, 1966), or in matrix form

$$\mathbf{F} = [\boldsymbol{B}]\mathbf{F},$$

which is the form of the equations used by Main (1967) and by Crowther (1967). Colman (1974) arrived at the same conclusions by an application of Shannon's sampling theorem. It should be noted that the elements of $[\boldsymbol{B}]$ are dependent only on knowledge of the noncrystallographic symmetry and the volume within which it is valid. Substitution of approximate phases into the right-hand side of (2.3.8.12) produces a set of calculated structure factors exactly analogous to those produced by back-transforming the averaged electron density in real space. The new phases can then be used in a renewed cycle of molecular replacement. The reciprocal-space molecular replacement procedure has been implemented and tested in a computer program (Tong & Rossmann, 1995).

Computationally, it has been found more convenient and faster to work in real space. This may, however, change with the advent of vector processing in 'supercomputers'. Obtaining improved phases by substitution of current phases on the right-hand side of the molecular replacement equations (2.3.8.1) seems less cumbersome than the repeated forward and backward Fourier transformation, intermediate sorting, and averaging required in the real-space procedure.

2.3.9. Conclusions

Complete interpretation of Patterson maps is no longer used frequently in structure analysis, although most determinations of heavy-atom positions of isomorphous pairs are based on Patterson analyses. Incorporation of the Patterson concept is crucial in many sophisticated techniques essential for the solution of complex problems, particularly in the application to biological macromolecular structures. Patterson techniques provide important physical insights in a link between real- and reciprocal-space formulation of crystal structures and diffraction data.

This article, first written in December 1984 (by MGR and EA) and completed in January 1986, was published in the first edition of this volume 1993, and in a mildly revised form in the second edition in 2001. We are grateful for generous support of our laboratories from the National Science Foundation (to LT and MGR) and from the National Institutes of Health (LT, MGR and EA). We acknowledge the many authors whose insights, innovation and writings make up the subject matter of this review. We also acknowledge Sharon Wilder for her painstaking attention to detail in preparation of the original manuscript and an article by Argos & Rossmann (1980) as the source of some material in this article.

2.4. Isomorphous replacement and anomalous scattering

By M. Vijayan and S. Ramaseshan†

2.4.1. Introduction

Isomorphous replacement is among the earliest methods to be employed for crystal structure determination (Cork, 1927). The power of this method was amply demonstrated in the classical X-ray work of J. M. Robertson on phthalocyanine in the 1930s using centric data (Robertson, 1936; Robertson & Woodward, 1937). The structure determination of strychnine sulfate pentahydrate by Bijvoet and others provides an early example of the application of this method to acentric reflections (Bokhoven *et al.*, 1951). The usefulness of isomorphous replacement in the analysis of complex protein structures was demonstrated by Perutz and colleagues (Green *et al.*, 1954). This was closely followed by developments in the methodology for the application of isomorphous replacement to protein work (Harker, 1956; Blow & Crick, 1959) and rapidly led to the first ever structure solution of two related protein crystals, namely, those of myoglobin and haemoglobin (Kendrew *et al.*, 1960; Cullis *et al.*, 1961*b*). Since then isomorphous replacement has been the method of choice in macromolecular crystallography and most of the subsequent developments in and applications of this method have been concerned with biological macromolecules, mainly proteins (Blundell & Johnson, 1976; McPherson, 1982).

The application of anomalous-scattering effects has often developed in parallel with that of isomorphous replacement. Indeed, the two methods are complementary to a substantial extent and they are often treated together, as in this article. Although the most important effect of anomalous scattering, namely, the violation of Friedel's law, was experimentally observed as early as 1930 (Coster *et al.*, 1930), two decades elapsed before this effect was made use of for the first time by Bijvoet and his associates for the determination of the absolute configuration of asymmetric molecules as well as for phase evaluation (Bijvoet, 1949, 1954; Bijvoet *et al.*, 1951). Since then there has been a phenomenal spurt in the application of anomalous-scattering effects (Srinivasan, 1972; Ramaseshan & Abrahams, 1975; Vijayan, 1987). A quantitative formulation for the determination of phase angles using intensity differences between Friedel equivalents was derived by Ramachandran & Raman (1956), while Okaya & Pepinsky (1956) successfully developed a Patterson approach involving anomalous effects. The anomalous-scattering method of phase determination has since been used in the structure analysis of several structures, including those of a complex derivative of vitamin B_{12} (Dale *et al.*, 1963) and a small protein (Hendrickson & Teeter, 1981). In the meantime, the effect of changes in the real component of the dispersion correction as a function of the wavelength of the radiation used, first demonstrated by Mark & Szillard (1925), also received considerable attention. This effect, which is formally equivalent to that of isomorphous replacement, was demonstrated to be useful in structure determination (Ramaseshan *et al.*, 1957; Ramaseshan, 1963). Protein crystallographers have been quick to exploit anomalous-scattering effects (Rossmann, 1961; Kartha & Parthasarathy, 1965; North, 1965; Matthews, 1966; Hendrickson, 1979) and, as in the case of the isomorphous replacement method, the most useful applications of anomalous scattering during the last two decades have been perhaps in the field of macromolecular crystallography (Kartha, 1975; Watenpaugh *et al.*, 1975; Vijayan, 1981). In addition to anomalous scattering of X-rays, that of neutrons was also found to have interesting applications (Koetzle & Hamilton, 1975; Sikka & Rajagopal, 1975). More recently there has been a further revival in the development of anomalous-scattering methods with the advent of synchrotron radiation, particularly in view of the possibility of choosing any desired wavelength from a synchrotron-radiation source (Helliwell, 1984).

It is clear from the foregoing that the isomorphous replacement and the anomalous-scattering methods have a long and distinguished history. It is therefore impossible to do full justice to them in a comparatively short presentation like the present one. Several procedures for the application of these methods have been developed at different times. Many, although of considerable historical importance, are not extensively used at present for a variety of reasons. No attempt has been made to discuss them in detail here; the emphasis is primarily on the state of the art as it exists now. The available literature on isomorphous replacement and anomalous scattering is extensive. The reference list given at the end of this part is representative rather than exhaustive.

During the past few years, rapid developments have taken place in the isomorphous replacement and anomalous-scattering methods, particularly in the latter, as applied to macromolecular crystallography. These developments are described in detail in *International Tables for Crystallography*, Volume F (2001). Therefore, they have not been dealt with in this chapter. Significant developments in applications of direct methods to macromolecular crystallography have also occurred in recent years. A summary of these developments as well as the traditional direct methods on which the recent progress is based are presented in Chapter 2.2.

2.4.2. Isomorphous replacement method

2.4.2.1. Isomorphous replacement and isomorphous addition

Two crystals are said to be isomorphous if (*a*) both have the same space group and unit-cell dimensions and (*b*) the types and the positions of atoms in both are the same except for a replacement of one or more atoms in one structure with different types of atoms in the other (isomorphous replacement) or the presence of one or more additional atoms in one of them (isomorphous addition). Consider two crystal structures with identical space groups and unit-cell dimensions, one containing N atoms and the other M atoms. The N atoms in the first structure contain subsets P and Q whereas the M atoms in the second structure contain subsets P, Q' and R. The subset P is common to both structures in terms of atomic positions and atom types. The atomic positions are identical in subsets Q and Q', but at any given atomic position the atom type is different in Q and Q'. The subset R exists only in the second structure. If $\mathbf{F}_N$ and $\mathbf{F}_M$ denote the structure factors of the two structures for a given reflection,

$$\mathbf{F}_N = \mathbf{F}_P + \mathbf{F}_Q \qquad (2.4.2.1)$$

and

$$\mathbf{F}_M = \mathbf{F}_P + \mathbf{F}_{Q'} + \mathbf{F}_R, \qquad (2.4.2.2)$$

where the quantities on the right-hand side represent contributions from different subsets. From (2.4.2.1) and (2.4.2.2) we have

† Deceased.

Copyright © 2010 International Union of Crystallography

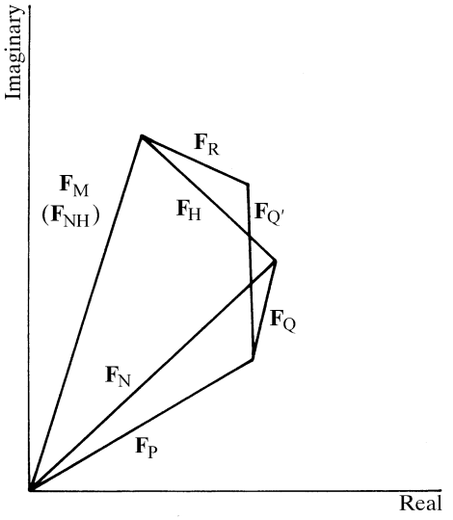

Fig. 2.4.2.1. Vector relationship between $\mathbf{F}_N$ and $\mathbf{F}_M$ ($\equiv \mathbf{F}_{NH}$).

$$\mathbf{F}_M - \mathbf{F}_N = \mathbf{F}_H = \mathbf{F}_{Q'} - \mathbf{F}_Q + \mathbf{F}_R. \qquad (2.4.2.3)$$

The above equations are illustrated in the Argand diagram shown in Fig. 2.4.2.1. $\mathbf{F}_Q$ and $\mathbf{F}_{Q'}$ would be collinear if all the atoms in Q were of the same type and those in Q' of another single type, as in the replacement of chlorine atoms in a structure by bromine atoms.

We have a case of 'isomorphous replacement' if $\mathbf{F}_R = 0$ ($\mathbf{F}_H = \mathbf{F}_{Q'} - \mathbf{F}_Q$) and a case of 'isomorphous addition' if $\mathbf{F}_Q = \mathbf{F}_{Q'} = 0$ ($\mathbf{F}_H = \mathbf{F}_R$). Once $\mathbf{F}_H$ is known, in addition to the magnitudes of $\mathbf{F}_N$ and $\mathbf{F}_M$, which can be obtained experimentally, the two cases can be treated in an equivalent manner in reciprocal space. In deference to common practice, the term 'isomorphous replacement' will be used to cover both cases. Also, in as much as $\mathbf{F}_M$ is the vector sum of $\mathbf{F}_N$ and $\mathbf{F}_H$, $\mathbf{F}_M$ and $\mathbf{F}_{NH}$ will be used synonymously. Thus

$$\mathbf{F}_M \equiv \mathbf{F}_{NH} = \mathbf{F}_N + \mathbf{F}_H. \qquad (2.4.2.4)$$

2.4.2.2. Single isomorphous replacement method

The number of replaceable (or 'added') atoms is usually small and they generally have high atomic numbers. Their positions are often determined by a Patterson synthesis of one type or another (see Chapter 2.3). It will therefore be assumed in the following discussion that $\mathbf{F}_H$ is known. Then it can be readily seen by referring to Fig. 2.4.2.2 that

$$\alpha_N = \alpha_H - \cos^{-1}\frac{F_{NH}^2 - F_N^2 - F_H^2}{2F_N F_H} = \alpha_H \pm \varphi; \qquad (2.4.2.5)$$

when φ is derived from its cosine function, it could obviously be positive or negative. Hence, there are two possible solutions for α_N. These two solutions are distributed symmetrically about $\mathbf{F}_H$. One of these would correspond to the correct value of α_N. Therefore, in general, the phase angle cannot be unambiguously determined using a pair of isomorphous crystals.

The twofold ambiguity in phase angle vanishes when the structures are centrosymmetric. $\mathbf{F}_{NH}$, $\mathbf{F}_N$ and $\mathbf{F}_H$ are all real in centric data and the corresponding phase angles are 0 or 180°. From (2.4.2.4)

$$F_{NH} \pm F_N = F_H. \qquad (2.4.2.6)$$

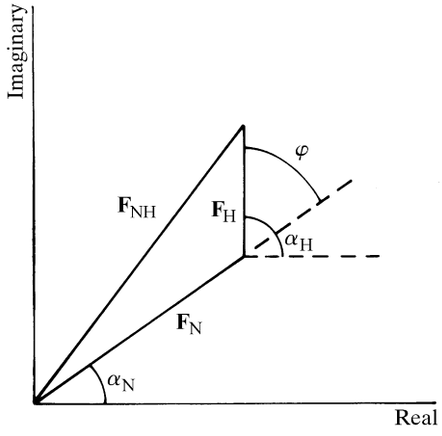

Fig. 2.4.2.2. Relationship between α_N, α_H and φ.

The sign of F_H is already known and the signs of F_{NH} and F_N can be readily determined from (2.4.2.6) (Robertson & Woodward, 1937).

When the data are acentric, the best one can do is to use both the possible phase angles simultaneously in a Fourier synthesis (Bokhoven *et al.*, 1951). This double-phased synthesis, which is equivalent to the isomorphous synthesis of Ramachandran & Raman (1959), contains the structure and its inverse when the replaceable atoms have a centrosymmetric distribution (Ramachandran & Srinivasan, 1970). When the distribution is noncentrosymmetric, however, the synthesis contains peaks corresponding to the structure and general background. Fourier syntheses computed using the single isomorphous replacement method of Blow & Rossmann (1961) and Kartha (1961) have the same properties. In this method, the phase angle is taken to be the average of the two possible solutions of α_N, which is always α_H or $\alpha_H + 180°$. Also, the Fourier coefficients are multiplied by cos φ, following arguments based on the Blow & Crick (1959) formulation of phase evaluation (see Section 2.4.4.4). Although Blow & Rossmann (1961) have shown that this method could yield interpretable protein Fourier maps, it is rarely used as such in protein crystallography as the Fourier maps computed using it usually have unacceptable background levels (Blundell & Johnson, 1976).

2.4.2.3. Multiple isomorphous replacement method

The ambiguity in α_N in a noncentrosymmetric crystal can be resolved only if at least two crystals isomorphous to it are available (Bokhoven *et al.*, 1951). We then have two equations of the type (2.4.2.5), namely,

$$\alpha_N = \alpha_{H1} \pm \varphi_1 \quad \text{and} \quad \alpha_N = \alpha_{H2} \pm \varphi_2, \qquad (2.4.2.7)$$

where subscripts 1 and 2 refer to isomorphous crystals 1 and 2, respectively. This is demonstrated graphically in Fig. 2.4.2.3 with the aid of the Harker (1956) construction. A circle is drawn with F_N as radius and the origin of the vector diagram as the centre. Two more circles are drawn with F_{NH1} and F_{NH2} as radii and the ends of vectors $-\mathbf{F}_{H1}$ and $-\mathbf{F}_{H2}$, respectively as centres. Each of these circles intersects the F_N circle at two points corresponding to the two possible solutions. One of the points of intersection is common and this point defines the correct value of α_N. With the assumption of perfect isomorphism and if errors are neglected, the phase circles corresponding to all the crystals would intersect at a common point if a number of isomorphous crystals were used for phase determination.

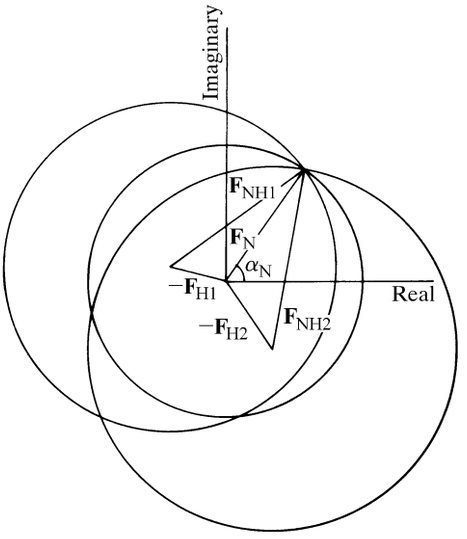

Fig. 2.4.2.3. Harker construction when two heavy-atom derivatives are available.

2.4.3. Anomalous-scattering method

2.4.3.1. Dispersion correction

Atomic scattering factors are normally calculated on the assumption that the binding energy of the electrons in an atom is negligible compared to the energy of the incident X-rays and the distribution of electrons is spherically symmetric. The transition frequencies within the atom are then negligibly small compared to the frequency of the radiation used and the scattering power of each electron in the atom is close to that of a free electron. When this assumption is valid, the atomic scattering factor is a real positive number and its value decreases as the scattering angle increases because of the finite size of the atom. When the binding energy of the electrons is appreciable, the atomic scattering factor at any given angle is given by

$$f_0 + f' + if'', \tag{2.4.3.1}$$

where f_0 is a real positive number and corresponds to the atomic scattering factor for a spherically symmetric collection of free electrons in the atom. The second and third terms are, respectively, referred to as the real and the imaginary components of the 'dispersion correction' (*IT* IV, 1974). f' is usually negative whereas f'' is positive. For any given atom, f'' is obviously 90° ahead of the real part of the scattering factor given by

$$f = f_0 + f'. \tag{2.4.3.2}$$

The variation of f' and f'' as a function of atomic number for two typical radiations is given in Fig. 2.4.3.1 (Srinivasan, 1972; Cromer, 1965). The dispersion effects are pronounced when an absorption edge of the atom concerned is in the neighbourhood of the wavelength of the incident radiation. Atoms with high atomic numbers have several absorption edges and the dispersion-correction terms in their scattering factors always have appreciable values. The values of f' and f'' do not vary appreciably with the angle of scattering as they are caused by core electrons confined to a very small volume around the nucleus. An atom is usually referred to as an anomalous scatterer if the dispersion-correction terms in its scattering factor have appreciable values. The effects on the structure factors or intensities of Bragg reflections resulting from dispersion corrections are referred to as anomalous-dispersion effects or anomalous-scattering effects.

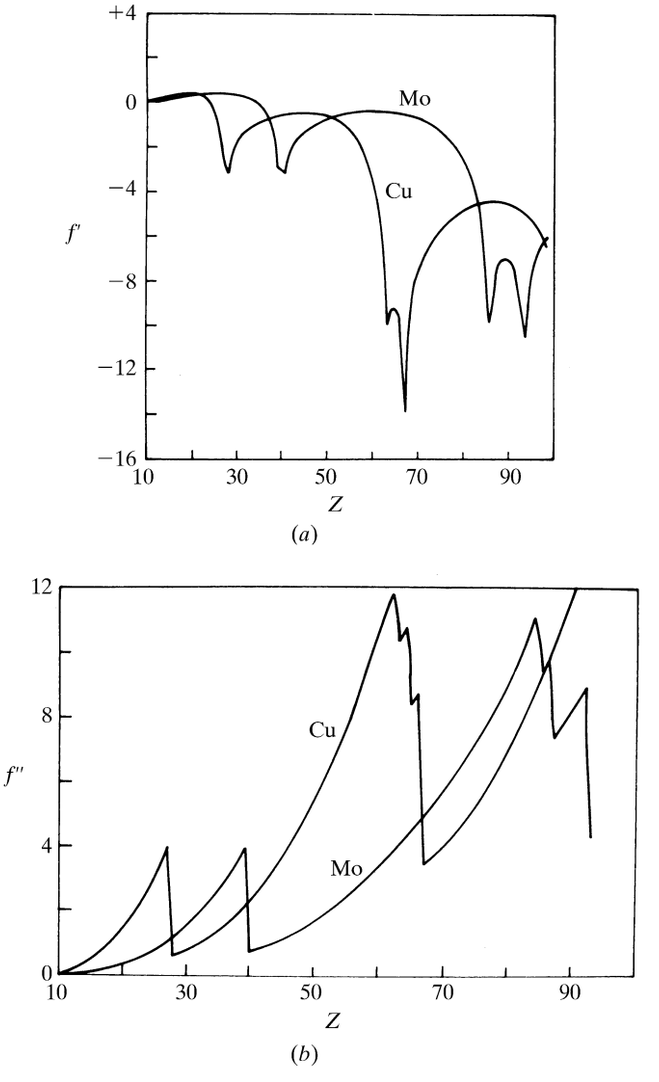

Fig. 2.4.3.1. Variation of (*a*) f' and (*b*) f'' as a function of atomic number for Cu $K\alpha$ and Mo $K\alpha$ radiations. Adapted from Fig. 3 of Srinivasan (1972).

2.4.3.2. Violation of Friedel's law

Consider a structure containing N atoms of which P are normal atoms and the remaining Q anomalous scatterers. Let $\mathbf{F}_P$ denote the contribution of the P atoms to the structure, and $\mathbf{F}_Q$ and $\mathbf{F}''_Q$ the real and imaginary components of the contribution of the Q atoms. The relation between the different contributions to a reflection $\mathbf{h}$ and its Friedel equivalent $-\mathbf{h}$ is illustrated in Fig. 2.4.3.2. For simplicity we assume here that all Q atoms are of the same type. The phase angle of $\mathbf{F}''_Q$ is then exactly 90° ahead of that of $\mathbf{F}_Q$. The structure factors of $\mathbf{h}$ and $-\mathbf{h}$ are denoted in the figure by $\mathbf{F}_N(+)$ and $\mathbf{F}_N(-)$, respectively. In the absence of anomalous scattering, or when the imaginary component of the dispersion correction is zero, the magnitudes of the two structure factors are equal and Friedel's law is obeyed; the phase angles have equal magnitudes, but opposite signs. As can be seen from Fig. 2.4.3.2, this is no longer true when $\mathbf{F}''_Q$ has a nonzero value. Friedel's law is then violated. A composite view of the vector relationship for $\mathbf{h}$ and $-\mathbf{h}$ can be obtained, as in Fig. 2.4.3.3, by reflecting the vectors corresponding to $-\mathbf{h}$ about the real axis of the vector diagram. $\mathbf{F}_P$ and $\mathbf{F}_Q$ corresponding to the two reflections superpose exactly, but $\mathbf{F}''_Q$ do not. $\mathbf{F}_N(+)$ and $\mathbf{F}_N(-)$ then have different magnitudes and phases.

It is easily seen that Friedel's law is obeyed in centric data even when anomalous scatterers are present. $\mathbf{F}_P$ and $\mathbf{F}_Q$ are then parallel to the real axis and $\mathbf{F}''_Q$ perpendicular to it. The vector sum of the three components is the same for $\mathbf{h}$ and $-\mathbf{h}$. It may, however, be noted that the phase angle of the structure factor is

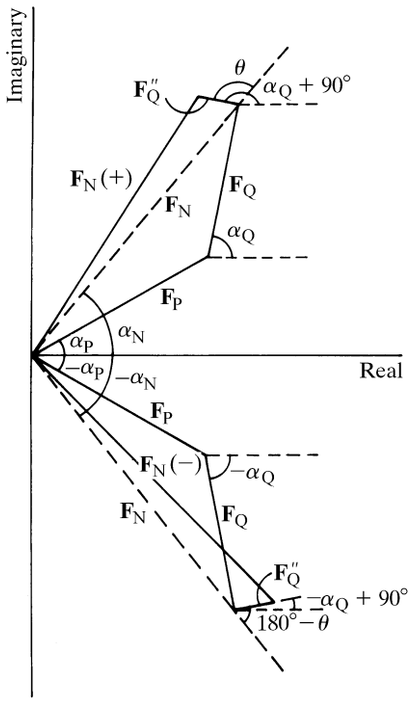

Fig. 2.4.3.2. Vector diagram illustrating the violation of Friedel's law when $\mathbf{F}''_Q \neq 0$.

then no longer 0 or 180°. Even when the structure is noncentrosymmetric, the effect of anomalous scattering in terms of intensity differences between Friedel equivalents varies from reflection to reflection. The difference between $\mathbf{F}_N(+)$ and $\mathbf{F}_N(-)$ is zero when $\alpha_P = \alpha_Q$ or $\alpha_Q + 180°$. The difference tends to the maximum possible value ($2F''_Q$) when $\alpha_P = \alpha_Q \pm 90°$.

Intensity differences between Friedel equivalents depend also on the ratio (in terms of number and scattering power) between anomalous and normal scatterers. Differences obviously do not occur when all the atoms are normal scatterers. On the other hand, a structure containing only anomalous scatterers of the same type also does not give rise to intensity differences. Expressions for intensity differences between Friedel equivalents have been derived by Zachariasen (1965) for the most general case of a structure containing normal as well as different types of anomalous scatterers. Statistical distributions of such differences under various conditions have also been derived (Parthasarathy & Srinivasan, 1964; Parthasarathy, 1967). It turns out that, with a single type of anomalous scatterer in the structure, the ratio

$$\frac{|F_N^2(+) - F_N^2(-)|}{F_N^2(+) + F_N^2(-)}$$

has a maximum mean value when the scattering powers of the anomalous scatterers and the normal scatterers are nearly the same (Srinivasan, 1972). Also, for a given ratio between the scattering powers, the smaller the number of anomalous scatterers, the higher is the mean ratio.

2.4.3.3. Friedel and Bijvoet pairs

The discussion so far has been concerned essentially with crystals belonging to space groups $P1$ and $P\bar{1}$. In the centrosymmetric space group, the crystal and the diffraction pattern have the same symmetry, namely, an inversion centre. In $P1$, however, the crystals are noncentrosymmetric while the diffraction pattern has an inversion centre, in the absence of anomalous scattering. When anomalous scatterers are present in the structure ($\mathbf{F}''_Q \neq 0$), Friedel's law breaks down and the diffraction pattern no longer has an inversion centre. Thus the diffraction

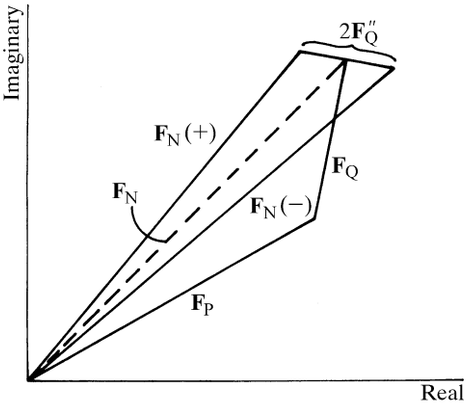

Fig. 2.4.3.3. A composite view of the vector relationship between $\mathbf{F}_N(+)$ and $\mathbf{F}_N(-)$.

pattern displays the same symmetry as that of the crystal in the presence of anomalous scattering. The same is true with higher-symmetry space groups also. For example, consider a crystal with space group $P222$, containing anomalous scatterers. The magnitudes of $\mathbf{F}_P$ are the same for all equivalent reflections; so are those of $\mathbf{F}_Q$ and $\mathbf{F}''_Q$. Their phase angles, however, differ from one equivalent to another, as can be seen from Table 2.4.3.1. When $\mathbf{F}''_Q = 0$, the magnitudes of the vector sum of $\mathbf{F}_P$ and $\mathbf{F}_Q$ are the same for all the equivalent reflections. The intensity pattern thus has point-group symmetry $2/m\ 2/m\ 2/m$. When $\mathbf{F}''_Q \neq 0$, the equivalent reflections can be grouped into two sets in terms of their intensities: hkl, $h\bar{k}\bar{l}$, $\bar{h}k\bar{l}$ and $\bar{h}\bar{k}l$; and $\bar{h}\bar{k}\bar{l}$, $\bar{h}kl$, $h\bar{k}l$ and $hk\bar{l}$. The equivalents belonging to the first group have the same intensity; so have the equivalents in the second group. But the two intensities are different. Thus the symmetry of the pattern is 222, the same as that of the crystal.

In general, under conditions of anomalous scattering, equivalent reflections generated by the symmetry elements in the crystal have intensities different from those of equivalent reflections generated by the introduction of an additional inversion centre in normal scattering. There have been suggestions that a reflection from the first group and another from the second group should be referred to as a 'Bijvoet pair' instead of a 'Friedel pair', when the two reflections are not inversely related. Most often, however, the terms are used synonymously. The same practice will be followed in this article.

2.4.3.4. Determination of absolute configuration

The determination of the absolute configuration of chiral molecules has been among the most important applications of anomalous scattering. Indeed, anomalous scattering is the only effective method for this purpose and the method, first used in the early 1950s (Peerdeman *et al.*, 1951), has been extensively employed in structural crystallography (Ramaseshan, 1963; Vos, 1975).

Many molecules, particularly biologically important ones, are chiral in that the molecular structure is not superimposable on its mirror image. Chirality (handedness) arises primarily on account of the presence of asymmetric carbon atoms in the molecule. A tetravalent carbon is asymmetric when the four atoms (or groups) bonded to it are all different from one another. The substituents can then have two distinct arrangements which are mirror images

Table 2.4.3.1. *Phase angles of different components of the structure factor in space group P222*

	Phase angle (°) of		
Reflection	$\mathbf{F}_P$	$\mathbf{F}_Q$	$\mathbf{F}''_Q$
hkl, $h\bar{k}\bar{l}$, $\bar{h}k\bar{l}$, $\bar{h}\bar{k}l$	α_P	α_Q	$90 + \alpha_Q$
$\bar{h}\bar{k}\bar{l}$, $\bar{h}kl$, $h\bar{k}l$, $hk\bar{l}$	$-\alpha_P$	$-\alpha_Q$	$90 - \alpha_Q$

of (or related by inversion to) each other. These optical isomers or enantiomers have the same chemical and physical properties except that they rotate the plane of polarization in opposite directions when polarized light passes through them. It is not, however, possible to calculate the sign of optical rotation, given the exact spatial arrangement or the 'absolute configuration' of the molecule. Therefore, one cannot distinguish between the possible enantiomorphic configurations of a given asymmetric molecule from measurements of optical rotation. This is also true of molecules with chiralities generated by overall asymmetric geometry instead of the presence of asymmetric carbon atoms in them.

Normal X-ray scattering does not distinguish between enantiomers. Two structures A (x_j, y_j, z_j) and B $(-x_j, -y_j, -z_j)$ $(j = 1, \ldots, N)$ obviously produce the same diffraction pattern on account of Friedel's law. The situation is, however, different when anomalous scatterers are present in the structure. The intensity difference between reflections $\mathbf{h}$ and $-\mathbf{h}$, or that between members of any Bijvoet pair, has the same magnitude, but opposite sign for structures A and B. If the atomic coordinates are known, the intensities of Bijvoet pairs can be readily calculated. The absolute configuration can then be determined, *i.e.* one can distinguish between A and B by comparing the calculated intensities with the observed ones for a few Bijvoet pairs with pronounced anomalous effects.

2.4.3.5. Determination of phase angles

An important application of anomalous scattering is in the determination of phase angles using Bijvoet differences (Ramachandran & Raman, 1956; Peerdeman & Bijvoet, 1956). From Figs. 2.4.3.2 and 2.4.3.3, we have

$$F_{\rm N}^2(+) = F_{\rm N}^2 + F_{\rm Q}''^2 + 2F_{\rm N}F_{\rm Q}'' \cos\theta \qquad (2.4.3.3)$$

and

$$F_{\rm N}^2(-) = F_{\rm N}^2 + F_{\rm Q}''^2 - 2F_{\rm N}F_{\rm Q}'' \cos\theta. \qquad (2.4.3.4)$$

Then

$$\cos\theta = \frac{F_{\rm N}^2(+) - F_{\rm N}^2(-)}{4F_{\rm N}F_{\rm Q}''}. \qquad (2.4.3.5)$$

In the above equations $F_{\rm N}$ may be approximated to $[F_{\rm N}(+) + F_{\rm N}(-)]/2$. Then θ can be evaluated from (2.4.3.5) except for the ambiguity in its sign. Therefore, from Fig. 2.4.3.2, we have

$$\alpha_{\rm N} = \alpha_{\rm Q} + 90^\circ \pm \theta. \qquad (2.4.3.6)$$

The phase angle thus has two possible values symmetrically distributed about $\mathbf{F}_{\rm Q}''$. Anomalous scatterers are usually heavy atoms and their positions can most often be determined by Patterson methods. $\alpha_{\rm Q}$ can then be calculated and the two possible values of $\alpha_{\rm N}$ for each reflection evaluated using (2.4.3.6).

In practice, the twofold ambiguity in phase angles can often be resolved in a relatively straightforward manner. As indicated earlier, anomalous scatterers usually have relatively high atomic numbers. The 'heavy-atom' phases calculated from their positions therefore contain useful information. For any given reflection, that phase angle which is closer to the heavy-atom phase, from the two phases calculated using (2.4.3.6), may be taken as the correct phase angle. This method has been successfully used in several structure determinations including that of a derivative of vitamin B_{12} (Dale *et al.*, 1963). The same method was also employed in a probabilistic fashion in the structure solution of a small protein (Hendrickson & Teeter, 1981). A method for obtaining a unique, but approximate, solution for phase angles from (2.4.3.6) has also been suggested (Srinivasan & Chacko, 1970). An accurate unique solution for phase angles can be obtained if one collects two sets of intensity data using two different wavelengths which have different dispersion-correction terms for the anomalous scatterers in the structure. Two equations of the type (2.4.3.6) are then available for each reflection and the solution common to both is obviously the correct phase angle. Different types of Patterson and Fourier syntheses can also be employed for structure solution using intensity differences between Bijvoet equivalents (Srinivasan, 1972; Okaya & Pepinsky, 1956; Pepinsky *et al.*, 1957).

An interesting situation occurs when the replaceable atoms in a pair of isomorphous structures are anomalous scatterers. The phase angles can then be uniquely determined by combining isomorphous replacement and anomalous-scattering methods. Such situations normally occur in protein crystallography and are discussed in Section 2.4.4.5.

2.4.3.6. Anomalous scattering without phase change

The phase determination, and hence the structure solution, outlined above relies on the imaginary component of the dispersion correction. Variation in the real component can also be used in structure analysis. In early applications of anomalous scattering, the real component of the dispersion correction was made use of to distinguish between atoms of nearly the same atomic numbers (Mark & Szillard, 1925; Bradley & Rodgers, 1934). For example, copper and manganese, with atomic numbers 29 and 25, respectively, are not easily distinguishable under normal X-ray scattering. However, the real components of the dispersion correction for the two elements are -1.129 and -3.367, respectively, when Fe $K\alpha$ radiation is used (*IT* IV, 1974). Therefore, the difference between the scattering factors of the two elements is accentuated when this radiation is used. The difference is more pronounced at high angles as the normal scattering factor falls off comparatively rapidly with increasing scattering angle whereas the dispersion-correction term does not.

The structure determination of $KMnO_4$ provides a typical example for the use of anomalous scattering without phase change in the determination of a centrosymmetric structure (Ramaseshan *et al.*, 1957; Ramaseshan & Venkatesan, 1957). f' and f'' for manganese for Cu $K\alpha$ radiation are -0.568 and 2.808, respectively. The corresponding values for Fe $K\alpha$ radiation are -3.367 and 0.481, respectively (*IT* IV, 1974). The data sets collected using the two radiations can now be treated as those arising from two perfectly isomorphous crystals. The intensity differences between a reflection in one set and the corresponding reflection in the other are obviously caused by the differences in the dispersion-correction terms. They can, however, be considered formally as intensity differences involving data from two perfectly isomorphous crystals. They can be used, as indeed they were, to determine the position of the manganese ion through an appropriate Patterson synthesis (see Section 2.4.4.2) and then to evaluate the signs of structure factors using (2.4.2.6) when the structure is centrosymmetric. When the structure is noncentrosymmetric, a twofold ambiguity exists in the phase angles in a manner analogous to that in the isomorphous replacement method. This ambiguity can be removed if the structure contains two different subsets of atoms $Q1$ and $Q2$ which, respectively, scatter radiations $\lambda_{\rm Q1}$ and $\lambda_{\rm Q2}$ anomalously. Data sets can then be collected with λ, which is scattered normally by all atoms, $\lambda_{\rm Q1}$ and $\lambda_{\rm Q2}$. The three sets can be formally treated as those from three perfectly isomorphous structures and the phase determination effected using (2.4.2.7) (Ramaseshan, 1963).

2.4.3.7. Treatment of anomalous scattering in structure refinement

The effect of anomalous scattering needs to be taken into account in the refinement of structures containing anomalous scatterers, if accurate atomic parameters are required. The effect of the real part of the dispersion correction is largely confined to the thermal parameters of anomalous scatterers. This effect can be eliminated by simply adding f' to the normal scattering factor of the anomalous scatterers.

The effects of the imaginary component of the dispersion correction are, however, more complex. These effects could lead to serious errors in positional parameters when the space group is polar, if data in the entire diffraction sphere are not used (Ueki *et al.*, 1966; Cruickshank & McDonald, 1967). For example, accessible data in a hemisphere are normally used for X-ray analysis when the space group is $P1$. If the hemisphere has say h positive, the x coordinates of all the atoms would be in error when the structure contains anomalous scatterers. The situation in other polar space groups has been discussed by Cruickshank & McDonald (1967). In general, in the presence of anomalous scattering, it is desirable to collect data for the complete sphere, if accurate structural parameters are required (Srinivasan, 1972).

Methods have been derived to correct for dispersion effects in observed data from centrosymmetric and noncentrosymmetric crystals (Patterson, 1963). The methods are empirical and depend upon the refined parameters at the stage at which corrections are applied. This is obviously an unsatisfactory situation and it has been suggested that the measured structure factors of Bijvoet equivalents should instead be treated as independent observations in structure refinement (Ibers & Hamilton, 1964). The effect of dispersion corrections needs to be taken into account to arrive at the correct scale and temperature factors also (Wilson, 1975; Gilli & Cruickshank, 1973).

2.4.4. Isomorphous replacement and anomalous scattering in protein crystallography

2.4.4.1. Protein heavy-atom derivatives

Perhaps the most spectacular applications of isomorphous replacement and anomalous-scattering methods have been in the structure solution of large biological macromolecules, primarily proteins. Since its first successful application on myoglobin and haemoglobin, the isomorphous replacement method, which is often used in conjunction with the anomalous-scattering method, has been employed in the solution of scores of proteins. The application of this method involves the preparation of protein heavy-atom derivatives, *i.e.* the attachment of heavy atoms like mercury, uranium and lead, or chemical groups containing them, to protein crystals in a coherent manner without changing the conformation of the molecules and their crystal packing. This is only rarely possible in ordinary crystals as the molecules in them are closely packed. Protein crystals, however, contain large solvent regions and isomorphous derivatives can be prepared by replacing the disordered solvent molecules by heavy-atom-containing groups without disturbing the original arrangement of protein molecules.

2.4.4.2. Determination of heavy-atom parameters

For any given reflection, the structure factor of the native protein crystal ($\mathbf{F}_{\rm N}$), that of a heavy-atom derivative ($\mathbf{F}_{\rm NH}$), and the contribution of the heavy atoms in that derivative ($\mathbf{F}_{\rm H}$) are related by the equation

$$\mathbf{F}_{\rm NH} = \mathbf{F}_{\rm N} + \mathbf{F}_{\rm H}. \qquad (2.4.4.1)$$

The value of $\mathbf{F}_{\rm H}$ depends not only on the positional and thermal parameters of the heavy atoms, but also on their occupancy factors, because, at a given position, the heavy atom may not often be present in all the unit cells. For example, if the heavy atom is present at a given position in only half the unit cells in the crystal, then the occupancy factor of the site is said to be 0.5.

For the successful determination of the heavy-atom parameters, as also for the subsequent phase determination, the data sets from the native and the derivative crystals should have the same relative scale. The different data sets should also have the same overall temperature factor. Different scaling procedures have been suggested (Blundell & Johnson, 1976) and, among them, the following procedure, based on Wilson's (1942) statistics, appears to be the most feasible in the early stages of structure analysis.

Assuming that the data from the native and the derivative crystals obey Wilson's statistics, we have, for any range of $\sin^2\theta/\lambda^2$,

$$\ln\left\{\frac{\sum f_{{\rm N}j}^2}{\langle F_{\rm N}^2\rangle}\right\} = \ln K_{\rm N} + 2B_{\rm N}\frac{\sin^2\theta}{\lambda^2} \qquad (2.4.4.2)$$

and

$$\ln\left\{\frac{\sum f_{{\rm N}j}^2 + \sum f_{{\rm H}j}^2}{\langle F_{\rm NH}^2\rangle}\right\} = \ln K_{\rm NH} + 2B_{\rm NH}\frac{\sin^2\theta}{\lambda^2}, \qquad (2.4.4.3)$$

where $f_{{\rm N}j}$ and $f_{{\rm H}j}$ refer to the atomic scattering factors of protein atoms and heavy atoms, respectively. $K_{\rm N}$ and $K_{\rm NH}$ are the scale factors to be applied to the intensities from the native and the derivative crystals, respectively, and $B_{\rm N}$ and $B_{\rm NH}$ the temperature factors of the respective structure factors. Normally one would be able to derive the absolute scale factor and the temperature factor for both the data sets from (2.4.4.2) and (2.4.4.3) using the well known Wilson plot. The data from protein crystals, however, do not follow Wilson's statistics as protein molecules contain highly non-random features. Therefore, in practice, it is difficult to fit a straight line through the points in a Wilson plot, thus rendering the parameters derived from it unreliable. (2.4.4.2) and (2.4.4.3) can, however, be used in a different way. From the two equations we obtain

$$\ln\left\{\frac{\sum f_{{\rm N}j}^2 + \sum f_{{\rm H}j}^2}{\sum f_{{\rm N}j}^2}\cdot\frac{\langle F_{\rm N}^2\rangle}{\langle F_{\rm NH}^2\rangle}\right\} = \ln\left(\frac{K_{\rm NH}}{K_{\rm N}}\right) + 2(B_{\rm NH} - B_{\rm N})\frac{\sin^2\theta}{\lambda^2}. \qquad (2.4.4.4)$$

The effects of structural non-randomness in the crystals obviously cancel out in (2.4.4.4). When the left-hand side of (2.4.4.4) is plotted against $(\sin^2\theta)/\lambda^2$, it is called a comparison or difference Wilson plot. Such plots yield the ratio between the scales of the derivative and the native data, and the additional temperature factor of the derivative data. Initially, the number and the occupancy factors of heavy-atom sites are unknown, and are roughly estimated from intensity differences to evaluate $\sum f_{{\rm H}j}^2$. These estimates usually undergo considerable revision in the course of the determination and the refinement of heavy-atom parameters.

At first, heavy-atom positions are most often determined by Patterson syntheses of one type or another. Such syntheses are discussed in some detail elsewhere in Chapter 2.3. They are therefore discussed here only briefly.

Equation (2.4.2.6) holds when the data are centric. $F_{\rm H}$ is usually small compared to $F_{\rm N}$ and $F_{\rm NH}$, and the minus sign is then relevant on the left-hand side of (2.4.2.6). Thus the difference between the magnitudes of $\mathbf{F}_{\rm NH}$ and $\mathbf{F}_{\rm N}$, which can be obtained

experimentally, normally gives a correct estimate of the magnitude of $\mathbf{F}_H$ for most reflections. Then a Patterson synthesis with $(F_{NH} - F_N)^2$ as coefficients corresponds to the distribution of vectors between heavy atoms, when the data are centric. But proteins are made up of L-amino acids and hence cannot crystallize in centrosymmetric space groups. However, many proteins crystallize in space groups with centrosymmetric projections. The centric data corresponding to these projections can then be used for determining heavy-atom positions through a Patterson synthesis of the type outlined above.

The situation is more complex for three-dimensional acentric data. It has been shown (Rossmann, 1961) that

$$(F_{NH} - F_N)^2 \simeq F_H^2 \cos^2(\alpha_{NH} - \alpha_H) \qquad (2.4.4.5)$$

when F_H is small compared to F_{NH} and F_N. Patterson synthesis with $(F_{NH} - F_N)^2$ as coefficients would, therefore, give an approximation to the heavy-atom vector distribution. An isomorphous difference Patterson synthesis of this type has been used extensively in protein crystallography to determine heavy-atom positions. The properties of this synthesis have been extensively studied (Ramachandran & Srinivasan, 1970; Rossmann, 1960; Phillips, 1966; Dodson & Vijayan, 1971) and it has been shown that this Patterson synthesis would provide a good approximation to the heavy-atom vector distribution even when F_H is large compared to F_N (Dodson & Vijayan, 1971).

As indicated earlier (see Section 2.4.3.1), heavy atoms are always anomalous scatterers, and the structure factors of any given reflection and its Friedel equivalent from a heavy-atom derivative have unequal magnitudes. If these structure factors are denoted by $\mathbf{F}_{NH}(+)$ and $\mathbf{F}_{NH}(-)$ and the real component of the heavy-atom contributions (including the real component of the dispersion correction) by $\mathbf{F}_H$, then it can be shown (Kartha & Parthasarathy, 1965) that

$$\left(\frac{k}{2}\right)^2 [F_{NH}(+) - F_{NH}(-)]^2 = F_H^2 \sin^2(\alpha_{NH} - \alpha_H), \qquad (2.4.4.6)$$

where $k = (f_H + f'_H)/f''_H$. Here it has been assumed that all the anomalous scatterers are of the same type with atomic scattering factor f_H and dispersion-correction terms f'_H and f''_H. A Patterson synthesis with the left-hand side of (2.4.4.6) as coefficients would also yield the vector distribution corresponding to the heavy-atom positions (Rossmann, 1961; Kartha & Parthasarathy, 1965). However, $F_{NH}(+) - F_{NH}(-)$ is a small difference between two large quantities and is liable to be in considerable error. Patterson syntheses of this type are therefore rarely used to determine heavy-atom positions.

It is interesting to note (Kartha & Parthasarathy, 1965) that addition of (2.4.4.5) and (2.4.4.6) readily leads to

$$(F_{NH} - F_N)^2 + \left(\frac{k}{2}\right)^2 [F_{NH}(+) - F_{NH}(-)]^2 \simeq F_H^2. \qquad (2.4.4.7)$$

Thus, the magnitude of the heavy-atom contribution can be estimated if intensities of Friedel equivalents have been measured from the derivative crystal. F_{NH} is then not readily available, but to a good approximation

$$F_{NH} = [F_{NH}(+) + F_{NH}(-)]/2. \qquad (2.4.4.8)$$

A different and more accurate expression for estimating F_H^2 from isomorphous and anomalous differences was derived by Matthews (1966). According to a still more accurate expression derived by Singh & Ramaseshan (1966),

$$\begin{aligned} F_H^2 &= F_{NH}^2 + F_N^2 - 2F_{NH}F_N \cos(\alpha_N - \alpha_{NH}) \\ &= F_{NH}^2 + F_N^2 \pm 2F_{NH}F_N \\ &\quad \times (1 - \{k[F_{NH}(+) - F_{NH}(-)]/2F_N\}^2)^{1/2}. \end{aligned} \qquad (2.4.4.9)$$

The lower estimate in (2.4.4.9) is relevant when $|\alpha_N - \alpha_{NH}| < 90^\circ$ and the upper estimate is relevant when $|\alpha_N - \alpha_{NH}| > 90^\circ$. The lower and the upper estimates may be referred to as F_{HLE} and F_{HUE}, respectively. It can be readily shown (Dodson & Vijayan, 1971) that the lower estimate would represent the correct value of F_H for a vast majority of reflections. Thus, a Patterson synthesis with F_{HLE}^2 as coefficients would yield the vector distribution of heavy atoms in the derivative. Such a synthesis would normally be superior to those with the left-hand sides of (2.4.4.5) and (2.4.4.6) as coefficients. However, when the level of heavy-atom substitution is low, the anomalous differences are also low and susceptible to large percentage errors. In such a situation, a synthesis with $(F_{NH} - F_N)^2$ as coefficients is likely to yield better results than that with F_{HLE}^2 as coefficients (Vijayan, 1981).

Direct methods employing different methodologies have also been used successfully for the determination of heavy-atom positions (Navia & Sigler, 1974). These methods, developed primarily for the analysis of smaller structures, have not yet been successful in *a priori* analysis of protein structures. The very size of protein structures makes the probability relations used in these methods weak. In addition, data from protein crystals do not normally extend to high enough angles to permit resolution of individual atoms in the structure and the feasibility of using many of the currently popular direct-method procedures in such a situation has been a topic of much discussion. The heavy atoms in protein derivative crystals, however, are small in number and are normally situated far apart from one another. They are thus expected to be resolved even when low-resolution X-ray data are used. In most applications, the magnitudes of the differences between F_{NH} and F_N are formally considered as the 'observed structure factors' of the heavy-atom distribution and conventional direct-method procedures are then applied to them.

Once the heavy-atom parameters in one or more derivatives have been determined, approximate protein phase angles, α_N's, can be derived using methods described later. These phase angles can then be readily used to determine the heavy-atom parameters in a new derivative employing a difference Fourier synthesis with coefficients

$$(F_{NH} - F_N) \exp(i\alpha_N). \qquad (2.4.4.10)$$

Such syntheses are also used to confirm and to improve upon the information on heavy-atom parameters obtained through Patterson or direct methods. They are obviously very powerful when centric data corresponding to centrosymmetric projections are used. The synthesis yields satisfactory results even when the data are acentric although the difference Fourier technique becomes progressively less powerful as the level of heavy-atom substitution increases (Dodson & Vijayan, 1971).

While the positional parameters of heavy atoms can be determined with a reasonable degree of confidence using the above-mentioned methods, the corresponding temperature and occupancy factors cannot. Rough estimates of the latter are usually made from the strength and the size of appropriate peaks in difference syntheses. The estimated values are then refined, along with the positional parameters, using the techniques outlined below.

2.4.4.3. Refinement of heavy-atom parameters

The least-squares method with different types of minimization functions is used for refining the heavy-atom parameters, including the occupancy factors. The most widely used method (Dickerson *et al.*, 1961; Muirhead *et al.*, 1967; Dickerson *et al.*, 1968) involves the minimization of the function

$$\varphi = \sum w(F_{\rm NH} - |\mathbf{F}_{\rm N} + \mathbf{F}_{\rm H}|)^2, \qquad (2.4.4.11)$$

where the summation is over all the reflections and w is the weight factor associated with each reflection. Here $F_{\rm NH}$ is the observed magnitude of the structure factor for the particular derivative and $\mathbf{F}_{\rm N} + \mathbf{F}_{\rm H}$ is the calculated structure factor. The latter obviously depends upon the protein phase angle $\alpha_{\rm N}$, and the magnitude and the phase angle of $\mathbf{F}_{\rm H}$ which are in turn dependent on the heavy-atom parameters. Let us assume that we have three derivatives A, B and C, and that we have already determined the heavy-atom parameters HA_i, HB_i and HC_i. Then,

$$\begin{aligned} \mathbf{F}_{\rm HA} &= \mathbf{F}_{\rm HA}(HA_i) \\ \mathbf{F}_{\rm HB} &= \mathbf{F}_{\rm HB}(HB_i) \\ \mathbf{F}_{\rm HC} &= \mathbf{F}_{\rm HC}(HC_i). \end{aligned} \qquad (2.4.4.12)$$

A set of approximate protein phase angles is first calculated, employing methods described later, making use of the unrefined heavy-atom parameters. These phase angles are used to construct $\mathbf{F}_{\rm N} + \mathbf{F}_{\rm H}$ for each derivative. (2.4.4.11) is then minimized, separately for each derivative, by varying HA_i for derivative A, HB_i for derivative B, and HC_i for derivative C. The refined values of HA_i, HB_i and HC_i are subsequently used to calculate a new set of protein phase angles. Alternate cycles of parameter refinement and phase-angle calculation are carried out until convergence is reached. The progress of refinement may be monitored by computing an R factor defined as (Kraut *et al.*, 1962)

$$R_{\rm K} = \frac{\sum |F_{\rm NH} - |\mathbf{F}_{\rm N} + \mathbf{F}_{\rm H}||}{F_{\rm NH}}. \qquad (2.4.4.13)$$

The above method has been successfully used for the refinement of heavy-atom parameters in the X-ray analysis of many proteins. However, it has one major drawback in that the refined parameters in one derivative are dependent on those in other derivatives through the calculation of protein phase angles. Therefore, it is important to ensure that the derivative, the heavy-atom parameters of which are being refined, is omitted from the phase-angle calculation (Blow & Matthews, 1973). Even when this is done, serious problems might arise when different derivatives are related by common sites. In practice, the occupancy factors of the common sites tend to be overestimated compared to those of the others (Vijayan, 1981; Dodson & Vijayan, 1971). Yet another factor which affects the occupancy factors is the accuracy of the phase angles. The inclusion of poorly phased reflections tends to result in the underestimation of occupancy factors. It is therefore advisable to omit from refinement cycles reflections with figures of merit less than a minimum threshold value or to assign a weight proportional to the figure of merit (as defined later) to each term in the minimization function (Dodson & Vijayan, 1971; Blow & Matthews, 1973).

If anomalous-scattering data from derivative crystals are available, the values of $F_{\rm H}$ can be estimated using (2.4.4.7) or (2.4.4.9) and these can be used as the 'observed' magnitudes of the heavy-atom contributions for the refinement of heavy-atom parameters, as has been done by many workers (Watenpaugh *et al.*, 1975; Vijayan, 1981; Kartha, 1965). If (2.4.4.9) is used for estimating $F_{\rm H}$, the minimization function has the form

$$\varphi = \sum w(F_{\rm HLE} - F_{\rm H})^2. \qquad (2.4.4.14)$$

The progress of refinement may be monitored using a reliability index defined as

$$R = \frac{\sum |F_{\rm HLE} - F_{\rm H}|}{\sum F_{\rm HLE}}. \qquad (2.4.4.15)$$

The major advantage of using $F_{\rm HLE}$'s in refinement is that the heavy-atom parameters in each derivative can now be refined independently of all other derivatives. Care should, however, be taken to omit from calculations all reflections for which $F_{\rm HUE}$ is likely to be the correct estimate of $F_{\rm H}$. This can be achieved in practice by excluding from least-squares calculations all reflections for which $F_{\rm HUE}$ has a value less than the maximum expected value of $F_{\rm H}$ for the given derivative (Vijayan, 1981; Dodson & Vijayan, 1971).

A major problem associated with this refinement method is concerned with the effect of experimental errors on refined parameters. The values of $F_{\rm NH}(+) - F_{\rm NH}(-)$ are often comparable to the experimental errors associated with $F_{\rm NH}(+)$ and $F_{\rm NH}(-)$. In such a situation, even random errors in $F_{\rm NH}(+)$ and $F_{\rm NH}(-)$ tend to increase systematically the observed difference between them (Dodson & Vijayan, 1971). In (2.4.4.7) and (2.4.4.9), this difference is multiplied by k or $k/2$, a quantity much greater than unity, and then squared. This could lead to the systematic overestimation of $F_{\rm HLE}$'s and the consequent overestimation of occupancy factors. The situation can be improved by employing empirical values of k, evaluated using the relation (Kartha & Parthasarathy, 1965; Matthews, 1966)

$$k = \frac{2\sum |F_{\rm NH} - F_{\rm N}|}{\sum |F_{\rm NH}(+) - F_{\rm NH}(-)|}, \qquad (2.4.4.16)$$

for estimating $F_{\rm HLE}$ or by judiciously choosing the weighting factors in (2.4.4.14) (Dodson & Vijayan, 1971). The use of a modified form of $F_{\rm HLE}$, arrived at through statistical considerations, along with appropriate weighting factors, has also been advocated (Dodson *et al.*, 1975).

When the data are centric, (2.4.4.9) reduces to

$$F_{\rm H} = F_{\rm NH} \pm F_{\rm N}. \qquad (2.4.4.17)$$

Here, again, the lower estimate most often corresponds to the correct value of $F_{\rm H}$. (2.4.4.17) does not involve $F_{\rm NH}(+) - F_{\rm NH}(-)$ which, as indicated earlier, is prone to substantial error. Therefore, $F_{\rm H}$'s estimated using centric data are more reliable than those estimated using acentric data. Consequently, centric reflections, when available, are extensively used for the refinement of heavy-atom parameters. It may also be noted that in conditions under which $F_{\rm HLE}$ corresponds to the correct estimate of $F_{\rm H}$, minimization functions (2.4.4.11) and (2.4.4.14) are identical for centric data.

A Patterson function correlation method with a minimization function of the type

$$\varphi = \sum w[(F_{\rm NH} - F_{\rm N})^2 - F_{\rm H}^2]^2 \qquad (2.4.4.18)$$

was among the earliest procedures suggested for heavy-atom-parameter refinement (Rossmann, 1960). This procedure would obviously work well when centric reflections are used. A modified version of this procedure, in which the origins of the Patterson functions are removed from the correlation, and

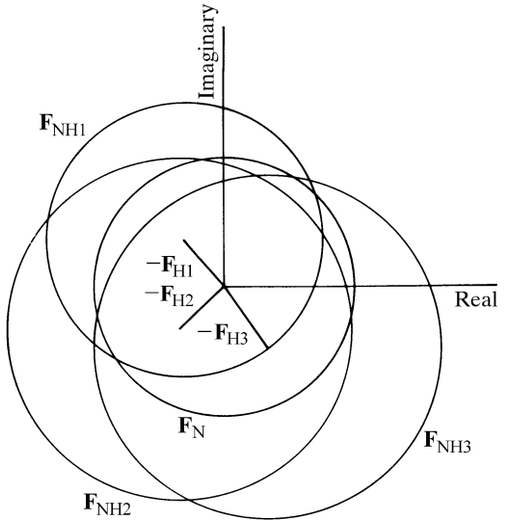

Fig. 2.4.4.1. Distribution of intersections in the Harker construction under non-ideal conditions.

centric and acentric data are treated separately, has been proposed (Terwilliger & Eisenberg, 1983).

2.4.4.4. Treatment of errors in phase evaluation: Blow and Crick formulation

As shown in Section 2.4.2.3, ideally, protein phase angles can be evaluated if two isomorphous heavy-atom derivatives are available. However, in practice, conditions are far from ideal on account of several factors such as imperfect isomorphism, errors in the estimation of heavy-atom parameters, and the experimental errors in the measurement of intensity from the native and the derivative crystals. It is therefore desirable to use as many derivatives as are available for phase determination. When isomorphism is imperfect and errors exist in data and heavy-atom parameters, all the circles in a Harker diagram would not intersect at a single point; instead, there would be a distribution of intersections, such as that illustrated in Fig. 2.4.4.1. Consequently, a unique solution for the phase angle cannot be deduced.

The statistical procedure for computing protein phase angles using multiple isomorphous replacement (MIR) was derived by Blow & Crick (1959). In their treatment, Blow and Crick assume, for mathematical convenience, that all errors, including those arising from imperfect isomorphism, could be considered as residing in the magnitudes of the derivative structure factors only. They further assume that these errors could be described by a Gaussian distribution. With these simplifying assumptions, the statistical procedure for phase determination could be derived in the following manner.

Consider the vector diagram, shown in Fig. 2.4.4.2, for a reflection from the ith derivative for an arbitrary value α for the protein phase angle. Then,

$$D_{Hi}(\alpha) = [F_N^2 + F_{Hi}^2 + 2F_N F_{Hi}\cos(\alpha_{Hi} - \alpha)]^{1/2}. \qquad (2.4.4.19)$$

If α corresponds to the true protein phase angle α_N, then D_{Hi} coincides with F_{NHi}. The amount by which $D_{Hi}(\alpha)$ differs from F_{NHi}, namely,

$$\xi_{Hi}(\alpha) = F_{NHi} - D_{Hi}(\alpha), \qquad (2.4.4.20)$$

is a measure of the departure of α from α_N. ξ is called the lack of closure. The probability for α being the correct protein phase angle could now be defined as

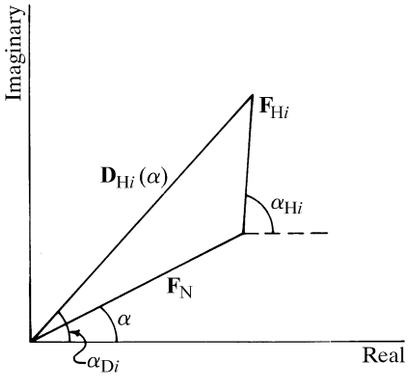

Fig. 2.4.4.2. Vector diagram indicating the calculated structure factor, $\mathbf{D}_{Hi}(\alpha)$, of the ith heavy-atom derivative for an arbitrary value α for the phase angle of the structure factor of the native protein.

$$P_i(\alpha) = N_i \exp[-\xi_{Hi}^2(\alpha)/2E_i^2], \qquad (2.4.4.21)$$

where N_i is the normalization constant and E_i is the estimated r.m.s. error. The methods for estimating E_i will be outlined later. When several derivatives are used for phase determination, the total probability of the phase angle α being the protein phase angle would be

$$P(\alpha) = \prod P_i(\alpha) = N \exp\left\{-\sum_i [\xi_{Hi}^2(\alpha)/2E_i^2]\right\}, \qquad (2.4.4.22)$$

where the summation is over all the derivatives. A typical distribution of $P(\alpha)$ plotted around a circle of unit radius is shown in Fig. 2.4.4.3. The phase angle corresponding to the highest value of $P(\alpha)$ would obviously be the most probable protein phase, α_M, of the given reflection. The most probable electron-density distribution is obtained if each F_N is associated with the corresponding α_M in a Fourier synthesis.

Blow and Crick suggested a different way of using the probability distribution. In Fig. 2.4.4.3, the centroid of the probability distribution is denoted by P. The polar coordinates of P are m and α_B, where m, a fractional positive number with a maximum value of unity, and α_B are referred to as the 'figure of merit' and the 'best phase', respectively. One can then compute a 'best Fourier' with coefficients

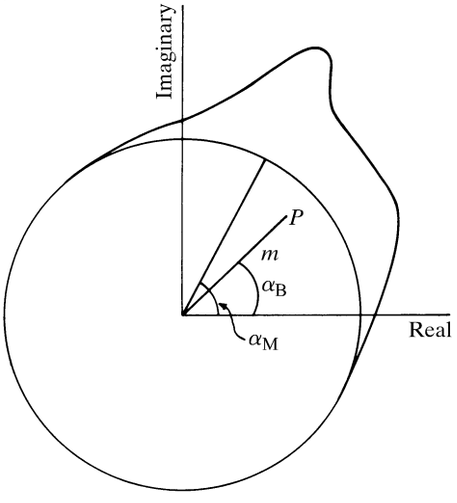

Fig. 2.4.4.3. The probability distribution of the protein phase angle. The point P is the centroid of the distribution.

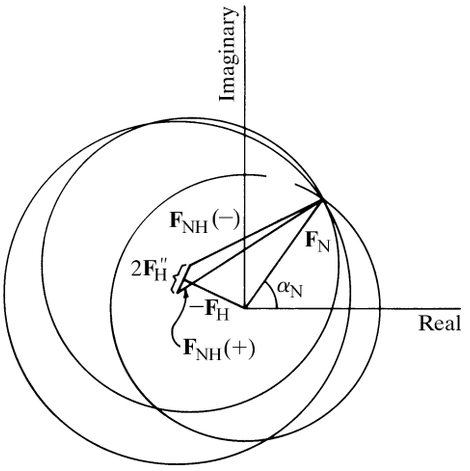

Fig. 2.4.4.4. Harker construction using anomalous-scattering data from a single derivative.

$$mF_N \exp(i\alpha_B).$$

The best Fourier is expected to provide an electron-density distribution with the lowest r.m.s. error. The figure of merit and the best phase are usually calculated using the equations

$$\begin{aligned} m\cos\alpha_B &= \sum_i P(\alpha_i)\cos(\alpha_i)/\sum_i P(\alpha_i) \\ m\sin\alpha_B &= \sum_i P(\alpha_i)\sin(\alpha_i)/\sum_i P(\alpha_i), \end{aligned} \qquad (2.4.4.23)$$

where $P(\alpha_i)$ are calculated, say, at 5° intervals (Dickerson *et al.*, 1961). The figure of merit is statistically interpreted as the cosine of the expected error in the calculated phase angle and it is obviously a measure of the precision of phase determination. In general, m is high when α_M and α_B are close to each other and low when they are far apart.

2.4.4.5. Use of anomalous scattering in phase evaluation

When anomalous-scattering data have been collected from derivative crystals, $F_{NH}(+)$ and $F_{NH}(-)$ can be formally treated as arising from two independent derivatives. The corresponding Harker diagram is shown in Fig. 2.4.4.4. Thus, in principle, protein phase angles can be determined using a single derivative when anomalous-scattering effects are also made use of. It is interesting to note that the information obtained from isomorphous differences, $F_{NH} - F_N$, and that obtained from anomalous differences, $F_{NH}(+) - F_{NH}(-)$, are complementary. The isomorphous difference for any given reflection is a maximum when F_N and F_H are parallel or antiparallel. The anomalous difference is then zero, if all the anomalous scatterers are of the same type, and α_N is determined uniquely on the basis of the isomorphous difference. The isomorphous difference decreases and the anomalous difference increases as the inclination between $\mathbf{F}_N$ and $\mathbf{F}_H$ increases. The isomorphous difference tends to be small and the anomalous difference tends to have the maximum possible value when $\mathbf{F}_N$ and $\mathbf{F}_H$ are perpendicular to each other. The anomalous difference then has the predominant influence in determining the phase angle.

Although isomorphous and anomalous differences have a complementary role in phase determination, their magnitudes are obviously unequal. Therefore, when $F_{NH}(+)$ and $F_{NH}(-)$ are treated as arising from two derivatives, the effect of anomalous differences on phase determination would be only marginal as, for any given reflection, $F_{NH}(+) - F_{NH}(-)$ is usually much smaller than $F_{NH} - F_N$. However, the magnitude of the error in the anomalous difference would normally be much smaller than that in the corresponding isomorphous difference. Firstly, the former is obviously free from the effects of imperfect isomorphism. Secondly, $F_{NH}(+)$ and $F_{NH}(-)$ are expected to have the same systematic errors as they are measured from the same crystal. These errors are eliminated in the difference between the two quantities. Therefore, as pointed out by North (1965), the r.m.s. error used for anomalous differences should be much smaller than that used for isomorphous differences. Denoting the r.m.s. error in anomalous differences by E', the new expression for the probability distribution of protein phase angle may be written as

$$\begin{aligned} P_i(\alpha) = N_i \exp[-\xi^2_{Hi}(\alpha)/2E_i^2] \\ \times \exp\{-[\Delta H_i - \Delta H_{ical}(\alpha)]^2/2E_i'^2\}, \end{aligned} \qquad (2.4.4.24)$$

where

$$\Delta H_i = F_{NHi}(+) - F_{NHi}(-)$$

and

$$\Delta H_{ical}(\alpha) = 2F''_{Hi}\sin(\alpha_{Di} - \alpha_{Hi}).$$

Here α_{Di} is the phase angle of $D_{Hi}(\alpha)$ [see (2.4.4.19) and Fig. 2.4.4.2]. $\Delta H_{ical}(\alpha)$ is the anomalous difference calculated for the assumed protein phase angle α. F_{NHi} may be taken as the average of $F_{NHi}(+)$ and $F_{NHi}(-)$ for calculating $\xi^2_{Hi}(\alpha)$ using (2.4.4.20).

2.4.4.6. Estimation of r.m.s. error

Perhaps the most important parameters that control the reliability of phase evaluation using the Blow and Crick formulation are the isomorphous r.m.s. error E_i and the anomalous r.m.s. error E'_i. For a given derivative, the sharpness of the peak in the phase probability distribution obviously depends upon the value of E and that of E' when anomalous-scattering data have also been used. When several derivatives are used, an overall underestimation of r.m.s. errors leads to artifically sharper peaks, the movement of α_B towards α_M, and deceptively high figures of merit. Opposite effects result when E's are overestimated. Underestimation or overestimation of the r.m.s. error in the data from a particular derivative leads to distortions in the relative contribution of that derivative to the overall phase probability distributions. It is therefore important that the r.m.s. error in each derivative is correctly estimated.

Centric reflections, when present, obviously provide the best means for evaluating E using the expression

$$E^2 = \sum_n (|F_{NH} \pm F_N| - F_N)^2/n. \qquad (2.4.4.25)$$

As suggested by Blow & Crick (1959), values of E thus estimated can be used for acentric reflections as well. Once a set of approximate protein phase angles is available, E_i can be calculated as the r.m.s. lack of closure corresponding to α_B [*i.e.* $\alpha = \alpha_B$ in (2.4.4.20)] (Kartha, 1976). E'_i can be similarly evaluated as the r.m.s. difference between the observed anomalous difference and the anomalous difference calculated for α_B [see (2.4.4.24)]. Normally, the value of E'_i is about a third of that of E_i (North, 1965).

A different method, outlined below, can also be used to evaluate E and E' when anomalous scattering is present (Vijayan, 1981; Adams, 1968). From Fig. 2.4.2.2, we have

$$\cos\psi = (F_{\rm NH}^2 + F_{\rm H}^2 - F_{\rm N}^2)/2F_{\rm NH}F_{\rm H} \qquad (2.4.4.26)$$

and

$$F_{\rm N}^2 = F_{\rm NH}^2 + F_{\rm H}^2 - 2F_{\rm NH}F_{\rm H}\cos\psi, \qquad (2.4.4.27)$$

where $\psi = \alpha_{\rm NH} - \alpha_{\rm H}$. Using arguments similar to those used in deriving (2.4.3.5), we obtain

$$\sin\psi = [F_{\rm NH}^2(+) - F_{\rm NH}^2(-)]/4F_{\rm NH}F_{\rm H}''. \qquad (2.4.4.28)$$

If $F_{\rm NH}$ is considered to be equal to $[F_{\rm NH}(+) + F_{\rm NH}(-)]/2$, we obtain from (2.4.4.28)

$$F_{\rm NH}(+) - F_{\rm NH}(-) = 2F_{\rm H}''\sin\psi. \qquad (2.4.4.29)$$

We obtain what may be called $\psi_{\rm iso}$ if the magnitude of ψ is determined from (2.4.4.26) and the quadrant from (2.4.4.28). Similarly, we obtain $\psi_{\rm ano}$ if the magnitude of ψ is determined from (2.4.4.28) and the quadrant from (2.4.4.26). Ideally, $\psi_{\rm iso}$ and $\psi_{\rm ano}$ should have the same value and the difference between them is a measure of the errors in the data. $F_{\rm N}$ obtained from (2.4.4.27) using $\psi_{\rm ano}$ may be considered as its calculated value ($F_{\rm Ncal}$). Then, assuming all errors to lie in $F_{\rm N}$, we may write

$$E^2 = \sum_n (F_{\rm N} - F_{\rm Ncal})^2/n. \qquad (2.4.4.30)$$

Similarly, the calculated anomalous difference ($\Delta H_{\rm cal}$) may be evaluated from (2.4.4.29) using $\psi_{\rm iso}$. Then

$$E'^2 = \sum_n [|F_{\rm NH}(+) - F_{\rm NH}(-)| - \Delta H_{\rm cal}]^2/n. \qquad (2.4.4.31)$$

If all errors are assumed to reside in $F_{\rm H}$, E can be evaluated in yet another way using the expression

$$E^2 = \sum_n (F_{\rm HLE} - F_{\rm H})^2/n. \qquad (2.4.4.32)$$

2.4.4.7. Suggested modifications to Blow and Crick formulation and the inclusion of phase information from other sources

Modifications to the Blow and Crick procedure of phase evaluation have been suggested by several workers, although none represent a fundamental departure from the essential features of their formulation. In one of the modifications (Cullis *et al.*, 1961*a*; Ashida, 1976), all E_i's are assumed to be the same, but the lack-of-closure error $\xi_{{\rm H}i}$ for the ith derivative is measured as the distance from the mean of all intersections between phase circles to the point of intersection of the phase circle of that derivative with the phase circle of the native protein. Alternatively, individual values of E_i are retained, but the lack of closure is measured from the weighted mean of all intersections (Ashida, 1976). This is obviously designed to undo the effects of the unduly high weight given to $F_{\rm N}$ in the Blow and Crick formulation. In another modification (Raiz & Andreeva, 1970; Einstein, 1977), suggested for the same purpose, the $F_{\rm N}$ and $F_{{\rm NH}i}$ circles are treated as circular bands, the width of each band being related to the error in the appropriate structure factor. A comprehensive set of modifications suggested by Green (1979) treats different types of errors separately. In particular, errors arising from imperfect isomorphism are treated in a comprehensive manner.

Although the isomorphous replacement method still remains the method of choice for the *ab initio* determination of protein structures, additional items of phase information from other sources are increasingly being used to replace, supplement, or extend the information obtained through the application of the isomorphous replacement. Methods have been developed for the routine refinement of protein structures (Watenpaugh *et al.*, 1973; Huber *et al.*, 1974; Sussman *et al.*, 1977; Jack & Levitt, 1978; Isaacs & Agarwal, 1978; Hendrickson & Konnert, 1980) and they provide a rich source of phase information. However, the nature of the problem and the inherent limitations of the Fourier technique are such that the possibility of refinement yielding misleading results exists (Vijayan, 1980*a*,*b*). It is therefore sometimes desirable to combine the phases obtained during refinement with the original isomorphous replacement phases. The other sources of phase information include molecular replacement (see Chapter 2.3), direct methods (Hendrickson & Karle, 1973; Sayre, 1974; de Rango *et al.*, 1975; see also Chapter 2.2) and different types of electron-density modifications (Hoppe & Gassmann, 1968; Collins, 1975; Schevitz *et al.*, 1981; Bhat & Blow, 1982; Agard & Stroud, 1982; Cannillo *et al.*, 1983; Raghavan & Tulinsky, 1979; Wang, 1985).

The problem of combining isomorphous replacement phases with those obtained by other methods was first addressed by Rossmann & Blow (1961). The problem was subsequently examined by Hendrickson & Lattman (1970) and their method, which involves a modification of the Blow and Crick formulation, is perhaps the most widely used for combining phase information from different sources.

The Blow and Crick procedure is based on an assumed Gaussian 'lumped' error in $F_{{\rm NH}i}$ which leads to a lack of closure, $\xi_{{\rm H}i}(\alpha)$, in $F_{{\rm NH}i}$ defined by (2.4.4.20). Hendrickson and Lattman make an equally legitimate assumption that the lumped error, again assumed to be Gaussian, is associated with $F_{{\rm NH}i}^2$. Then, as in (2.4.4.20), we have

$$\xi_{{\rm H}i}''(\alpha) = F_{{\rm NH}i}^2 - D_{{\rm H}i}^2(\alpha), \qquad (2.4.4.33)$$

where $\xi_{{\rm H}i}''(\alpha)$ is the lack of closure associated with $F_{{\rm NH}i}^2$ for an assumed protein phase angle α. Then the probability for α being the correct phase angle can be expressed as

$$P_i(\alpha) = N_i \exp[-\xi_{{\rm H}i}''^2(\alpha)/2E_i''^2], \qquad (2.4.4.34)$$

where E_i'' is the r.m.s. error in $F_{{\rm NH}i}^2$, which can be evaluated using methods similar to those employed for evaluating E_i. Hendrickson and Lattman have shown that the exponent in the probability expression (2.4.4.34) can be readily expressed as a linear combination of five terms in the following manner.

$$-\xi_{{\rm H}i}''^2(\alpha)/2E_i''^2 = K_i + A_i\cos\alpha + B_i\sin\alpha + C_i\cos 2\alpha + D_i\sin 2\alpha, \qquad (2.4.4.35)$$

where K_i, A_i, B_i, C_i and D_i are constants dependent on $F_{\rm N}$, $F_{{\rm H}i}$, $F_{{\rm NH}i}$ and E_i''. Thus, five constants are enough to store the complete probability distribution of any reflection. Expressions for the five constants have been derived for phase information from anomalous scattering, tangent formula, partial structure and molecular replacement. The combination of the phase information from all sources can then be achieved by simply taking the total value of each constant. Thus, the total probability of the protein phase angle being α is given by

$$P(\alpha) = \prod P_s(\alpha) = N \exp\Bigg(\sum_s K_s + \sum_s A_s \cos\alpha + \sum_s B_s \sin\alpha + \sum_s C_s \cos 2\alpha + \sum_s D_s \sin 2\alpha \Bigg), \tag{2.4.4.36}$$

where K_s, A_s *etc.* are the constants appropriate for the sth source and N is the normalization constant.

2.4.4.8. Fourier representation of anomalous scatterers

It is often useful to have a Fourier representation of only the anomalous scatterers in a protein. The imaginary component of the electron-density distribution obviously provides such a representation. When the structure is known and $F_N(+)$ and $F_N(-)$ have been experimentally determined, Chacko & Srinivasan (1970) have shown that this representation is obtained in a Fourier synthesis with $i[\mathbf{F}_N(+) + \mathbf{F}_N^*(-)]/2$ as coefficients, where $\mathbf{F}_N^*(-)$, whose magnitude is $F_N(-)$, is the complex conjugate of $\mathbf{F}_N(+)$. They also indicated a method for calculating the phase angles of $\mathbf{F}_N(+)$ and $\mathbf{F}_N^*(-)$. It has been shown (Hendrickson & Sheriff, 1987) that the Bijvoet-difference Fourier synthesis proposed earlier by Kraut (1968) is an approximation of the true imaginary component of the electron density. The imaginary synthesis can be useful in identifying minor anomalous-scattering centres when the major centres are known and also in providing an independent check on the locations of anomalous scatterers and in distinguishing between anomalous scatterers with nearly equal atomic numbers (Sheriff & Hendrickson, 1987; Kitagawa *et al.*, 1987).

2.4.5. Anomalous scattering of neutrons and synchrotron radiation. The multiwavelength method

The multiwavelength anomalous-scattering method (Ramaseshan, 1982) relies on the variation of dispersion-correction terms as a function of the wavelength used. The success of the method therefore depends upon the size of the correction terms and the availability of incident beams of comparable intensities at different appropriate wavelengths. Thus, although this method was used as early as 1957 (Ramaseshan *et al.*, 1957) as an aid to structure solution employing characteristic X-rays, it is, as outlined below, ideally suited in structural work employing neutrons and synchrotron radiation. In principle, γ-radiation can also be used for phase determination (Raghavan, 1961; Moon, 1961) as the anomalous-scattering effects in γ-ray scattering could be very large; the wavelength is also easily tunable. However, the intensity obtainable for γ-rays is several orders lower than that obtainable from X-ray and neutron sources, and hence γ-ray anomalous scattering is of hardly any practical value in structural analysis.

2.4.5.1. Neutron anomalous scattering

Apart from the limitations introduced by experimental factors, such as the need for large crystals and the comparatively low flux of neutron beams, there are two fundamental reasons why neutrons are less suitable than X-rays for the *ab initio* determination of crystal structures. First, the neutron scattering lengths of different nuclei have comparable magnitudes whereas the atomic form factors for X-rays vary by two orders of magnitude. Therefore, Patterson techniques and the related heavy-atom method are much less suitable for use with neutron diffraction data than with X-ray data. Secondly, neutron scattering lengths could be positive or negative and hence, in general, the positivity criterion (Karle & Hauptman, 1950) or the squarability criterion (Sayre, 1952) does not hold good for nuclear density. Therefore, the direct methods based on these criteria are not strictly applicable to structure analysis using neutron data, although it has been demonstrated that these methods could be successfully used in favourable situations in neutron crystallography (Sikka, 1969). The anomalous-scattering method is, however, in principle more powerful in the neutron case than in the X-ray case for *ab initio* structure determination.

Thermal neutrons are scattered anomalously at appropriate wavelengths by several nuclei. In a manner analogous to (2.4.3.1), the neutron scattering length of these nuclei can be written as

$$b_0 + b' + ib'' = b + ib''. \tag{2.4.5.1}$$

The correction terms b' and b'' are strongly wavelength-dependent. In favourable cases, b'/b_0 and b''/b_0 can be of the order of 10 whereas they are small fractions in X-ray anomalous scattering. In view of this pronounced anomalous effect in neutron scattering, Ramaseshan (1966) suggested that it could be used for structure solution. Subsequently, Singh & Ramaseshan (1968) proposed a two-wavelength method for unique structure analysis using neutron diffraction. The first part of the method is the determination of the positions of the anomalous scatterers from the estimated values of F_Q. The method employed for estimating F_Q is analogous to that using (2.4.4.9) except that data collected at two appropriate wavelengths are used instead of those from two isomorphous crystals. The second stage of the two-wavelength method involves phase evaluation. Referring to Fig. 2.4.3.2 and in a manner analogous to (2.4.3.5), we have

$$\sin\psi_1 = \frac{F_{N1}^2(+) - F_{N1}^2(-)}{4F_{N1}F_{Q1}''}, \tag{2.4.5.2}$$

where $\psi = \alpha_N - \alpha_Q$ and subscript 1 refers to data collected at wavelength $\lambda 1$. Singh and Ramaseshan showed that $\cos\psi_1$ can also be determined when data are available at wavelength $\lambda 1$ and $\lambda 2$. We may define

$$F_m^2 = [F_N^2(+) + F_N^2(-)]/2 \tag{2.4.5.3}$$

and we have from (2.4.3.3), (2.4.3.4) and (2.4.5.3)

$$F_N = (F_m^2 - F_Q''^2)^{1/2}. \tag{2.4.5.4}$$

Then,

$$\cos\psi_1 = \frac{F_{m1}^2 - F_{m2}^2 - [(b_1^2 + b_1''^2) - (b_2^2 + b_2''^2)]x^2}{2(b_1 - b_2)F_{N1}x} + \frac{F_{Q1}}{F_{N1}}, \tag{2.4.5.5}$$

where x is the magnitude of the temperature-corrected geometrical part of $\mathbf{F}_Q$. ψ_1 and hence α_{N1} can be calculated using (2.4.5.2) and (2.4.5.5). α_{N2} can also be obtained in a similar manner.

During the decade that followed Ramaseshan's suggestion, neutron anomalous scattering was used to solve half a dozen crystal structures, employing the multiple-wavelength methods as well as the methods developed for structure determination using X-ray anomalous scattering (Koetzle & Hamilton, 1975; Sikka & Rajagopal, 1975; Flook *et al.*, 1977). It has also been demonstrated that measurable Bijvoet differences could be obtained, in favourable situations, in neutron diffraction patterns from protein crystals (Schoenborn, 1975). However, despite the early promise held by neutron anomalous scattering, the method has

not been as successful as might have been hoped. In addition to the need for large crystals, the main problem with using this method appears to be the time and expense involved in data collection (Koetzle & Hamilton, 1975).

2.4.5.2. Anomalous scattering of synchrotron radiation

The most significant development in recent years in relation to anomalous scattering of X-rays has been the advent of synchrotron radiation (Helliwell, 1984). The advantage of using synchrotron radiation for making anomalous-scattering measurements essentially arises out of the tunability of the wavelength. Unlike the characteristic radiation from conventional X-ray sources, synchrotron radiation has a smooth spectrum and the wavelength to be used can be finely selected. Accurate measurements have shown that values in the neighbourhood of 30 electrons could be obtained in favourable cases for f' and f'' (Templeton, Templeton, Phillips & Hodgson, 1980; Templeton, Templeton & Phizackerley, 1980; Templeton *et al.*, 1982). Schemes for the optimization of the wavelengths to be used have also been suggested (Narayan & Ramaseshan, 1981). Interestingly, the anomalous differences obtainable using synchrotron radiation are comparable in magnitude to the isomorphous differences normally encountered in protein crystallography. Thus, the use of anomalous scattering at several wavelengths would obviously eliminate the need for employing many heavy-atom derivatives. The application of anomalous scattering of synchrotron radiation for macromolecular structure analysis began to yield encouraging results in the 1980s (Helliwell, 1985). Intensity measurements from macromolecular X-ray diffraction patterns using synchrotron radiation at first relied primarily upon oscillation photography (Arndt & Wonacott, 1977). This method is not particularly suitable for accurately evaluating anomalous differences. Much higher levels of accuracy began to be achieved with the use of position-sensitive detectors (Arndt, 1986). Anomalous scattering, in combination with such detectors, has developed into a major tool in macromolecular crystallography (see *IT* F, 2001).

2.5. Electron diffraction and electron microscopy in structure determination

By J. M. Cowley,† J. C. H. Spence, M. Tanaka, B. K. Vainshtein,† B. B. Zvyagin,† P. A. Penczek and D. L. Dorset

2.5.1. Foreword

By J. M. Cowley and J. C. H. Spence

Given that electrons have wave properties and the wavelengths lie in a suitable range, the diffraction of electrons by matter is completely analogous to the diffraction of X-rays. While for X-rays the scattering function is the electron-density distribution, for electrons it is the potential distribution which is similarly peaked at the atomic sites. Hence, in principle, electron diffraction may be used as the basis for crystal structure determination. In practice it is used much less widely than X-ray diffraction for the determination of crystal structures but is receiving increasing attention as a means for obtaining structural information not readily accessible with X-ray- or neutron-diffraction techniques.

Electrons having wavelengths comparable with those of the X-rays commonly used in diffraction experiments have energies of the order of 100 eV. For such electrons, the interactions with matter are so strong that they can penetrate only a few layers of atoms on the surfaces of solids. They are used extensively for the study of surface structures by low-energy electron diffraction (LEED) and associated techniques. These techniques are not covered in this series of volumes, which include the principles and practice of only those diffraction and imaging techniques making use of high-energy electrons, having energies in the range of 20 keV to 1 MeV or more, in transmission through thin specimens.

For the most commonly used energy ranges of high-energy electrons, 100 to 400 keV, the wavelengths are about 50 times smaller than for X-rays. Hence the scattering angles are much smaller, of the order of 10^{-2} rad, the recording geometry is relatively simple and the diffraction pattern represents, to a useful first approximation, a planar section of reciprocal space. Extinction distances are hundreds of ångstroms, which, when combined with typical lattice spacings, produces rocking-curve widths which are, unlike the X-ray case, a significant fraction of the Bragg angle.

The elastic scattering of electrons by atoms is several orders of magnitude greater than for X-rays. This fact has profound consequences, which in some cases are highly favourable and in other cases are serious hindrances to structure analysis work. On the one hand it implies that electron-diffraction patterns can be obtained from very small single-crystal regions having thicknesses equal to only a few layers of atoms and, with recently developed techniques, having diameters equivalent to only a few interatomic distances. Hence single-crystal patterns can be obtained from microcrystalline phases.

However, the strong scattering of electrons implies that the simple kinematical single-scattering approximation, on which most X-ray diffraction structure analysis is based, fails for electrons except for very thin crystals composed of light-atom materials. Strong dynamical diffraction effects occur for crystals which may be 100 Å thick, or less for heavy-atom materials. As a consequence, the theory of dynamical diffraction for electrons has been well developed, particularly for the particular special diffracting conditions relevant to the transmission of fast electrons (see Chapter 5.2), and observations of dynamical diffraction effects are commonly made and quantitatively interpreted. The possibility has thus arisen of using the observation of dynamical diffraction effects as the basis for obtaining crystal structure information. The fact that dynamical diffraction is dependent on the relative phases of the diffracted waves then implies that relative phase information can be deduced from the diffraction intensities and the limitations of kinematical diffraction, such as Friedel's law, do not apply. The most immediately practicable method for making use of this possibility is convergent-beam electron diffraction (CBED) as described in Section 2.5.3.

A further important factor, determining the methods for observing electron diffraction, is that, being charged particles, electrons can be focused by electromagnetic lenses. Many of the resolution-limiting aberrations of cylindrical magnetic lenses have now been eliminated through the use of aberration-correction devices, so that for weakly scattering samples the resolution is limited to about 1 Å by electronic and mechanical instabilities. This is more than sufficient to distinguish the individual rows of atoms, parallel to the incident beam, in the principal orientations of most crystalline phases. Thus 'structure images' can be obtained, sometimes showing direct representation of projections of crystal structures [see *IT* C (2004), Section 4.3.8]. However, the complications of dynamical scattering and of the coherent imaging processes are such that the image intensities vary strongly with crystal thickness and tilt, and with the defocus or other parameters of the imaging system, making the interpretation of images difficult except in special circumstances. Fortunately, computer programs are readily available whereby image intensities can be calculated for model structures [see *IT* C (2004), Section 4.3.6]. Hence the means exist for deriving the projection of the structure if only by a process of trial and error and not, as would be desirable, from a direct interpretation of the observations.

The accuracy with which the projection of a structure can be deduced from an image, or series of images, improves as the resolution of the microscope improves but is not at all comparable with the accuracy attainable with X-ray diffraction methods. A particular virtue of high-resolution electron microscopy as a structural tool is that it may give information on individual small regions of the sample. Structures can be determined of 'phases' existing over distances of only a few unit cells and the defects and local disorders can be examined, one by one.

The observation of electron-diffraction patterns forms an essential part of the technique of structure imaging in high-resolution electron microscopy, because the diffraction patterns are used to align the crystals to appropriate axial orientations. More generally, for all electron microscopy of crystalline materials the image interpretation depends on knowledge of the diffraction conditions. Fortunately, the diffraction pattern and image of any specimen region can be obtained in rapid succession by a simple switching of lens currents. The ready comparison of the image and diffraction data has become an essential component of the electron microscopy of crystalline materials but has also been of fundamental importance for the development of electron-diffraction theory and techniques. The development of the nanodiffraction method in the field-emission scanning transmission electron microscope (STEM) has allowed microdiffraction patterns to be obtained from subnanometre-sized regions, and so has become the ideal tool for the structural analysis of the new microcrystalline phases important to nanoscience. The direct phasing of these coherent nanodiffraction patterns is an active field of research.

The individual specimen regions giving single-crystal electron-diffraction patterns are, with few exceptions, so small that they can be seen only by use of an electron microscope. Hence, historically, it was only after electron microscopes were commonly available that the direct correlations of diffraction intensities with crystal size and shape could be made, and a proper basis was available for the development of the adequate dynamical diffraction theory.

For the complete description of a diffraction pattern or image intensities obtained with electrons, it is necessary to include the effects of inelastic scattering as well as elastic scattering. In contrast to the X-ray diffraction case, the inelastic scattering does not produce just a broad and generally negligible background. The average energy loss for an inelastic scattering event is about 20 eV, which is small compared with the energy of about 100 keV for the incident electrons. The inelastically scattered electrons have a narrow angular distribution and are diffracted in much the same way as the incident or elastically scattered electrons in a crystal. They therefore produce a highly modulated contribution to the diffraction pattern, strongly peaked about the Bragg spot positions (see Chapter 4.3). Also, as a result of the inelastic scattering processes, including thermal diffuse scattering, an effective absorption function must be added in the calculation of intensities for elastically scattered electrons.

The inelastic scattering processes in themselves give information about the specimen in that they provide a measure of the excitations of both the valence-shell and the inner-shell electrons of the solid. The inner-shell electron excitations are characteristic of the type of atom, so that microanalysis of small volumes of specimen material (a few hundreds or thousands of atoms) may be achieved by detecting either the energy losses of the transmitted electrons or the emission of the characteristic X-ray [see *IT* C (2004), Section 4.3.4]. The development of the annular dark field (ADF) mode in STEM provides a favourable detector geometry for microanalysis, in which the forward scattered beam may be passed to an electron energy-loss spectrometer (EELS) for spectral analysis, while scattering at larger angles is collected to form a simultaneous scanning image. The arrangement is particularly efficient because, using a magnetic sector dispersive spectrometer, electrons of all energy losses may be detected simultaneously (parallel detection). Fine structure on the EELS absorption edges is analysed in a manner analogous to soft X-ray absorption spectroscopy, but with a spatial resolution of a few nanometres. The spectra are obtained from points in the corresponding ADF image which can be identified with subnanometre accuracy.

An adverse effect of the inelastic scattering processes, however, is that the transfer of energy to the specimen material results in radiation damage; this is a serious limitation of the application of electron-scattering methods to radiation-sensitive materials such as organic, biological and many inorganic compounds. The amount of radiation damage increases rapidly as the amount of information per unit volume, derived from the elastic scattering, is increased, *i.e.* as the microscope resolution is improved or as the specimen volume irradiated during a diffraction experiment is decreased. At the current limits of microscopic resolution, radiation damage is a significant factor even for the radiation-resistant materials such as semiconductors and alloys.

In the historical development of electron-diffraction techniques the progress has depended to an important extent on the level of understanding of the dynamical diffraction processes and this understanding has followed, to a considerable degree, from the availability of electron microscopes. For the first 20 years of the development, with few exceptions, the lack of a precise knowledge of the specimen morphology meant that diffraction intensities were influenced to an unpredictable degree by dynamical scattering and the impression grew that electron-diffraction intensities could not meaningfully be interpreted.

It was the group in the Soviet Union, led initially by Dr Z. G. Pinsker and later by Dr B. K. Vainshtein and others, which showed that patterns from thin layers of a powder of microcrystals could be interpreted reliably by use of the kinematical approximation. The averaging over crystal orientation reduced the dynamical diffraction effects to the extent that practical structure analysis was feasible. The development of the techniques of using films of crystallites having strongly preferred orientations, to give patterns somewhat analogous to the X-ray rotation patterns, provided the basis for the collection of three-dimensional diffraction data on which many structure analyses have been based [see Section 2.5.4 and *IT* C (2004), Section 4.3.5].

In recent years improvements in the techniques of specimen preparation and in the knowledge of the conditions under which dynamical diffraction effects become significant have allowed progress to be made with the use of high-energy electron-diffraction patterns from thin single crystals for crystal structure analysis. Particularly for crystals of light-atom materials, including biological and organic compounds, the methods of structure analysis developed for X-ray diffraction, including the direct methods (see Section 2.5.8), have been successfully applied in an increasing number of cases. Often it is possible to deduce some structural information from high-resolution electron-microscope images and this information may be combined with that from the diffraction intensities to assist the structure analysis process [see *IT* C (2004), Section 4.3.8.8].

The determination of crystal symmetry by use of CBED (Section 2.5.3) and the accurate determination of structure amplitudes by use of methods depending on the observation of dynamical diffraction effects [*IT* C (2004), Section 4.3.7] came later, after the information on morphologies of crystals, and the precision electron optics associated with electron microscopes, became available. This powerful convergent-beam microdiffraction method has now been widely adopted as the preferred method for space-group determination of microphases, quasicrystals, incommensurate, twinned and other imperfectly crystalline structures. Advantage is taken of the fact that multiple scattering preserves information on the absence of inversion symmetry, while the use of an electron probe which is smaller than a mosaic block allows extinction-free structure-factor measurements to be made. Finally, an enhanced sensitivity to ionicity is obtained from electron-diffraction measurements of structure factors by the very large difference between electron scattering factors for atoms and those for ions at small angles. This section by M. Tanaka replaces the corresponding section by the late P. Goodman in previous editions, which researchers may also find useful.

In spite of the problem of radiation damage, a great deal of progress has been made in the study of organic and biological materials by electron-scattering methods. In some respects these materials are very favourable because, with only light atoms present, the scattering from thin films can be treated using the kinematical approximation without serious error. Because of the problem of radiation damage, however, special techniques have been evolved to maximize the information on the required structural aspects with minimum irradiation of the specimen. Image-processing techniques have been evolved to take advantage of the redundancy of information from a periodic structure and the means have been devised for combining information from multiple images and diffraction data to reconstruct specimen structure in three dimensions. These techniques are outlined in Sections 2.5.5, 2.5.6 and 2.5.7. Section 2.5.6, written for the first and second editions by Boris Vainshtein, has been revised and extended for this third edition by Pawel Penczek. It deals with the general theory of three-dimensional reconstruction from projections and compares several popular methods. Section 2.5.7 describes the application of electron-microscope imaging to the structure analysis of proteins which cannot be crystallized,

and so addresses a crucial problem in structural biology. This is done by the remarkably successful method of single-particle image reconstruction, in which images of the same protein, lying in random orientations within a thin film of vitreous ice, are combined in the correct orientation to form a three-dimensional reconstructed charge-density map at nanometre or better resolution. The summation over many particles achieves the same radiation-damage-reduction effect as does crystallographic redundancy in protein crystallography. Finally, Section 2.5.8 describes experience with the application of numerical direct methods to the phase problem in electron diffraction. Although direct imaging 'solves' the phase problem, there are many practical problems in combining electron-microdiffraction intensities with corresponding high-resolution images of a structure over a large tilt range. In cases where multiple scattering can be minimized, some success has therefore been obtained using direct phasing methods, as reviewed in this section.

For most inorganic materials the complications of many-beam dynamical diffraction processes prevent the direct application of these techniques of image analysis, which depend on having a linear relationship between the image intensity and the value of the projected potential distribution of the sample. The smaller sensitivities to radiation damage can, to some extent, remove the need for the application of such methods by allowing direct visualization of structure with ultra-high-resolution images and the use of microdiffraction techniques.

2.5.2. Electron diffraction and electron microscopy[1]

By J. M. Cowley

2.5.2.1. Introduction

The contributions of electron scattering to the study of the structures of crystalline solids are many and diverse. This section will deal only with the scattering of high-energy electrons (in the energy range of 10^4 to 10^6 eV) in transmission through thin samples of crystalline solids and the derivation of information on crystal structures from diffraction patterns and high-resolution images. The range of wavelengths considered is from about 0.122 Å (12.2 pm) for 10 kV electrons to 0.0087 Å (0.87 pm) for 1 MeV electrons. Given that the scattering amplitudes of atoms for electrons have much the same form and variation with $(\sin\theta)/\lambda$ as for X-rays, it is apparent that the angular range for strong scattering of electrons will be of the order of 10^{-2} rad. Only under special circumstances, usually involving multiple elastic and inelastic scattering from very thick specimens, are scattering angles of more than 10^{-1} rad of importance.

The strength of the interaction of electrons with matter is greater than that of X-rays by two or three orders of magnitude. The single-scattering, first Born approximation fails significantly for scattering from single heavy atoms. Diffracted beams from single crystals may attain intensities comparable with that of the incident beam for crystal thicknesses of 10^2 Å, rather than 10^4 Å or more. It follows that electrons may be used for the study of very thin samples, and that dynamical scattering effects, or the coherent interaction of multiply scattered electron waves, will modify the diffracted amplitudes in a significant way for all but very thin specimens containing only light atoms.

The experimental techniques for electron scattering are largely determined by the possibility of focusing electron beams by use of strong axial magnetic fields, which act as electron lenses having focal lengths as short as 1 mm or less. Electron microscopes employing such lenses have been produced with resolutions approaching 1 Å. With such instruments, images showing individual isolated atoms of moderately high atomic number may be obtained. The resolution available is sufficient to distinguish neighbouring rows of adjacent atoms in the projected structures of thin crystals viewed in favourable orientations. It is therefore possible in many cases to obtain information on the structure of crystals and of crystal defects by direct inspection of electron micrographs.

The electromagnetic electron lenses may also be used to form electron beams of very small diameter and very high intensity. In particular, by the use of cold field-emission electron guns, it is possible to obtain a current of 10^{-10} A in an electron beam of diameter 10 Å or less with a beam divergence of less than 10^{-2} rad, *i.e.* a current density of 10^4 A cm^{-2} or more. The magnitudes of the electron scattering amplitudes then imply that detectable signals may be obtained in diffraction from assemblies of fewer than 10^2 atoms. On the other hand, electron beams may readily be collimated to better than 10^{-6} rad.

The cross sections for inelastic scattering processes are, in general, less than for the elastic scattering of electrons, but signals may be obtained by the observation of electron energy losses, or the production of secondary radiations, which allow the analysis of chemical compositions or electronic excited states for regions of the crystal 100 Å or less in diameter.

On the other hand, the transfer to the sample of large amounts of energy through inelastic scattering processes produces radiation damage which may severely limit the applicability of the imaging and diffraction techniques, especially for biological and organic materials, unless the information is gathered from large specimen volumes with low incident electron beam densities.

Structure analysis of crystals can be performed using electron diffraction in the same way as with X-ray or neutron diffraction. The mathematical expressions and the procedures are much the same. However, there are peculiarities of the electron-diffraction case which should be noted.

(1) Structure analysis based on electron diffraction is possible for thin specimens for which the conditions for kinematical scattering are approached, *e.g.* for thin mosaic single-crystal specimens, for thin polycrystalline films having a preferred orientation of very small crystallites or for very extensive, very thin single crystals of biological molecules such as membranes one or a few molecules thick.

(2) Dynamical diffraction effects are used explicitly in the determination of crystal symmetry (with no Friedel's law limitations) and for the measurement of structure amplitudes with high accuracy.

(3) For many radiation-resistant materials, the structures of crystals and of some molecules may be determined directly by imaging atom positions in projections of the crystal with a resolution of 2 Å or better. The information on atom positions is not dependent on the periodicity of the crystal and so it is equally possible to determine the structures of individual crystal defects in favourable cases.

(4) Techniques of microanalysis may be applied to the determination of the chemical composition of regions of diameter 100 Å or less using the same instrument as for diffraction, so that the chemical information may be correlated directly with morphological and structural information.

(5) Crystal-structure information may be derived from regions containing as few as 10^2 or 10^3 atoms, including very small crystals and single or multiple layers of atoms on surfaces.

The material of this section is also reviewed in the text by Spence (2003).

2.5.2.2. The interactions of electrons with matter

(1) The *elastic* scattering of electrons results from the interaction of the charged electrons with the electrostatic potential distribution, $\varphi(\mathbf{r})$, of the atoms or crystals. An incident electron of kinetic energy eW gains energy $e\varphi(\mathbf{r})$ in the potential field. Alternatively it may be stated that an incident electron wave of

[1] Questions related to this section may be addressed to Professor J. C. H. Spence (see list of contributing authors).

wavelength $\lambda = h/mv$ is diffracted by a region of variable refractive index

$$n(\mathbf{r}) = k/K_0 = \{[W + \varphi(\mathbf{r})]/W\}^{1/2} \simeq 1 + \varphi(\mathbf{r})/2W.$$

(2) The most important *inelastic* scattering processes are:

(*a*) thermal diffuse scattering, with energy losses of the order of 2×10^{-2} eV, separable from the elastic scattering only with specially devised equipment; the angular distribution of thermal diffuse scattering shows variations with $(\sin\theta)/\lambda$ which are much the same as for the X-ray case in the kinematical limit;

(*b*) bulk plasmon excitation, or the excitation of collective energy states of the conduction electrons, giving energy losses of 3 to 30 eV and an angular range of scattering of 10^{-4} to 10^{-3} rad;

(*c*) surface plasmons, or the excitation of collective energy states of the conduction electrons at discontinuities of the structure, with energy losses less than those for bulk plasmons and a similar angular range of scattering;

(*d*) interband or intraband excitation of valence-shell electrons giving energy losses in the range of 1 to 10^2 eV and an angular range of scattering of 10^{-4} to 10^{-2} rad;

(*e*) inner-shell excitations, with energy losses of 10^2 eV or more and an angular range of scattering of 10^{-3} to 10^{-2} rad, depending on the energy losses involved.

(3) In the original treatment by Bethe (1928) of the elastic scattering of electrons by crystals, the Schrödinger equation is written for electrons in the periodic potential of the crystal; *i.e.*

$$\nabla^2\psi(\mathbf{r}) + K_0^2[1 + \varphi(\mathbf{r})/W]\psi(\mathbf{r}) = 0, \tag{2.5.2.1}$$

where

$$\begin{aligned}\varphi(\mathbf{r}) &= \int V(\mathbf{u}) \exp\{-2\pi i\mathbf{u}\cdot\mathbf{r}\}\,\mathrm{d}\mathbf{u} \\ &= \sum_{\mathbf{h}} V_{\mathbf{h}} \exp\{-2\pi i\mathbf{h}\cdot\mathbf{r}\},\end{aligned} \tag{2.5.2.2}$$

$\mathbf{K}_0$ is the wavevector in zero potential (outside the crystal) (magnitude $2\pi/\lambda$) and W is the accelerating voltage. The solutions of the equation are Bloch waves of the form

$$\psi(\mathbf{r}) = \sum_{\mathbf{h}} C_{\mathbf{h}}(\mathbf{k}) \exp\{-i(\mathbf{k}_0 + 2\pi\mathbf{h})\cdot\mathbf{r}\}, \tag{2.5.2.3}$$

where $\mathbf{k}_0$ is the incident wavevector in the crystal and $\mathbf{h}$ is a reciprocal-lattice vector. Substitution of (2.5.2.2) and (2.5.2.3) in (2.5.2.1) gives the dispersion equations

$$(\kappa^2 - k_{\mathbf{h}}^2)C_{\mathbf{h}} + \sum_{\mathbf{g}}{}' V_{\mathbf{h}-\mathbf{g}}C_{\mathbf{g}} = 0. \tag{2.5.2.4}$$

Here κ is the magnitude of the wavevector in a medium of constant potential V_0 (the 'inner potential' of the crystal). The refractive index of the electron in the average crystal potential is then

$$n = \kappa/K = (1 + V_0/W)^{1/2} \simeq 1 + V_0/2W. \tag{2.5.2.5}$$

Since V_0 is positive and of the order of 10 V and W is 10^4 to 10^6 V, $n - 1$ is positive and of the order of 10^{-4}.

Solution of equation (2.5.2.4) gives the Fourier coefficients $C_{\mathbf{h}}^{(i)}$ of the Bloch waves $\psi^{(i)}(\mathbf{r})$ and application of the boundary conditions gives the amplitudes of individual Bloch waves (see Chapter 5.2).

(4) The experimentally important case of transmission of high-energy electrons through thin specimens is treated on the assumption of a plane wave incident in a direction almost perpendicular to an infinitely extended plane-parallel lamellar crystal, making use of the *small-angle scattering approximation* in which the forward-scattered wave is represented in the paraboloidal approximation to the sphere. The incident-beam direction, assumed to be almost parallel to the z axis, is unique and the z component of $\mathbf{k}$ is factored out to give

$$\nabla^2\psi + 2k\sigma\varphi\psi = \pm i2k\frac{\partial\psi}{\partial z}, \tag{2.5.2.6}$$

where $k = 2\pi/\lambda$ and $\sigma = 2\pi me\lambda/h^2$. [See Lynch & Moodie (1972), Portier & Gratias (1981), Tournarie (1962), and Chapter 5.2.]

This equation is analogous to the time-dependent Schrödinger equation with z replacing t. Retention of the $\pm$ signs on the right-hand side is consistent with both ψ and ψ^* being solutions, corresponding to propagation in opposite directions with respect to the z axis. The double-valued solution is of importance in consideration of reciprocity relationships which provide the basis for the description of some dynamical diffraction symmetries. (See Section 2.5.3.)

(5) The integral form of the wave equation, commonly used for scattering problems, is written, for electron scattering, as

$$\psi(\mathbf{r}) = \psi^{(0)}(\mathbf{r}) + (\sigma/\lambda)\int \frac{\exp\{-i\mathbf{k}|\mathbf{r} - \mathbf{r}'|\}}{|\mathbf{r} - \mathbf{r}'|}\varphi(\mathbf{r}')\psi(\mathbf{r}')\,\mathrm{d}\mathbf{r}'. \tag{2.5.2.7}$$

The wavefunction $\psi(\mathbf{r})$ within the integral is approximated by using successive terms of a Born series

$$\psi(\mathbf{r}) = \psi^{(0)}(\mathbf{r}) + \psi^{(1)}(\mathbf{r}) + \psi^{(2)}(\mathbf{r}) + \ldots. \tag{2.5.2.8}$$

The first Born approximation is obtained by putting $\psi(\mathbf{r}) = \psi^{(0)}(\mathbf{r})$ in the integral and subsequent terms $\psi^{(n)}(\mathbf{r})$ are generated by putting $\psi^{(n-1)}(\mathbf{r})$ in the integral.

For an incident plane wave, $\psi^{(0)}(\mathbf{r}) = \exp\{-i\mathbf{k}_0\cdot\mathbf{r}\}$ and for a point of observation at a large distance $\mathbf{R} = \mathbf{r} - \mathbf{r}'$ from the scattering object ($|\mathbf{R}| \gg |\mathbf{r}'|$), the first Born approximation is generated as

$$\psi^{(1)}(\mathbf{r}) = \frac{i\sigma}{\lambda R}\exp\{-i\mathbf{k}\cdot\mathbf{R}\}\int \varphi(\mathbf{r}')\exp\{i\mathbf{q}\cdot\mathbf{r}'\}\,\mathrm{d}\mathbf{r}',$$

where $\mathbf{q} = \mathbf{k} - \mathbf{k}_0$ or, putting $\mathbf{u} = \mathbf{q}/2\pi$ and collecting the pre-integral terms into a parameter μ,

$$\Psi(\mathbf{u}) = \mu\int \varphi(\mathbf{r})\exp\{2\pi i\mathbf{u}\cdot\mathbf{r}\}\,\mathrm{d}\mathbf{r}. \tag{2.5.2.9}$$

This is the Fourier-transform expression which is the basis for the *kinematical scattering approximation*. It is derived on the basis that all $\psi^{(n)}(\mathbf{r})$ terms for $n \neq 0$ are very much smaller than $\psi^{(0)}(\mathbf{r})$ and so is a weak scattering approximation.

In this approximation, the scattered amplitude for an atom is related to the atomic structure amplitude, $f(\mathbf{u})$, by the relationship, derived from (2.5.2.8),

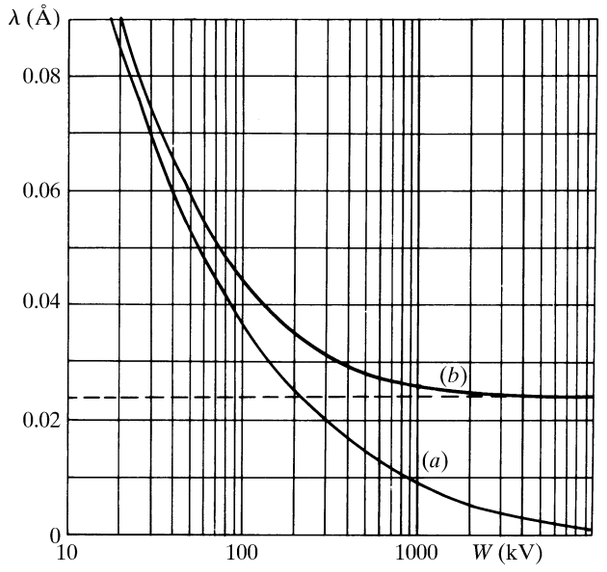

Fig. 2.5.2.1. The variation with accelerating voltage of electrons of (*a*) the wavelength, λ and (*b*) the quantity $\lambda[1 + (h^2/m_0^2c^2\lambda^2)] = \lambda_c/\beta$ which is proportional to the interaction constant σ [equation (2.5.2.14)]. The limit is the Compton wavelength λ_c (after Fujiwara, 1961).

$$\psi(\mathbf{r}) = \exp\{-i\mathbf{k}_0 \cdot \mathbf{r}\} + i\frac{\exp\{-i\mathbf{k} \cdot \mathbf{r}\}}{R\lambda}\sigma f(\mathbf{u}),$$
$$f(\mathbf{u}) = \int \varphi(\mathbf{r}) \exp\{2\pi i\mathbf{u} \cdot \mathbf{r}\}\, \mathrm{d}\mathbf{r}. \qquad (2.5.2.10)$$

For centrosymmetrical atom potential distributions, the $f(\mathbf{u})$ are real, positive and monotonically decreasing with $|\mathbf{u}|$. A measure of the extent of the validity of the first Born approximation is given by the fact that the effect of adding the higher-order terms of the Born series may be represented by replacing $f(\mathbf{u})$ in (2.5.2.10) by the complex quantities $f(\mathbf{u}) = |\mathbf{f}| \exp\{i\eta(\mathbf{u})\}$ and for single heavy atoms the phase factor η may vary from 0.2 for $|\mathbf{u}| = 0$ to 4 or 5 for large $|\mathbf{u}|$, as seen from the tables of *IT* C (2004, Section 4.3.3).

(6) Relativistic effects produce appreciable variations of the parameters used above for the range of electron energies considered. The relativistic values are

$$m = m_0(1 - v^2/c^2)^{-1/2} = m_0(1 - \beta^2)^{-1/2}, \qquad (2.5.2.11)$$
$$\lambda = h[2m_0|e|W(1 + |e|W/2m_0c^2)]^{-1/2} \qquad (2.5.2.12)$$
$$= \lambda_c(1 - \beta^2)^{1/2}/\beta, \qquad (2.5.2.13)$$

where λ_c is the Compton wavelength, $\lambda_c = h/m_0c = 0.0242$ Å, and

$$\sigma = 2\pi me\lambda/h^2 = (2\pi m_0 e/h^2)(\lambda_c/\beta)$$
$$= 2\pi/\{\lambda W[1 + (1 - \beta^2)^{1/2}]\}. \qquad (2.5.2.14)$$

Values for these quantities are listed in *IT* C (2004, Section 4.3.2). The variations of λ and σ with accelerating voltage are illustrated in Fig. 2.5.2.1. For high voltages, σ tends to a constant value, $2\pi m_0 e\lambda_c/h^2 = e/\hbar c$.

2.5.2.3. Recommended sign conventions

There are two alternative sets of signs for the functions describing wave optics. Both sets have been widely used in the literature. There is, however, a requirement for internal consistency within a particular analysis, independently of which set is adopted. Unfortunately, this requirement has not always been met and, in fact, it is only too easy at the outset of an analysis to make errors in this way. This problem might have come into prominence somewhat earlier were it not for the fact that, for centrosymmetric crystals (or indeed for centrosymmetric projections in the case of planar diffraction), only the signs used in the transmission and propagation functions can affect the results. It is not until the origin is set away from a centre of symmetry that there is a need to be consistent in every sign used.

Signs for electron diffraction have been chosen from two points of view: (1) defining as positive the sign of the exponent in the structure-factor expression and (2) defining the forward propagating free-space wavefunction with a positive exponent.

The second of these alternatives is the one which has been adopted in most solid-state and quantum-mechanical texts.

The first, or *standard crystallographic* convention, is the one which could most easily be adopted by crystallographers accustomed to retaining a positive exponent in the structure-factor equation. This also represents a consistent *International Tables* usage. It is, however, realized that both conventions will continue to be used in crystallographic computations, and that there are by now a large number of operational programs in use.

It is therefore recommended (*a*) that a particular sign usage be indicated as either *standard crystallographic* or *alternative crystallographic* to accord with Table 2.5.2.1, whenever there is a need for this to be explicit in publication, and (*b*) that either one or other of these systems be adhered to throughout an analysis in a self-consistent way, even in those cases where, as indicated above, some of the signs appear to have no effect on one particular conclusion.

2.5.2.4. Scattering of electrons by crystals; approximations

The forward-scattering approximation to the many-beam dynamical diffraction theory outlined in Chapter 5.2 provides the basis for the calculation of diffraction intensities and electron-microscope image contrast for thin crystals. [See Cowley (1995), Chapter 5.2 and *IT* C (2004) Sections 4.3.6 and 4.3.8.] On the other hand, there are various approximations which provide relatively simple analytical expressions, are useful for the determination of diffraction geometry, and allow estimates to be made of the relative intensities in diffraction patterns and electron micrographs in favourable cases.

(*a*) *The kinematical approximation*, derived in Section 2.5.2.2 from the first Born approximation, is analagous to the corresponding approximation of X-ray diffraction. It assumes that the scattering amplitudes are directly proportional to the three-dimensional Fourier transform of the potential distribution, $\varphi(\mathbf{r})$.

$$V(\mathbf{u}) = \int \varphi(\mathbf{r}) \exp\{2\pi i\mathbf{u} \cdot \mathbf{r}\}\, \mathrm{d}\mathbf{r}, \qquad (2.5.2.15)$$

so that the potential distribution $\varphi(\mathbf{r})$ takes the place of the charge-density distribution, $\rho(\mathbf{r})$, relevant for X-ray scattering.

The validity of the kinematical approximation as a basis for structure analysis is severely limited. For light-atom materials, such as organic compounds, it has been shown by Jap & Glaeser (1980) that the thickness for which the approximation gives reasonable accuracy for zone-axis patterns from single crystals is of the order of 100 Å for 100 keV electrons and increases, approximately as σ^{-1}, for higher energies. The thickness limits quoted for polycrystalline samples, having crystallite dimensions smaller than the sample thickness, are usually greater (Vainshtein, 1956). For heavy-atom materials the approximation is more limited since it may fail significantly for single heavy atoms.

(*b*) *The phase-object approximation* (POA), or high-voltage limit, is derived from the general many-beam dynamical

Table 2.5.2.1. *Standard crystallographic and alternative crystallographic sign conventions for electron diffraction*

	Standard	Alternative
Free-space wave	$\exp[-i(\mathbf{k}\cdot\mathbf{r}-\omega t)]$	$\exp[+i(\mathbf{k}\cdot\mathbf{r}-\omega t)]$
Fourier transforming from real space to reciprocal space	$\int \psi(\mathbf{r})\exp[+2\pi i(\mathbf{u}\cdot\mathbf{r})]\,\mathrm{d}\mathbf{r}$	$\int \psi(\mathbf{r})\exp[-2\pi i(\mathbf{u}\cdot\mathbf{r})]\,\mathrm{d}\mathbf{r}$
Fourier transforming from reciprocal space to real space	$\psi(\mathbf{r}) = \int \Psi(\mathbf{u})\exp[-2\pi i(\mathbf{u}\cdot\mathbf{r})]\,\mathrm{d}\mathbf{u}$	$\int \Psi(\mathbf{u})\exp[+2\pi i(\mathbf{u}\cdot\mathbf{r})]\,\mathrm{d}\mathbf{u}$
Structure factors	$V(\mathbf{h}) = (1/\Omega)\sum_j f_j(\mathbf{h})\exp(+2\pi i\mathbf{h}\cdot\mathbf{r}_j)$	$(1/\Omega)\sum_j f_j(\mathbf{h})\exp(-2\pi i\mathbf{h}\cdot\mathbf{r}_j)$
Transmission function (real space)	$\exp[-i\sigma\varphi(x,y)\Delta z]$	$\exp[+i\sigma\varphi(x,y)\Delta z]$
Phenomenological absorption	$\sigma\varphi(\mathbf{r}) - i\mu(\mathbf{r})$	$\sigma\varphi(\mathbf{r}) + i\mu(\mathbf{r})$
Propagation function $P(h)$ (reciprocal space) within the crystal	$\exp(-2\pi i\zeta_{\mathbf{h}}\Delta z)$	$\exp(+2\pi i\zeta_{\mathbf{h}}\Delta z)$
Iteration (reciprocal space)	$\Psi_{n+1}(\mathbf{h}) = [\Psi_n(\mathbf{h})\cdot P(\mathbf{h})] * Q(\mathbf{h})$	
Unitarity test (for no absorption)	$T(\mathbf{h}) = Q(\mathbf{h}) * Q^*(-\mathbf{h}) = \delta(\mathbf{h})$	
Propagation to the image plane-wave aberration function, where $\chi(U) = \pi\lambda\Delta f U^2 + \frac{1}{2}\pi C_s\lambda^3 U^4$, $U^2 = u^2 + v^2$ and Δf is positive for overfocus	$\exp[i\chi(U)]$	$\exp[-i\chi(U)]$

σ = electron interaction constant $= 2\pi me\lambda/h^2$; m = (relativistic) electron mass; λ = electron wavelength; e = (magnitude of) electron charge; h = Planck's constant; $k = 2\pi/\lambda$; Ω = volume of the unit cell; $\mathbf{u}$ = continuous reciprocal-space vector, components u, v; $\mathbf{h}$ = discrete reciprocal-space coordinate; $\varphi(x, y)$ = crystal potential averaged along beam direction (positive); Δz = slice thickness; $\mu(\mathbf{r})$ = absorption potential [positive; typically $\leq 0.1\sigma\varphi(\mathbf{r})$]; Δf = defocus (defined as negative for underfocus); C_s = spherical aberration coefficient; $\zeta_{\mathbf{h}}$ = excitation error relative to the incident-beam direction and defined as negative when the point h lies outside the Ewald sphere; $f_j(\mathbf{h})$ = atomic scattering factor for electrons, f_e, related to the atomic scattering factor for X-rays, f_X, by the Mott formula $f_e = (e/\pi U^2)(Z - f_X)$. $Q(\mathbf{h})$ = Fourier transform of periodic slice transmission function.

diffraction expression, equation (5.2.13.1), Chapter 5.2, by assuming the Ewald sphere curvature to approach zero. Then the scattering by a thin sample can be expressed by multiplying the incoming wave amplitude by the transmission function

$$q(xy) = \exp\{-i\sigma\varphi(xy)\}, \tag{2.5.2.16}$$

where $\varphi(xy) = \int \varphi(\mathbf{r})\,\mathrm{d}z$ is the projection of the potential distribution of the sample in the z direction, the direction of the incident beam. The diffraction-pattern amplitudes are then given by two-dimensional Fourier transform of (2.5.2.16).

This approximation is of particular value in relation to the electron microscopy of thin crystals. The thickness for its validity for 100 keV electrons is within the range 10 to 50 Å, depending on the accuracy and spatial resolution involved, and increases with accelerating voltage approximately as $\lambda^{-1/2}$. In computational work, it provides the starting point for the multislice method of dynamical diffraction calculations (*IT* C, 2004, Section 4.3.6.1).

(*c*) *The two-beam approximation* for dynamical diffraction of electrons assumes that only two beams, the incident beam and one diffracted beam (or two Bloch waves, each with two component amplitudes), exist in the crystal. This approximation has been adapted, notably by Hirsch *et al.* (1965), for use in the electron microscopy of inorganic materials.

It forms a convenient basis for the study of defects in crystals having small unit cells (metals, semiconductors *etc.*) and provides good preliminary estimates for the determination of crystal thicknesses and structure amplitudes for orientations well removed from principal axes, and for electron energies up to 200–500 keV, but it has decreasing validity, even for favourable cases, for higher energies. It has been used in the past as an 'extinction correction' for powder-pattern intensities (Vainshtein, 1956).

(*d*) *The Bethe second approximation*, proposed by Bethe (1928) as a means for correcting the two-beam approximation for the effects of weakly excited beams, replaces the Fourier coefficients of potential by the 'Bethe potentials'

$$U_{\mathbf{h}} = V_{\mathbf{h}} - 2k_0\sigma\sum_{\mathbf{g}}\frac{V_{\mathbf{g}}\cdot V_{\mathbf{h}-\mathbf{g}}}{\kappa^2 - k_{\mathbf{g}}^2}. \tag{2.5.2.17}$$

Use of these potentials has been shown to account well for the deviations of powder-pattern intensities from the predictions of two-beam theory (Horstmann & Meyer, 1965) and to predict accurately the extinctions of Kikuchi lines at particular accelerating voltages due to relativistic effects (Watanabe *et al.*, 1968), but they give incorrect results for the small-thickness limit.

2.5.2.5. Kinematical diffraction formulae

(1) *Comparison with X-ray diffraction.* The relations of real-space and reciprocal-space functions are analogous to those for X-ray diffraction [see equations (2.5.2.2), (2.5.2.10) and (2.5.2.15)]. For diffraction by crystals

$$\varphi(\mathbf{r}) = \sum_{\mathbf{h}} V_{\mathbf{h}}\exp\{-2\pi i\mathbf{h}\cdot\mathbf{r}\},$$

$$V_{\mathbf{h}} = \int \varphi(\mathbf{r})\exp\{2\varphi i\mathbf{h}\cdot\mathbf{r}\}\,\mathrm{d}\mathbf{r} \tag{2.5.2.18}$$

$$= \frac{1}{\Omega}\sum_i f_i(\mathbf{h})\exp\{2\pi i\mathbf{h}\cdot\mathbf{r}_i\}, \tag{2.5.2.19}$$

where the integral of (2.5.2.18) and the summation of (2.5.2.19) are taken over one unit cell of volume (see Dawson *et al.*, 1974).

Important differences from the X-ray case arise because

(*a*) the wavelength is relatively small so that the Ewald-sphere curvature is small in the reciprocal-space region of appreciable scattering amplitude;

(*b*) the dimensions of the single-crystal regions giving appreciable scattering amplitudes are small so that the 'shape transform' regions of scattering power around the reciprocal-lattice points are relatively large;

(*c*) the spread of wavelengths is small (10^{-5} or less, with no white-radiation background) and the degree of collimation is better (10^{-4} to 10^{-6}) than for conventional X-ray sources.

As a consequence of these factors, single-crystal diffraction patterns may show many simultaneous reflections, representing almost-planar sections of reciprocal space, and may show fine structure or intensity variations reflecting the crystal dimensions and shape.

(2) Kinematical diffraction-pattern intensities are calculated in a manner analogous to that for X-rays except that

(*a*) no polarization factor is included because of the small-angle scattering conditions;

(*b*) integration over regions of scattering power around reciprocal-lattice points cannot be assumed unless appropriate experimental conditions are ensured.

For a thin, flat, lamellar crystal of thickness H, the observed intensity is

$$I_{\mathbf{h}}/I_{\mathbf{0}} = |\sigma(V_{\mathbf{h}}/\Omega)(\sin \pi\zeta_{\mathbf{h}} H)/(\pi\zeta_{\mathbf{h}})|^2, \tag{2.5.2.20}$$

where $\zeta_{\mathbf{h}}$ is the excitation error for the $\mathbf{h}$ reflection and Ω is the unit-cell volume.

For a single-crystal diffraction pattern obtained by rotating a crystal or from a uniformly bent crystal or for a mosaic crystal with a uniform distribution of orientations, the intensity is

$$I_{\mathbf{h}} = I_{\mathbf{0}} \frac{\sigma^2 |V_{\mathbf{h}}|^2 V_{\mathrm{c}} d_{\mathbf{h}}}{4\pi^2 \Omega^2}, \tag{2.5.2.21}$$

where V_{c} is the crystal volume and $d_{\mathbf{h}}$ is the lattice-plane spacing. For a polycrystalline sample of randomly oriented small crystals, the intensity per unit length of the diffraction ring is

$$I_{\mathbf{h}} = I_{\mathbf{0}} \frac{\sigma^2 |V_{\mathbf{h}}|^2 V_{\mathrm{c}} d_{\mathbf{h}}^2 M_{\mathbf{h}}}{8\pi^2 \Omega^2 L\lambda}, \tag{2.5.2.22}$$

where $M_{\mathbf{h}}$ is the multiplicity factor for the $\mathbf{h}$ reflection and L is the camera length, or the distance from the specimen to the detector plane. The special cases of 'oblique texture' patterns from powder patterns having preferred orientations are treated in *IT* C (2004, Section 4.3.5).

(3) *Two-beam dynamical diffraction formulae: complex potentials including absorption.* In the two-beam dynamical diffraction approximation, the intensities of the directly transmitted and diffracted beams for transmission through a crystal of thickness H, in the absence of absorption, are

$$I_{\mathbf{0}} = (1 + w^2)^{-1} \left[w^2 + \cos^2 \left\{ \frac{\pi H (1 + w^2)^{1/2}}{\xi_{\mathbf{h}}} \right\} \right] \tag{2.5.2.23}$$

$$I_{\mathbf{h}} = (1 + w^2)^{-1} \sin^2 \left\{ \frac{\pi H (1 + w^2)^{1/2}}{\xi_{\mathbf{h}}} \right\}, \tag{2.5.2.24}$$

where $\xi_{\mathbf{h}}$ is the extinction distance, $\xi_{\mathbf{h}} = (2\sigma|V_{\mathbf{h}}|)^{-1}$, and

$$w = \xi_{\mathbf{h}} \zeta_{\mathbf{h}} = \Delta\theta/(2\sigma|V_{\mathbf{h}}|d_{\mathbf{h}}), \tag{2.5.2.25}$$

where $\Delta\theta$ is the deviation from the Bragg angle.

For the case that $\zeta_{\mathbf{h}} = 0$, with the incident beam at the Bragg angle, this reduces to the simple *Pendellösung* expression

$$I_{\mathbf{h}} = 1 - I_{\mathbf{0}} = \sin^2\{2\pi\sigma|V_{\mathbf{h}}|H\}. \tag{2.5.2.26}$$

The effects on the elastic Bragg scattering amplitudes of the inelastic or diffuse scattering may be introduced by adding an out-of-phase component to the structure amplitudes, so that for a centrosymmetric crystal, $V_{\mathbf{h}}$ becomes complex by addition of an imaginary component. Alternatively, an absorption function $\mu(\mathbf{r})$, having Fourier coefficients $\mu_{\mathbf{h}}$, may be postulated so that $\sigma V_{\mathbf{h}}$ is replaced by $\sigma V_{\mathbf{h}} + i\mu_{\mathbf{h}}$. The $\mu_{\mathbf{h}}$ are known as phenomenological absorption coefficients and their validity in many-beam diffraction has been demonstrated by, for example, Rez (1978).

The magnitudes $\mu_{\mathbf{h}}$ depend on the nature of the experiment and the extent to which the various inelastically or diffusely scattered electrons are included in the measurements being made. If measurements are made of purely elastic scattering intensities for Bragg reflections or of image intensity variations due to the interaction of the sharp Bragg reflections only, the main contributions to the absorption coefficients are as follows (Radi, 1970):

(*a*) from plasmon and single-electron excitations, $\mu_{\mathbf{0}}$ is of the order of 0.1 $V_{\mathbf{0}}$ and $\mu_{\mathbf{h}}$, for $\mathbf{h} \neq 0$, is negligibly small;

(*b*) from thermal diffuse scattering; $\mu_{\mathbf{h}}$ is of the order of 0.1 $V_{\mathbf{h}}$ and decreasing more slowly than $V_{\mathbf{h}}$ with scattering angle.

Including absorption effects in (2.5.2.26) for the case $\zeta_{\mathbf{h}} = 0$ gives

$$\begin{aligned} I_{\mathbf{0}} &= \tfrac{1}{2}\exp\{-\mu_{\mathbf{0}} H\}[\cosh \mu_{\mathbf{h}} H + \cos(2\pi\sigma V_{\mathbf{h}} H)], \\ I_{\mathbf{h}} &= \tfrac{1}{2}\exp\{-\mu_{\mathbf{0}} H\}[\cosh \mu_{\mathbf{h}} H - \cos(2\pi\sigma V_{\mathbf{h}} H)]. \end{aligned} \tag{2.5.2.27}$$

The Borrmann effect is not very pronounced for electrons because $\mu_{\mathbf{h}} \ll \mu_{\mathbf{0}}$, but can be important for the imaging of defects in thick crystals (Hirsch *et al.*, 1965; Hashimoto *et al.*, 1961).

Attempts to obtain analytical solutions for the dynamical diffraction equations for more than two beams have met with few successes. There are some situations of high symmetry, with incident beams in exact zone-axis orientations, for which the many-beam solution can closely approach equivalent two- or three-beam behaviour (Fukuhara, 1966). Explicit solutions for the three-beam case, which displays some aspects of many-beam character, have been obtained (Gjønnes & Høier, 1971; Hurley & Moodie, 1980).

2.5.2.6. Imaging with electrons

Electron optics. Electrons may be focused by use of axially symmetric magnetic fields produced by electromagnetic lenses. The focal length of such a lens used as a projector lens (focal points outside the lens field) is given by

$$f_{\mathrm{p}}^{-1} = \frac{e}{8mW_{\mathrm{r}}} \int_{-\infty}^{\infty} H_z^2(z)\,\mathrm{d}z, \tag{2.5.2.28}$$

where W_{r} is the relativistically corrected accelerating voltage and H_z is the z component of the magnetic field. An expression in terms of experimental constants was given by Liebman (1955) as

$$\frac{1}{f} = \frac{A_0 (NI)^2}{W_{\mathrm{r}}(S + D)}, \tag{2.5.2.29}$$

where A_0 is a constant, NI is the number of ampere turns of the lens winding, S is the length of the gap between the magnet pole pieces and D is the bore of the pole pieces.

Lenses of this type have irreducible aberrations, the most important of which for the paraxial conditions of electron microscopy is the third-order spherical aberration, coefficient C_{s}, giving a variation of focal length of $C_{\mathrm{s}}\alpha^2$ for a beam at an angle α to the axis. Chromatic aberration, coefficient C_{c}, gives a spread of focal lengths

$$\Delta f = C_{\mathrm{c}} \left(\frac{\Delta W_0}{W_0} + 2\frac{\Delta I}{I} \right) \tag{2.5.2.30}$$

for variations ΔW_0 and ΔI of the accelerating voltage and lens currents, respectively.

The objective lens of an electron microscope is the critical lens for the determination of image resolution and contrast. The action of this lens in a conventional transmission electron microscope (TEM) is described by use of the Abbe theory for coherent incident illumination transmitted through the object to produce a wavefunction $\psi_0(xy)$ (see Fig. 2.5.2.2).

The amplitude distribution in the back focal plane of the objective lens is written

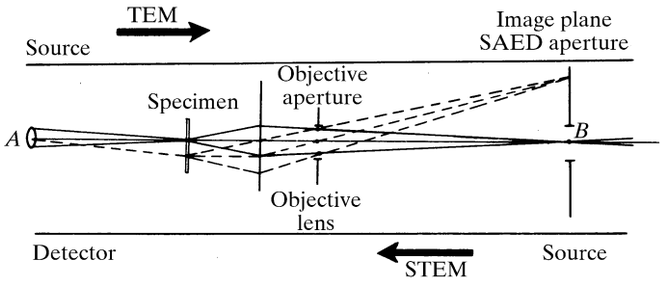

Fig. 2.5.2.2. Diagram representing the critical components of a conventional transmission electron microscope (TEM) and a scanning transmission electron microscope (STEM). For the TEM, electrons from a source A illuminate the specimen and the objective lens forms an image of the transmitted electrons on the image plane, B. For the STEM, a source at B is imaged by the objective lens to form a small probe on the specimen and some part of the transmitted beam is collected by a detector at A.

$$\Psi_0(u, v) \cdot T(u, v), \tag{2.5.2.31}$$

where $\Psi_0(u, v)$ is the Fourier transform of $\psi_0(x, y)$ and $T(u, v)$ is the transfer function of the lens, consisting of an aperture function

$$A(u, v) = \begin{cases} 1 & \text{for } (u^2 + v^2)^{1/2} \leq A \\ 0 & \text{elsewhere} \end{cases} \tag{2.5.2.32}$$

and a phase function $\exp\{i\chi(u, v)\}$ where the phase perturbation $\chi(uv)$ due to lens defocus Δf and aberrations is usually approximated as

$$\chi(uv) = \pi \cdot \Delta f \cdot \lambda(u^2 + v^2) + \frac{\pi}{2} C_s \lambda^3 (u^2 + v^2)^2, \tag{2.5.2.33}$$

and u, v are the reciprocal-space variables related to the scattering angles φ_x, φ_y by

$$u = (\sin \varphi_x)/\lambda,$$
$$v = (\sin \varphi_y)/\lambda.$$

The image amplitude distribution, referred to the object coordinates, is given by Fourier transform of (2.5.2.31) as

$$\psi(xy) = \psi_0(xy) * t(xy), \tag{2.5.2.34}$$

where $t(xy)$, given by Fourier transform of $T(u, v)$, is the spread function. The image intensity is then

$$I(xy) = |\psi(xy)|^2 = |\psi_0(xy) * t(xy)|^2. \tag{2.5.2.35}$$

In practice the coherent imaging theory provides a good approximation but limitations of the coherence of the illumination have appreciable effects under high-resolution imaging conditions.

The variation of focal lengths according to (2.5.2.30) is described by a function $G(\Delta f)$. Illumination from a finite incoherent source gives a distribution of incident-beam angles $H(u_1, v_1)$. Then the image intensity is found by integrating incoherently over Δf and u_1, v_1:

$$I(xy) = \int\int G(\Delta f) \cdot H(u_1 v_1) \times |\mathscr{F}\{\Psi_0(u - u_1, v - v_1) \cdot T_{\Delta f}(u, v)\}|^2 \, \mathrm{d}(\Delta f) \cdot \mathrm{d}u_1 \, \mathrm{d}v_1, \tag{2.5.2.36}$$

where $\mathscr{F}$ denotes the Fourier-transform operation.

In the scanning transmission electron microscope (STEM), the objective lens focuses a small bright source of electrons on the object and directly transmitted or scattered electrons are detected to form an image as the incident beam is scanned over the object (see Fig. 2.5.2.2). Ideally the image amplitude can be related to that of the conventional transmission electron microscope by use of the 'reciprocity relationship' which refers to point sources and detectors for scalar radiation in scalar fields with elastic scattering processes only. It may be stated: 'The amplitude at a point B due to a point source at A is identical to that which would be produced at A for the identical source placed at B'.

For an axial point source, the amplitude distribution produced by the objective lens on the specimen is

$$\mathscr{F}[T(u, v)] = t(xy). \tag{2.5.2.37}$$

If this is translated by the scan to X, Y, the transmitted wave is

$$\psi_0(xy) = q(xy) \cdot t(x - X, y - Y). \tag{2.5.2.38}$$

The amplitude on the plane of observation following the specimen is then

$$\Psi(uv) = Q(u, v) * \{T(uv) \exp[2\pi i(uX + vY)]\}, \tag{2.5.2.39}$$

and the image signal produced by a detector having a sensitivity function $H(u, v)$ is

$$I(X, Y) = \int H(u, v) |Q(u, v) * T(u, v) \times \exp\{2\pi i(uX + vY)\}|^2 \, \mathrm{d}u \, \mathrm{d}v. \tag{2.5.2.40}$$

If $H(u, v)$ represents a small detector, approximated by a delta function, this becomes

$$I(x, y) = |q(xy) * t(xy)|^2, \tag{2.5.2.41}$$

which is identical to the result (2.5.2.35) for a plane incident wave in the conventional transmission electron microscope.

2.5.2.7. Imaging of very thin and weakly scattering objects

(*a*) *The weak-phase-object approximation.* For sufficiently thin objects, the effect of the object on the incident-beam amplitude may be represented by the transmission function (2.5.2.16) given by the phase-object approximation. If the fluctuations, $\varphi(xy) - \bar{\varphi}$, about the mean value of the projected potential are sufficiently small so that $\sigma[\varphi(xy) - \bar{\varphi}] \ll 1$, it is possible to use the *weak-phase-object approximation* (WPOA)

$$q(xy) = \exp\{-i\sigma\varphi(xy)\} = 1 - i\sigma\varphi(xy), \tag{2.5.2.42}$$

where $\varphi(xy)$ is referred to the average value, $\bar{\varphi}$. The assumption that only first-order terms in $\sigma\varphi(xy)$ need be considered is the equivalent of a single-scattering, or kinematical, approximation applied to the two-dimensional function, the projected potential

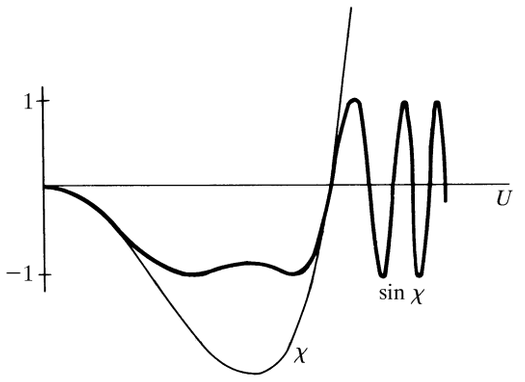

Fig. 2.5.2.3. The functions $\chi(U)$, the phase factor for the transfer function of a lens given by equation (2.5.2.33), and $\sin\chi(U)$ for the Scherzer optimum defocus condition, relevant for weak phase objects, for which the minimum value of $\chi(U)$ is $-2\pi/3$.

of (2.5.2.16). From (2.5.2.42), the image intensity (2.5.2.35) becomes

$$I(xy) = 1 + 2\sigma\varphi(xy) * s(xy), \tag{2.5.2.43}$$

where the spread function $s(xy)$ is the Fourier transform of the imaginary part of $T(uv)$, namely $A(uv)\sin\chi(uv)$.

The optimum imaging condition is then found, following Scherzer (1949), by specifying that the defocus should be such that $|\sin\chi|$ is close to unity for as large a range of $U = (u^2 + v^2)^{1/2}$ as possible. This is so for a negative defocus such that $\chi(uv)$ decreases to a minimum of about $-2\pi/3$ before increasing to zero and higher as a result of the fourth-order term of (2.5.2.33) (see Fig. 2.5.2.3). This optimum, 'Scherzer defocus' value is given by

$$\frac{\mathrm{d}\chi}{\mathrm{d}u} = 0 \quad \text{for} \quad \chi = -2\pi/3$$

or

$$\Delta f = -\left(\tfrac{4}{3} C_\mathrm{s}\lambda\right)^{1/2}. \tag{2.5.2.44}$$

The resolution limit is then taken as corresponding to the value of $U = 1.51 C_\mathrm{s}^{-1/4}\lambda^{-3/4}$ when $\sin\chi$ becomes zero, before it begins to oscillate rapidly with U. The resolution limit is then

$$\Delta x = 0.66 C_\mathrm{s}^{1/4}\lambda^{3/4}. \tag{2.5.2.45}$$

For example, for $C_\mathrm{s} = 1$ mm and $\lambda = 2.51 \times 10^{-2}$ Å (200 keV), $\Delta x = 2.34$ Å.

Within the limits of the WPOA, the image intensity can be written simply for a number of other imaging modes in terms of the Fourier transforms $c(\mathbf{r})$ and $s(\mathbf{r})$ of the real and imaginary parts of the objective-lens transfer function $T(\mathbf{u}) = A(\mathbf{u})\exp\{i\chi(\mathbf{u})\}$, where $\mathbf{r}$ and $\mathbf{u}$ are two-dimensional vectors in real and reciprocal space, respectively.

For dark-field TEM images, obtained by introducing a central stop to block out the central beam in the diffraction pattern in the back-focal plane of the objective lens,

$$I(\mathbf{r}) = [\sigma\varphi(\mathbf{r}) * c(\mathbf{r})]^2 + [\sigma\varphi(\mathbf{r}) * s(\mathbf{r})]^2. \tag{2.5.2.46}$$

Here, as in (2.5.2.42), $\varphi(\mathbf{r})$ should be taken to imply the difference from the mean potential value, $\varphi(\mathbf{r}) - \bar{\varphi}$.

For bright-field STEM imaging with a very small detector placed axially in the central beam of the diffraction pattern (2.5.2.39) on the detector plane, the intensity, from (2.5.2.41), is given by (2.5.2.43).

For a finite axially symmetric detector, described by $D(\mathbf{u})$, the image intensity is

$$I(\mathbf{r}) = 1 + 2\sigma\varphi(\mathbf{r}) * \{s(\mathbf{r})[d(\mathbf{r}) * c(\mathbf{r})] - c(\mathbf{r})[d(\mathbf{r}) * s(\mathbf{r})]\}, \tag{2.5.2.47}$$

where $d(\mathbf{r})$ is the Fourier transform of $D(\mathbf{u})$ (Cowley & Au, 1978).

For STEM with an annular dark-field detector which collects all electrons scattered outside the central spot of the diffraction pattern in the detector plane, it can be shown that, to a good approximation (valid except near the resolution limit)

$$I(\mathbf{r}) = \sigma^2\varphi^2(\mathbf{r}) * [c^2(\mathbf{r}) + s^2(\mathbf{r})]. \tag{2.5.2.48}$$

Since $c^2(\mathbf{r}) + s^2(\mathbf{r}) = |t(\mathbf{r})|^2$ is the intensity distribution of the electron probe incident on the specimen, (2.5.2.48) is equivalent to the incoherent imaging of the function $\sigma^2\varphi^2(\mathbf{r})$.

Within the range of validity of the WPOA or, in general, whenever the zero beam of the diffraction pattern is very much stronger than any diffracted beam, the general expression (2.5.2.36) for the modifications of image intensities due to limited coherence may be conveniently approximated. The effect of integrating over the variables $\Delta f, u_1, v_1$, may be represented by multiplying the transfer function $T(u, v)$ by so-called 'envelope functions' which involve the Fourier transforms of the functions $G(\Delta f)$ and $H(u_1, v_1)$.

For example, if $G(\Delta f)$ is approximated by a Gaussian of width ε (at e^{-1} of the maximum) centred at Δf_0 and $H(u_1 v_1)$ is a circular aperture function

$$H(u_1 v_1) = \begin{cases} 1 & \text{if } u_1, v_1 < b \\ 0 & \text{otherwise,} \end{cases}$$

the transfer function $T_0(uv)$ for coherent radiation is multiplied by

$$\exp\{-\pi^2\lambda^2\varepsilon^2(u^2 + v^2)^2/4\} \cdot J_1(\pi B\eta)/(\pi B\eta)$$

where

$$\eta = f_0\lambda(u + v) + C_\mathrm{s}\lambda^3(u^3 + v^3) + \pi i\varepsilon^2\lambda^2(u^3 + u^2 v + uv^2 + v^3)/2. \tag{2.5.2.49}$$

(*b*) *The projected charge-density approximation.* For very thin specimens composed of moderately heavy atoms, the WPOA is inadequate. Within the region of validity of the phase-object approximation (POA), more complicated relations analagous to (2.5.2.43) to (2.5.2.47) may be written. A simpler expression may be obtained by use of the two-dimensional form of Poisson's equation, relating the projected potential distribution $\varphi(xy)$ to the projected charge-density distribution $\rho(xy)$. This is the PCDA (projected charge-density approximation) (Cowley & Moodie, 1960),

$$I(xy) = 1 + 2\Delta f \cdot \lambda\sigma\rho(xy). \tag{2.5.2.50}$$

This is valid for sufficiently small values of the defocus Δf, provided that the effects of the spherical aberration may be neglected, *i.e.* for image resolutions not too close to the Scherzer

resolution limit (Lynch *et al.*, 1975). The function $\rho(xy)$ includes contributions from both the positive atomic nuclei and the negative electron clouds. For underfocus (Δf negative), single atoms give dark spots in the image. The contrast reverses with defocus.

2.5.2.8. Crystal structure imaging

(*a*) *Introduction.* It follows from (2.5.2.43) and (2.5.2.42) that, within the severe limitations of validity of the WPOA or the PCDA, images of very thin crystals, viewed with the incident beam parallel to a principal axis, will show dark spots at the positions of rows of atoms parallel to the incident beam. Provided that the resolution limit is less than the projected distances between atom rows (1–3 Å), the projection of the crystal structure may be seen directly.

In practice, theoretical and experimental results suggest that images may give a direct, although nonlinear, representation of the projected potential or charge-density distribution for thicknesses much greater than the thicknesses for validity of these approximations, *e.g.* for thicknesses which may be 50 to 100 Å for 100 keV electrons for 3 Å resolutions and which increase for comparable resolutions at higher voltage but decrease with improved resolutions.

The use of high-resolution imaging as a means for determining the structures of crystals and for investigating the form of the defects in crystals in terms of the arrangement of the atoms has become a widely used and important branch of crystallography with applications in many areas of solid-state science. It must be emphasized, however, that image intensities are strongly dependent on the crystal thickness and orientation and also on the instrumental parameters (defocus, aberrations, alignment *etc.*). It is only when all of these parameters are correctly adjusted to lie within strictly defined limits that interpretation of images in terms of atom positions can be attempted [see *IT* C (2004, Section 4.3.8)].

Reliable interpretations of high-resolution images of crystals ('crystal structure images') may be made, under even the most favourable circumstances, only by the comparison of observed image intensities with intensities calculated by use of an adequate approximation to many-beam dynamical diffraction theory [see *IT* C (2004, Section 4.3.6)]. Most calculations for moderate or large unit cells are currently made by the multislice method based on formulation of the dynamical diffraction theory due to Cowley & Moodie (1957). For smaller unit cells, the matrix method based on the Bethe (1928) formulation is also frequently used (Hirsch *et al.*, 1965).

(*b*) *Fourier images.* For periodic objects in general, and crystals in particular, the amplitudes of the diffracted waves in the back focal plane are given from (2.5.2.31) by

$$\Psi_0(\mathbf{h}) \cdot T(\mathbf{h}). \qquad (2.5.2.51)$$

For rectangular unit cells of the projected unit cell, the vector $\mathbf{h}$ has components h/a and k/b. Then the set of amplitudes (2.5.2.34), and hence the image intensities, will be identical for two different sets of defocus and spherical aberration values Δf_1, C_{s1} and Δf_2, C_{s2} if, for an integer N,

$$\chi_1(h) = \chi_2(h) = 2N\pi;$$

i.e.

$$\pi\lambda\left(\frac{h^2}{a^2}+\frac{k^2}{b^2}\right)(\Delta f_1 - \Delta f_2) + \frac{1}{2}\pi\lambda^3\left(\frac{h^2}{a^2}+\frac{k^2}{b^2}\right)^2 (C_{s1} - C_{s2}) = 2\pi N.$$

This relationship is satisfied for all h, k if a^2/b^2 is an integer and

$$\Delta f_1 - \Delta f_2 = 2na^2/\lambda$$

and

$$C_{s1} - C_{s2} = 4ma^4/\lambda^3, \qquad (2.5.2.52)$$

where m, n are integers (Kuwabara, 1978). The relationship for Δf is an expression of the Fourier image phenomenon, namely that for a plane-wave incidence, the intensity distribution for the image of a periodic object repeats periodically with defocus (Cowley & Moodie, 1960). Hence it is often necessary to define the defocus value by observation of a nonperiodic component of the specimen such as a crystal edge (Spence *et al.*, 1977).

For the special case $a^2 = b^2$, the image intensity is also reproduced exactly for

$$\Delta f_1 - \Delta f_2 = (2n+1)a^2/\lambda, \qquad (2.5.2.53)$$

except that in this case the image is translated by a distance $a/2$ parallel to each of the axes.

2.5.2.9. Image resolution

(1) *Definition and measurement.* The 'resolution' of an electron microscope or, more correctly, the 'least resolvable distance', is usually defined by reference to the transfer function for the coherent imaging of a weak phase object under the Scherzer optimum defocus condition (2.5.2.44). The resolution figure is taken as the inverse of the U value for which $\sin\chi(U)$ first crosses the axis and is given, as in (2.5.2.45), by

$$\Delta x = 0.66C_s^{1/4}\lambda^{3/4}. \qquad (2.5.2.45)$$

It is assumed that an objective aperture is used to eliminate the contribution to the image for U values greater than the first zero crossing, since for these contributions the relative phases are distorted by the rapid oscillations of $\sin\chi(U)$ and the corresponding detail of the image is not directly interpretable in terms of the projection of the potential distribution of the object.

The resolution of the microscope in practice may be limited by the incoherent factors which have the effect of multiplying the WPOA transfer function by envelope functions as in (2.5.2.49).

The resolution, as defined above, and the effects of the envelope functions may be determined by Fourier transform of the image of a suitable thin, weakly scattering amorphous specimen. The Fourier-transform operation may be carried out by use of an optical diffractometer. A more satisfactory practice is to digitize the image directly by use of a two-dimensional detector system in the microscope or from a photographic recording, and perform the Fourier transform numerically.

For the optical diffractometer method, the intensity distribution obtained is given from (2.5.2.43) as a radially symmetric function of U,

$$\begin{aligned} I(U) &= |\mathscr{F} I(xy)|^2 \\ &= \delta(U) + 4\sigma^2|\Phi(u)|^2 \cdot \sin^2\chi(U) \cdot E^2(U), \end{aligned} \qquad (2.5.2.54)$$

where $E(U)$ is the product of the envelope functions.

In deriving (2.5.2.54) it has been assumed that:

(*a*) the WPOA applies;

(*b*) the optical transmission function of the photographic record is linearly related to the image intensity, $I(xy)$;

(*c*) the diffraction intensity $|\Phi(U)|^2$ is a radially symmetric, smoothly varying function such as is normally produced by a sufficiently large area of the image of an amorphous material;

(*d*) there is no astigmatism present and no drift of the specimen; either of these factors would remove the radial symmetry.

From the form of (2.5.2.54) and a preknowledge of $|\Phi(U)|^2$, the zero crossings of $\sin\chi$ and the form of $E(U)$ may be deduced. Analysis of a through-focus series of images provides more complete and reliable information.

(2) Detail on a scale much smaller than the resolution of the electron microscope, as defined above, is commonly seen in electron micrographs, especially for crystalline samples. For example, lattice fringes, having the periodicity of the crystal lattice planes, with spacings as small as 0.6 Å in one direction, have been observed using a microscope having a resolution of about 2.5 Å (Matsuda *et al.*, 1978), and two-dimensionally periodic images showing detail on the scale of 0.5 to 1 Å have been observed with a similar microscope (Hashimoto *et al.*, 1977).

Such observations are possible because

(*a*) for periodic objects the diffraction amplitude $\Psi_0(uv)$ in (2.5.2.31) is a set of delta functions which may be multiplied by the corresponding values of the transfer function that will allow strong interference effects between the diffracted beams and the zero beam, or between different diffracted beams;

(*b*) the envelope functions for the WPOA, arising from incoherent imaging effects, do not apply for strongly scattering crystals; the more general expression (2.5.2.36) provides that the incoherent imaging factors will have much less effect on the interference of some sets of diffracted beams.

The observation of finely spaced lattice fringes provides a measure of some important factors affecting the microscope performance, such as the presence of mechanical vibrations, electrical interference or thermal drift of the specimen. A measure of the fineness of the detail observable in this type of image may therefore be taken as a measure of 'instrumental resolution'.

2.5.2.10. Electron diffraction in electron microscopes

Currently most electron-diffraction patterns are obtained in conjunction with images, in electron microscopes of one form or another, as follows.

(*a*) Selected-area electron-diffraction (SAED) patterns are obtained by using intermediate and projector lenses to form an image of the diffraction pattern in the back-focal plane of the objective lens (Fig. 2.5.2.2). The area of the specimen from which the diffraction pattern is obtained is defined by inserting an aperture in the image plane of the objective lens. For parallel illumination of the specimen, sharp diffraction spots are produced by perfect crystals.

A limitation to the area of the specimen from which the diffraction pattern can be obtained is imposed by the spherical aberration of the objective lens. For a diffracted beam scattered through an angle α, the spread of positions in the object for which the diffracted beam passes through a small axial aperture in the image plane is $C_s\alpha^3$, *e.g.* for $C_s = 1$ mm, $\alpha = 5 \times 10^{-2}$ rad (10,0,0 reflection from gold for 100 keV electrons), $C_s\alpha^3 = 1250$ Å, so that a selected-area diameter of less than about 2000 Å is not feasible. For higher voltages, the minimum selected-area diameter decreases with λ^2 if the usual assumption is made that C_s increases for higher-voltage microscopes so that $C_s\lambda$ is a constant.

(*b*) Convergent-beam electron-diffraction (CBED) patterns are obtained when an incident convergent beam is focused on the specimen, as in an STEM instrument or an STEM attachment for a conventional TEM instrument.

For a large, effectively incoherent source, such as a conventional hot-filament electron gun, the intensities are added for each incident-beam direction. The resulting CBED pattern has an intensity distribution

$$I(uv) = \int |\Psi_{u_1v_1}(uv)|^2 \, \mathrm{d}u_1 \, \mathrm{d}v_1, \qquad (2.5.2.55)$$

where $\Psi_{u_1v_1}(uv)$ is the Fourier transform of the exit wave at the specimen for an incident-beam direction u_1, v_1.

(*c*) Coherent illumination from a small bright source such as a field emission gun may be focused on the specimen to give an electron probe having an intensity distribution $|t(xy)|^2$ and a diameter equal to the STEM dark-field image resolution [equation (2.5.2.47)] of a few Å. The intensity distribution of the resulting microdiffraction pattern is then

$$|\Psi(uv)|^2 = |\Psi_0(uv) * T(uv)|^2, \qquad (2.5.2.56)$$

where $\Psi_0(uv)$ is the Fourier transform of the exit wave at the specimen. Interference occurs between waves scattered from the various incident-beam directions. The diffraction pattern is thus an in-line hologram as envisaged by Gabor (1949).

(*d*) Diffraction patterns may be obtained by using an optical diffractometer (or computer) to produce the Fourier transform squared of a small selected region of a recorded image. The optical diffraction-pattern intensity obtained under the ideal conditions specified under equation (2.5.2.54) is given, in the case of weak phase objects, by

$$I(uv) = \delta(uv) + 4\sigma^2|\Phi(uv)|^2 \cdot \sin^2\chi(uv) \cdot E^2(uv) \qquad (2.5.2.57)$$

or, more generally, by

$$I(uv) = c\delta(uv) + |\Psi(uv) \cdot T(uv) * \Psi^*(uv) \cdot T^*(uv)|^2,$$

where $\Psi(uv)$ is the Fourier transform of the wavefunction at the exit face of the specimen and c is a constant depending on the characteristics of the photographic recording medium.

2.5.3. Point-group and space-group determination by convergent-beam electron diffraction

By M. Tanaka

2.5.3.1. Introduction

Because the cross section for electron scattering is at least a thousand times greater than that for X-rays, and because multiple Bragg scattering preserves information on symmetry (such as the absence of inversion symmetry), electron diffraction is exquisitely sensitive to symmetry. The additional ability of modern electron-optical lenses to focus an electron probe down to nanometre dimensions, and so allow the study of nanocrystals too small for analysis by X-rays, has meant that the method of convergent-beam diffraction described here has now become the preferred method of symmetry determination for very small crystals, domains, twinned structures, quasicrystals, incommensurate structures and other imperfectly crystalline materials.

Convergent-beam electron diffraction (CBED) originated with the experiments of Kossel & Möllenstedt (1938). However, modern crystallographic investigations by CBED began with the studies performed by Goodman & Lehmpfuhl (1965) in a modified transmission electron microscope. They obtained CBED patterns by converging a conical electron beam with an angle of more than 10^{-3} rad on an ~30 nm diameter specimen area, which had uniform thickness and no bending. Instead of the

usual diffraction spots, diffraction discs (in Laue or transmission geometry) were produced. The diffraction intensity within a disc shows a specific symmetry, which enables one to determine the point groups and space groups of microcrystals. Unlike X-ray diffraction, the method is extremely sensitive to the presence or absence of inversion symmetry.

The method corresponding to CBED in the field of light optics is the conoscope method. Using a conoscope, we can identify whether a crystal is isotropic, uniaxial or biaxial, and determine the optic axis and the sign of birefringence of a crystal. When CBED, a conoscope method using an electron beam, is utilized, more basic properties of a crystal – the crystal point group and space group – can be determined.

Point- and space-group determinations are routinely also carried out by X-ray diffraction. This method, to which kinematical diffraction is applicable, cannot determine whether a crystal is polar or nonpolar unless anomalous absorption is utilized. As a result, the X-ray diffraction method can only identify 11 Laue groups among 32 point groups. CBED, based fully upon dynamical diffraction, can distinguish polar crystals from nonpolar crystals using only a nanometre-sized crystal, thus allowing the unique identification of all the point groups by inspecting the symmetries appearing in CBED discs.

As pointed out above, an unambiguous experimental determination of crystal symmetry, in the case of X-ray diffraction, is usually not possible because of the apparent centrosymmetry of the diffraction pattern, even for noncentrosymmetric crystals. However, methods based on structure-factor and X-ray intensity statistics remain useful for the resolution of space-group ambiguities, and are routinely applied to structure determinations from X-ray data. These methods are described in Chapter 2.1 of this volume.

In the field of materials science, correct space-group determination by CBED is often requested prior to X-ray or neutron structure refinement, in particular in the case of Rietveld refinements based on powder diffraction data.

CBED can determine not only the point and space groups of crystals but also crystal structure parameters – lattice parameters, atom positions, Debye–Waller factors and low-order structure factors. The lattice parameters can be determined from submicron regions of thin crystals by using higher-order Laue zone (HOLZ) reflections with an accuracy of 1×10^{-4}. Cherns *et al.* (1988) were the first to perform strain analysis of artificial multilayer materials using the large-angle technique (LACBED) (Tanaka *et al.*, 1980). Since then, many strain measurements at interfaces of various multilayer materials have been successfully conducted. In recent years, strain analysis has been conducted using automatic analysis programs, which take account of dynamical diffraction effects (Krämer *et al.*, 2000). We refer to the book of Morniroli (2002), which carries many helpful figures, clear photographs and a comprehensive list of papers on this topic.

Vincent *et al.* (1984*a*,*b*) first applied the CBED method to the determination of the atom positions of AuGeAs. They analysed the intensities of HOLZ reflections by applying a quasi-kinematical approximation. Tanaka & Tsuda (1990, 1991) and Tsuda & Tanaka (1995) refined the structural parameters of $SrTiO_3$ by applying the dynamical theory of electron diffraction. The method was extended to the refinements of CdS, $LaCrO_3$ and hexagonal $BaTiO_3$ (Tsuda & Tanaka, 1999; Tsuda *et al.*, 2002; Ogata *et al.*, 2004). Rossouw *et al.* (1996) measured the order parameters of TiAl through a Bloch-wave analysis of HOLZ reflections in a CBED pattern. Midgley *et al.* (1996) refined two positional parameters of $AuSn_4$ from the diffraction data obtained with a small convergence angle using multislice calculations.

Low-order structure factors were first determined by Goodman & Lehmpfuhl (1967) for MgO. After much work on low-order structure-factor determination, Zuo & Spence determined the 200 and 400 structure factors of MgO in a very modern way, by fitting energy-filtered patterns and many-beam dynamical calculations using a least-squares procedure. For the low-order structure-factor determinations, the excellent comprehensive review of Spence (1993) should be referred to. Saunders *et al.* (1995) succeeded in obtaining the deformation charge density of Si using the low-order crystal structure factors determined by CBED. For the reliable determination of the low-order X-ray crystal structure factors or the charge density of a crystal, accurate determination of the Debye–Waller factors is indispensable. Zuo *et al.* (1999) determined the bond-charge distribution in cuprite. Simultaneous determination of the Debye–Waller factors and the low-order structure factors using HOLZ and zeroth-order Laue zone (ZOLZ) reflections was performed to determine the deformation charge density of $LaCrO_3$ accurately (Tsuda *et al.*, 2002).

CBED can also be applied to the determination of lattice defects, dislocations (Cherns & Preston, 1986), stacking faults (Tanaka, 1986) and twins (Tanaka, 1986). Since this topic is beyond the scope of the present chapter, readers are referred to pages 156 to 205 of the book by Tanaka *et al.* (1994).

We also mention the book by Spence & Zuo (1992), which deals with the whole topic of CBED, including the basic theory and a wealth of literature.

2.5.3.2. Point-group determination

When an electron beam traverses a thin slab of crystal parallel to a zone axis, one can easily imagine that symmetries parallel to the zone axis should appear in the resulting CBED pattern. It is, however, more difficult to imagine what symmetries appear due to symmetries perpendicular to the incident beam. Goodman (1975) pioneered the clarification of CBED symmetries for the twofold rotation axis and mirror plane perpendicular to the incident beam, and the symmetry of an inversion centre, with the help of the reciprocity theorem of scattering theory. Tinnappel (1975) solved many CBED symmetries at various crystal settings with respect to the incident beam using a group-theoretical treatment. Buxton *et al.* (1976) also derived these results from first principles, and generalized them to produce a systematic method for the determination of the crystal point group. Tanaka, Saito & Sekii (1983) developed a method to determine the point group using simultaneously excited many-beam patterns. The point-group-determination method given by Buxton *et al.* (1976) is described with the aid of the description by Tanaka, Saito & Sekii (1983) in the following.

2.5.3.2.1. Symmetry elements of a specimen and diffraction groups

Since CBED uses the Laue geometry, Buxton *et al.* (1976) assumed a perfectly crystalline specimen in the form of a parallel-sided slab which is infinite in two dimensions. The symmetry elements of the *specimen* (as distinct from those of an infinite crystal) form 'diffraction groups', which are isomorphic to the point groups of the diperiodic plane figures and Shubnikov groups of coloured plane figures. The diffraction groups of a specimen are determined from the symmetries of CBED patterns taken at various orientations of the specimen. The *crystal* point-group of the specimen is identified by referring to Fig. 2.5.3.4, which gives the relation between diffraction groups and crystal point groups.

A specimen that is parallel-sided and is infinitely extended in the x and y directions has ten symmetry elements. The symmetry elements consist of six two-dimensional symmetry elements and four three-dimensional ones. The operation of the former elements transforms an arbitrary coordinate (x, y, z) into (x', y', z), with z remaining the same. The operation of the latter transforms a coordinate (x, y, z) into (x', y', z'), where $z' \neq z$. A vertical mirror plane m and one-, two-, three-, four- and sixfold rotation axes that are parallel to the surface normal **z** are the two-

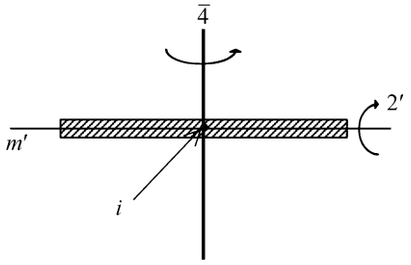

Fig. 2.5.3.1. Four symmetry elements m', i, $2'$ and $\bar{4}$ of an infinitely extended parallel-sided specimen.

m	

dimensional symmetry elements. A horizontal mirror plane m', an inversion centre i, a horizontal twofold rotation axis $2'$ and a fourfold rotary inversion $\bar{4}$ are the three-dimensional symmetry elements, and are shown in Fig. 2.5.3.1. The fourfold rotary inversion was not recognized as a symmetry element until the point groups of the diperiodic plane figures were considered (Buxton *et al*., 1976). Table 2.5.3.1 lists these symmetry elements, where the symbols in parentheses express symmetries of CBED patterns expected from three-dimensional symmetry elements.

The diffraction groups are constructed by combining these symmetry elements (Table 2.5.3.2). Two-dimensional symmetry elements and their combinations are given in the top row of the table. The third symmetry m in parentheses is introduced automatically when the first two symmetry elements are combined. Three-dimensional symmetry elements are given in the first column. The equations given below the table indicate that no additional three-dimensional symmetry elements can appear by combination of two symmetry elements in the first column. As a result, 31 diffraction groups are produced by combining the elements in the first column with those in the top row. Diffraction groups in square brackets have already appeared ealier in the table. In the fourth row, three columns have two diffraction groups, which are produced when symmetry elements are combined at different orientations. In the last row, five columns are empty because a fourfold rotary inversion cannot coexist with threefold and sixfold rotation axes. In the last column, the number of independent diffraction groups in each row is given, the sum of the numbers being 31.

2.5.3.2.2. Identification of three-dimensional symmetry elements

It is difficult to imagine the symmetries in CBED patterns generated by the three-dimensional symmetry elements of the sample. The reason is that if a three-dimensional symmetry element is applied to a specimen, it turns it upside down, which is impractical in most experiments. The reciprocity theorem of scattering theory (Pogany & Turner, 1968) enables us to clarify the symmetries of CBED patterns expected from these three-dimensional symmetry elements. A graphical method for obtaining CBED symmetries due to sample symmetry elements is described in the papers of Goodman (1975), Buxton *et al*. (1976) and Tanaka (1989). The CBED symmetries of the three-dimensional symmetries do not appear in the zone-axis patterns, but do in a diffraction disc set at the Bragg condition, each of which we call a dark-field pattern (DP). The CBED symmetries obtained are illustrated in Fig. 2.5.3.2. A horizontal twofold rotation axis $2'$, a horizontal mirror plane m', an inversion centre i and a fourfold rotary inversion $\bar{4}$ produce symmetries m_R (m_2), 1_R, 2_R and 4_R in DPs, respectively.

Next we explain the symbols of the CBED symmetries. (1) Operation m_R is shown in the left-hand part of Fig. 2.5.3.2(*a*), which implies successive operations of (*a*) a mirror m with respect to a twofold rotation axis, transforming an open circle beam (○) in reflection G into a beam (+) in reflection G' and (*b*) rotation R of this beam by π about the centre point of disc G' (or the exact Bragg position of reflection G'), resulting in position ○ in reflection G'. The combination of the two operations is written as m_R. When the twofold rotation axis is parallel to the diffraction vector **G**, two beams (○) in the left-hand part of the figure become one reflection G, and a mirror symmetry, whose mirror line is perpendicular to vector **G** and passes through the centre of disc G, appears between the two beams (the right-hand side figure of Fig. 2.5.3.2*a*). The mirror symmetry is labelled m_2 after the twofold rotation axis. (2) Operation 1_R (Fig. 2.5.3.2*b*) for a horizontal mirror plane is a combination of a rotation by 2π of a beam (○) about a zone axis O (symbol 1), which is equivalent to no rotation, and a rotation by π of the beam about the exact Bragg position or the centre of disc G. (3) Operation 2_R is a rotation by π of a beam (○) in reflection G about a zone axis (symbol 2), which transforms the beam into a beam (+) in reflection $-G$, followed by a rotation by π of the beam (+) about the centre of disc $-G$, resulting in the beam (○) in disc $-G$ (Fig. 2.5.3.2*c*). The symmetry is called translational symmetry after Goodman (1975) because the pattern of disc $+G$ coincides with that of disc $-G$ by a translation. It is emphasized that an inversion centre is identified by the test of translational symmetry about a pair of $\pm G$ dark-field patterns – if one disc can be translated into coincidence with the other, an inversion centre exists. We call the pair ±DP. (4) Operation 4_R (Fig. 2.5.3.2*d*) can be understood in a similar manner. It is noted that regular letters are symmetries about a zone axis, while subscripts R represent symmetries about the exact Bragg position. We call a pattern that contains an exact Bragg position (if possible at the disc centre) a dark-field pattern. As far as CBED symmetries are concerned, we

do not use the term dark-field pattern if a disc does not contain the exact Bragg position.

The four three-dimensional symmetry elements are found to produce different symmetries in the DPs. These facts imply that these symmetry elements can be identified unambiguously from the symmetries of CBED patterns.

2.5.3.2.3. Identification of two-dimensional symmetry elements

Two-dimensional symmetry elements that belong to a zone axis exhibit their symmetries in CBED patterns or zone-axis patterns (ZAPs) directly, even if dynamical diffraction takes place. A ZAP contains a bright-field pattern (BP) and a whole pattern (WP). The BP is the pattern appearing in the bright-field disc [the central or 'direct' (000) beam]. The WP is composed of the BP and the pattern formed by the surrounding diffraction discs, which are not exactly excited. The two-dimensional symmetry elements m, 1, 2, 3, 4 and 6 yield symmetry m_v and one-, two-, three-, four- and sixfold rotation symmetries, respectively, in WPs, where the suffix v for m_v is assigned to distinguish it from mirror symmetry m_2 caused by a horizontal twofold rotation axis.

It should be noted that a BP shows not only the zone-axis symmetry but also three-dimensional symmetries, indicating that the BP can have a higher symmetry than the symmetry of the corresponding WP. The symmetries of the BP due to three-dimensional symmetry elements are obtained by moving the DPs to the zone axis. As a result, the three-dimensional symmetry elements $m', i, 2'$ and $\bar{4}$ produce, respectively, symmetries 1_R, 1, m_2 and 4 in the BP, instead of 1_R, 2_R, m_2 and 4_R in the DPs (Fig. 2.5.3.2). We mention that the BP cannot distinguish whether a specimen crystal has an inversion centre or not, because an inversion centre forms the lowest symmetry 1 in the BP.

In conclusion, all the two-dimensional symmetry elements can be identified from the WP symmetries.

2.5.3.2.4. Diffraction-group determination

All the symmetry elements of the diffraction groups can be identified from the symmetries of a WP and DPs. But it is practical and convenient to use just the four patterns WP, BP, DP and ±DP to determine the diffraction group. The symmetries appearing in these four patterns are given for the 31 diffraction groups in Table 2.5.3.3 (Tanaka, Saito & Sekii, 1983), which is a detailed version of Table 2 of Buxton *et al.* (1976). All the possible symmetries of the DP and ±DP appearing at different crystal orientations are given in the present table. When a BP has a higher symmetry than the corresponding WP, the symmetry elements that produce the BP are given in parentheses in column II except only for the case of 4_R. When two types of vertical mirror planes exist, these are distinguished by symbols m_v and $m_{v'}$. Each of the two or three symmetries given in columns IV and V for many diffraction groups appears in a DP or ±DP in different directions.

It is emphasized again that no two diffraction groups exhibit the same combination of BP, WP, DP and ±DP, which implies that the diffraction groups are uniquely determined from an inspection of these pattern symmetries. Fig. 2.5.3.3 illustrates the symmetries of the DP and ±DP appearing in Table 2.5.3.3, which greatly eases the cumbersome task of determining the symmetries. The first four patterns illustrate the symmetries appearing in a single DP and the others treat those in ±DPs. The pattern symmetries are written beneath the figures. The other symbols are the symmetries of a specimen. The crosses outside the diffraction discs designate the zone axis. The crosses inside the diffraction discs indicate the exact Bragg position.

When the four patterns appearing in three photographs are taken and examined using Table 2.5.3.3 with the aid of Fig. 2.5.3.3, one diffraction group can be selected unambiguously. It is,

however, noted that many diffraction groups are determined from a WP and BP pair without using a DP or ±DP (or from one photograph) or from a set of a WP, a BP and a DP without using a ±DP (or from two photographs).

2.5.3.2.5. Point-group determination

Fig. 2.5.3.4 provides the relationship between the 31 diffraction groups for slabs and the 32 point groups for infinite crystals given by Buxton *et al.* (1976). When a diffraction group is determined, possible point groups are selected by consulting this figure. Each of the 11 high-symmetry diffraction groups corresponds to only one crystal point group. In this case, the point group is uniquely determined from the diffraction group. When more than one point group falls under a diffraction group, a different diffraction group has to be obtained for another zone axis. A point group is identified by finding a common point group among the point groups obtained for different zone axes. It is clear from the figure that high-symmetry zones should be used for quick determination of point groups because low-symmetry zone axes exhibit only a small portion of crystal symmetries in the CBED patterns. Furthermore, it should be noted that CBED cannot observe crystal symmetries oblique to an incident beam or horizontal three-, four- or sixfold rotation axes. The diffraction groups to be expected for different zone axes are given for all the point groups in Table 2.5.3.4 (Buxton *et al.*, 1976). The table is useful for finding a suitable zone axis to distinguish candidate point groups expected in advance.

We shall explain the point-group determination procedure using an Si crystal. Fig. 2.5.3.5(*a*) shows a [111] ZAP of the Si specimen. The BP has threefold rotation symmetry and mirror symmetry or symmetry $3m_v$, which are caused by the threefold rotation axis along the [111] direction and a vertical mirror plane. The WP has the same symmetry. Figs. 2.5.3.5(*b*) and (*c*) are $2\bar{2}0$ and $\bar{2}20$ DPs, respectively. Both show symmetry m_2 perpendicular to the reflection vector. This symmetry is caused by a twofold rotation axis parallel to the specimen surface. One DP coincides with the other upon translation. This translational or 2_R symmetry indicates the existence of an inversion centre. By consulting Table 2.5.3.3, the diffraction group giving rise to these pattern symmetries is found to be 6_Rmm_R. Fig. 2.5.3.4 shows that there are two point groups $\bar{3}m$ and $m\bar{3}m$ causing diffraction group 6_Rmm_R. Fig. 2.5.3.6 shows another ZAP, which shows symmetry $4mm$ in the BP and the WP. The point group which has fourfold rotation symmetry is not $\bar{3}m$ but $m\bar{3}m$. The point group of Si is thus determined to be $m\bar{3}m$.

2.5.3.2.6. Projection diffraction groups

HOLZ reflections appear as excess HOLZ rings far outside the ZOLZ reflection discs and as deficit lines in the ZOLZ discs. By ignoring these weak diffraction effects with components along the beam direction, we may obtain information about the symmetry of the sample as projected along the beam direction. Thus when HOLZ reflections are weak and no deficit HOLZ

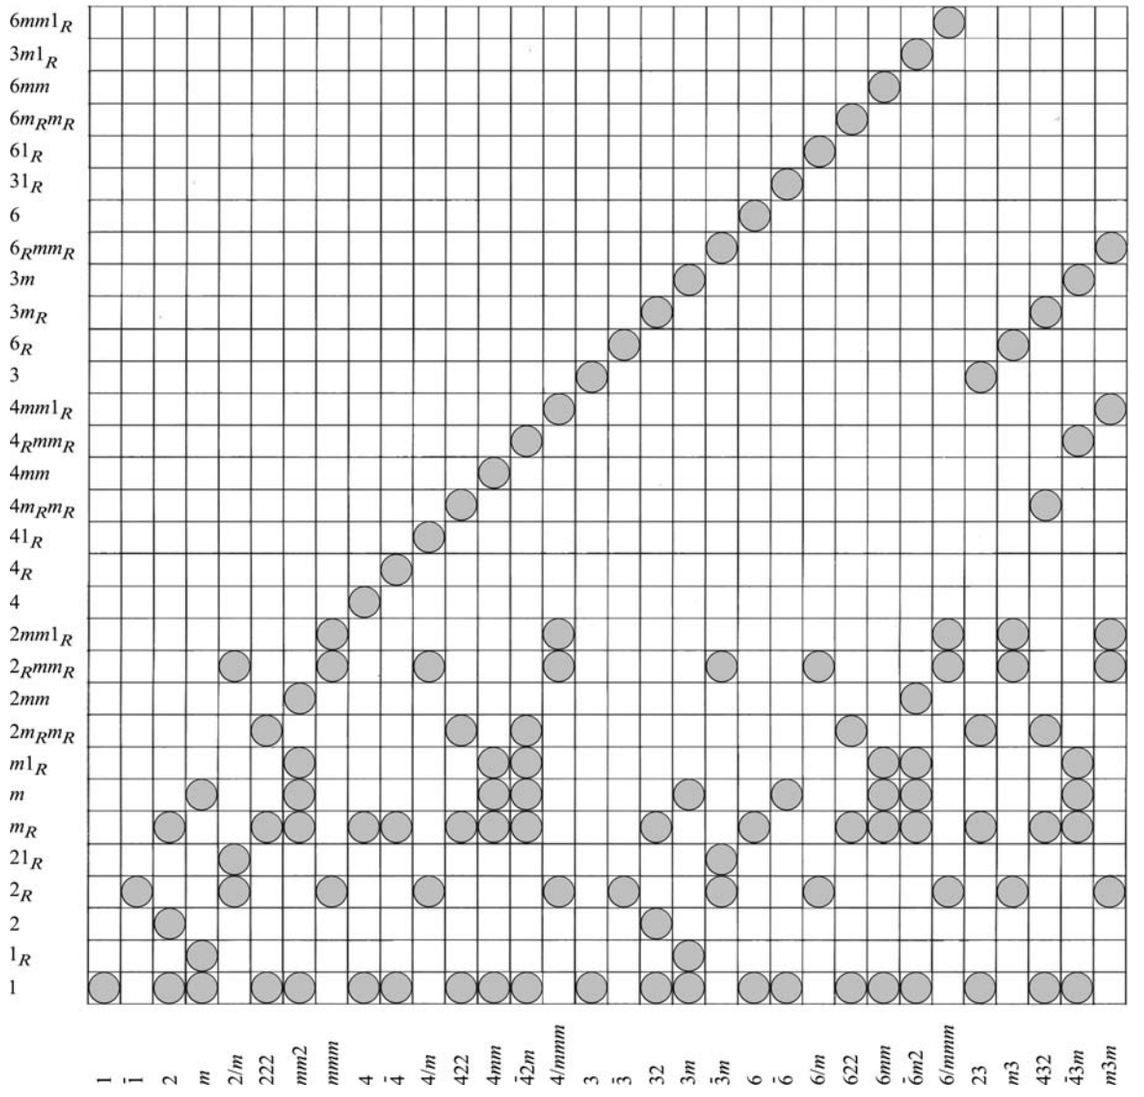

Fig. 2.5.3.4. Relation between diffraction groups and crystal point groups (after Buxton *et al.*, 1976).

lines are seen in the ZOLZ discs, the symmetry elements found from the CBED patterns are only those of the specimen projected along the zone axis. The projection of the specimen along the zone axis causes horizontal mirror symmetry m', the corresponding CBED symmetry being 1_R. When symmetry 1_R is added to the 31 diffraction groups, ten projection diffraction groups having symmetry symbol 1_R are derived as shown in column VI of Table 2.5.3.3. If only ZOLZ reflections are observed in CBED patterns, a projection diffraction group instead of a diffraction group is obtained, where only the pattern symmetries given in the rows of the diffraction groups having symmetry symbol 1_R in Table 2.5.3.3 should be consulted. Two projection diffraction groups obtained from two different zone axes are the minimum needed to determine a crystal point group, because it is constructed by the three-dimensional combination of symmetry elements. It should be noted that if a diffraction group is determined carelessly from CBED patterns with no HOLZ lines, the wrong crystal point group is obtained.

2.5.3.2.7. Symmetrical many-beam method

In the sections above, the point-group determination method established by Buxton *et al.* (1976) was described, where two- and three-dimensional symmetry elements were determined, respectively, from ZAPs and DPs.

The Laue circle is defined as the intersection of the Ewald sphere with the ZOLZ, and all reflections on this circle are simultaneously at the Bragg condition. If many such DPs are recorded (all simultaneously at the Bragg condition), many three-dimensional symmetry elements can be identified from one photograph. Using a group-theoretical method, Tinnappel (1975) studied the symmetries appearing in simultaneously excited DPs for various combinations of crystal symmetry elements. Based upon his treatment, Tanaka, Saito & Sekii (1983) developed a method for determining diffraction groups using simultaneously excited symmetrical hexagonal six-beam, square four-beam and rectangular four-beam CBED patterns. All the CBED symmetries appearing in the symmetrical many-beam (SMB) patterns were derived by the graphical method used in the paper of Buxton *et al.* (1976). From an experimental viewpoint, it is advantageous that symmetry elements can be identified from one photograph. It was found that twenty diffraction groups can be identified from one SMB pattern, whereas ten diffraction groups can be determined by Buxton *et al.*'s method. An experimental comparison between the two methods was performed by Howe *et al.* (1986).

SMB patterns are easily obtained by tilting a specimen crystal or the incident beam from a zone axis into an orientation to excite low-order reflections simultaneously. Fig. 2.5.3.7 illustrates the symmetries of the SMB patterns for all the diffraction groups except for the five groups 1, 1_R, 2, 2_R and 21_R. For these groups, the two-beam method for exciting one reflection is satisfactory because many-beam excitation gives no more information than the two-beam case. In the six-beam and square four-beam cases,

the CBED symmetries for the two crystal (or incident-beam) settings which excite respectively the $+G$ and $-G$ reflections are drawn because the vertical rotation axes create the SMB patterns at different incident-beam orientations. [This had already been experienced for the case of symmetry 2_R (Goodman, 1975; Buxton *et al.*, 1976).] In the rectangular four-beam case, the symmetries for four settings which excite the $+G$, $+H$, $-G$ and $-H$ reflections are shown. For the diffraction groups $3m$, $3m_R$, $3m1_R$ and $6_R mm_R$, two different patterns are shown for the two crystal settings, which differ by $\pi/6$ rad from each other about the zone axis. Similarly, for the diffraction group $4_R mm_R$, two different patterns are shown for the two crystal settings, which differ by $\pi/4$ rad. Illustrations of these different symmetries are given in Fig. 2.5.3.7. The combination of the vertical threefold axis and a horizontal mirror plane introduces a new CBED symmetry 3_R. Similarly, the combination of the vertical sixfold rotation axis and an inversion centre introduces a new CBED symmetry 6_R.

There is an empirical and conventional technique for reproducing the symmetries of the SMB patterns which uses three operations of two-dimensional rotations, a vertical mirror at the centre of disc *O* and a rotation of π about the centre of a disc (1_R) without involving the reciprocal process. For example, we may consider 3_R between discs *F* and *F*′ in Table 2.5.3.5 in the case of diffraction group 31_R. Disc *F*′ is rotated anticlockwise not about the zone axis but *about the centre of disc O* by $2\pi/3$ rad (symbol 3) to coincide with disc *F*, and followed by a rotation of π rad (symbol *R*) about the centre of disc *F*′, resulting in the correct symmetry seen in Fig. 2.5.3.7. When the symmetries appearing between different SMB patterns are considered, this technique assumes that the symmetry operations are conducted after discs *O* and $\bar{O}$ are superposed. Another assumption is that the vertical mirror plane perpendicular to the line connecting discs *O* and $\bar{O}$ acts at the centre of disc *O* when the symmetries between two SMB patterns are considered. As an example, symmetry 3_R between discs *S* and $\bar{S}$ appearing in the two SMB patterns is reproduced by a threefold anticlockwise rotation of disc *S* about the centre of disc *O* (or $\bar{O}$) and followed by a rotation of π rad (*R*) about the centre of disc $\bar{S}$.

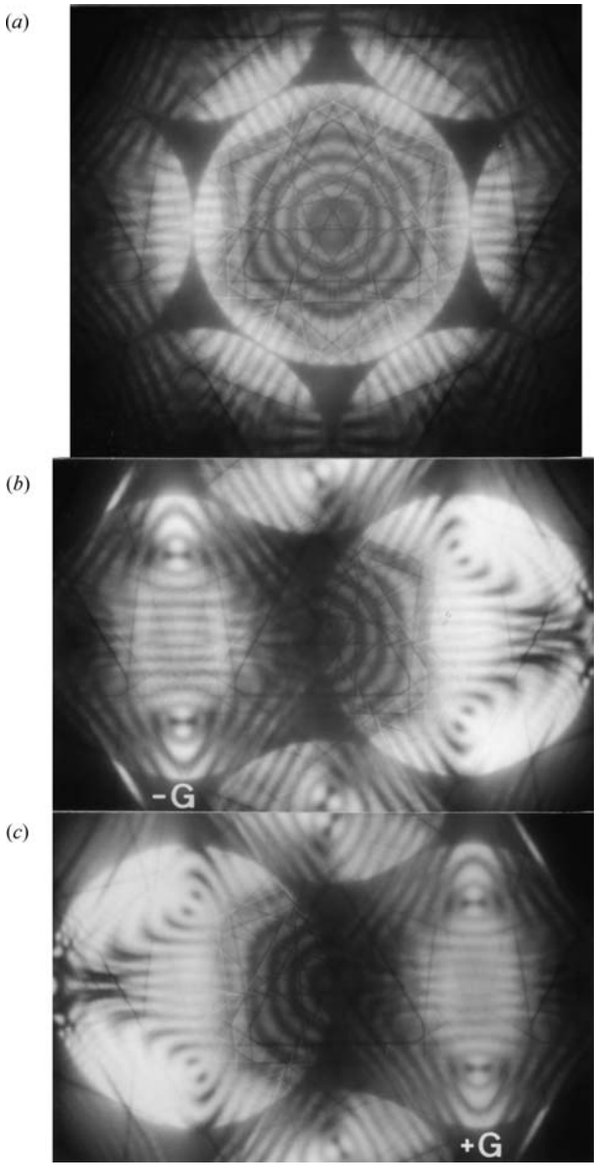

Fig. 2.5.3.5. CBED patterns of Si taken with the [111] incidence. (*a*) BP and WP show symmetry $3m_v$. (*b*) and (*c*) DPs show symmetry m_2 and DP symmetry $2_R m_{v'}$.

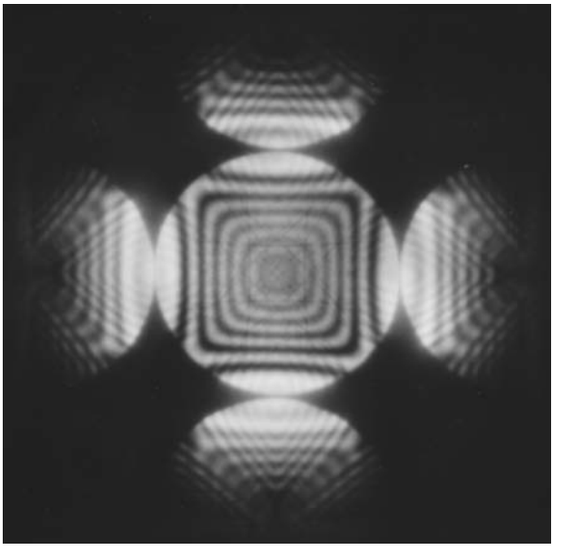

Fig. 2.5.3.6. CBED pattern of Si taken with the [100] incidence. The BP and WP show symmetry 4*mm*.

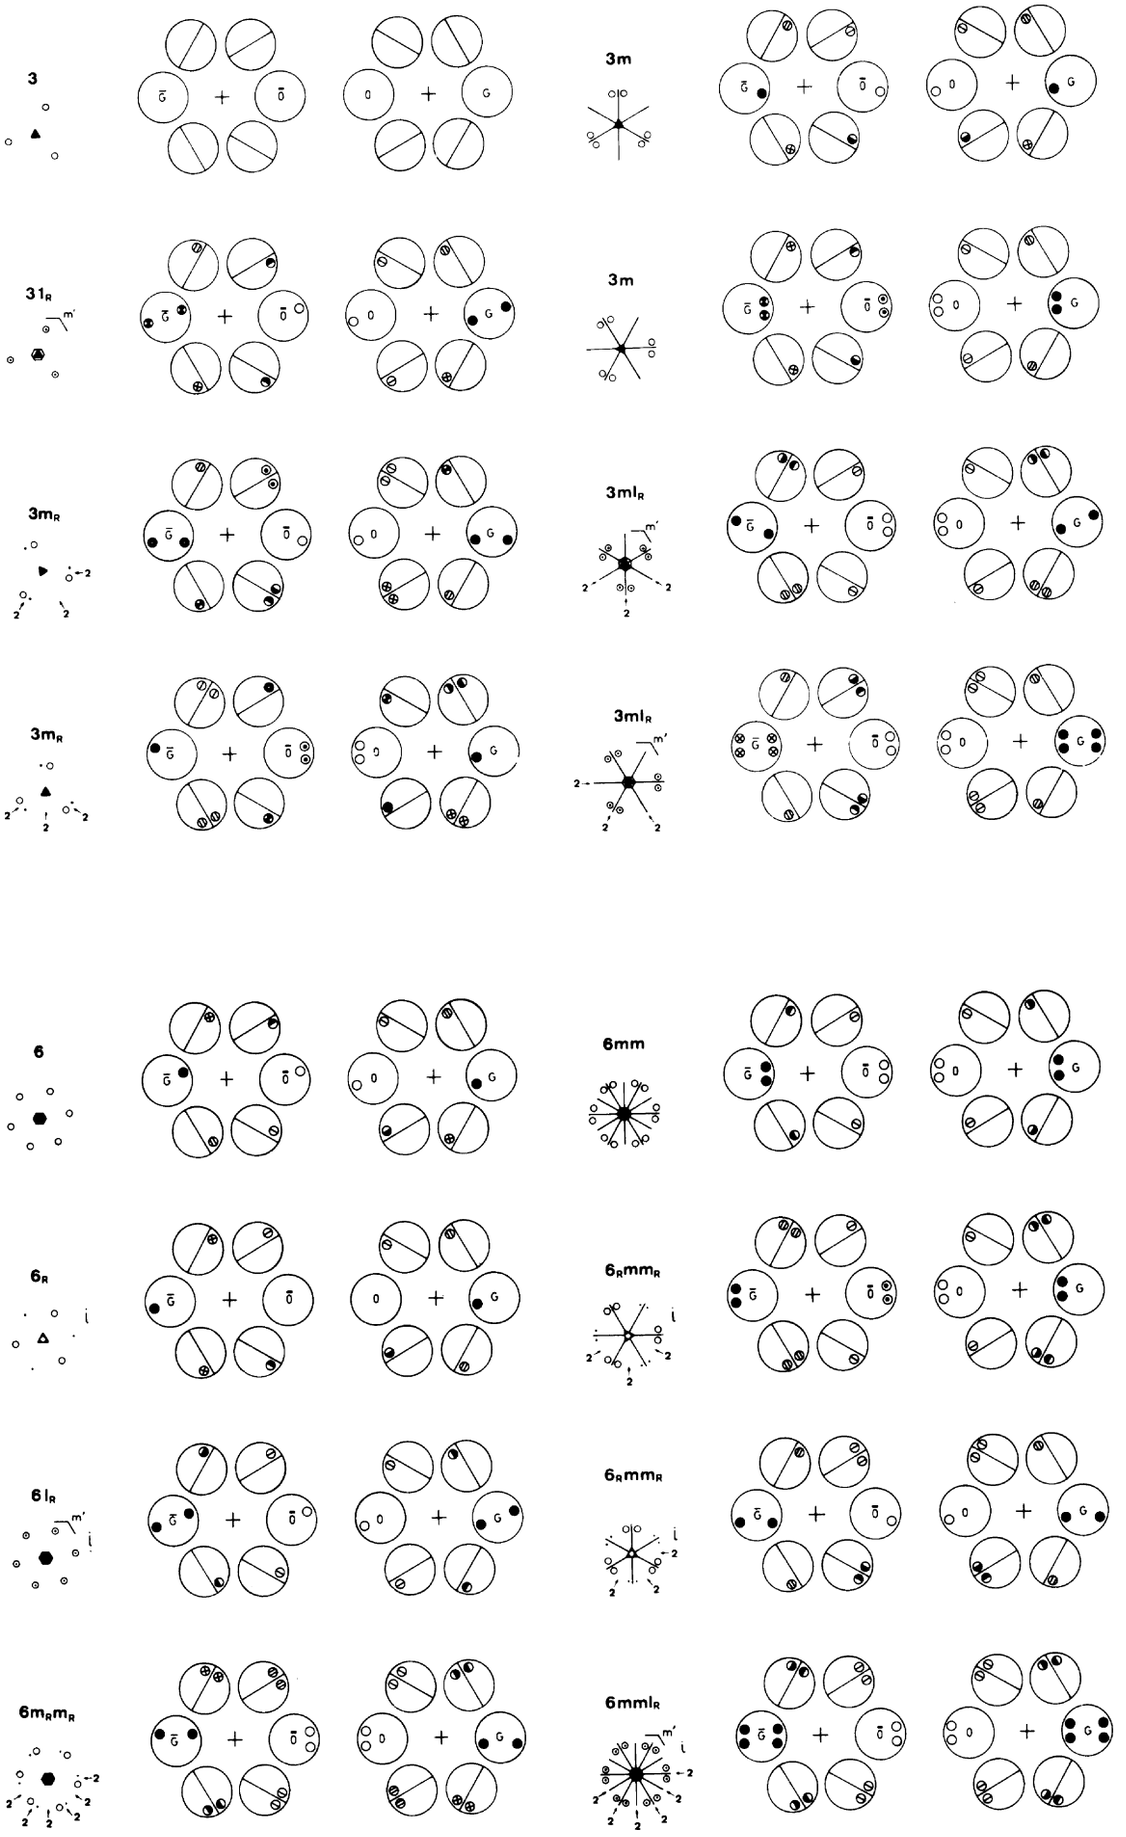

Fig. 2.5.3.7. Illustration of symmetries appearing in hexagonal six-beam, square four-beam and rectangular four-beam dark-field patterns expected for all the diffraction groups except for 1, 1_R, 2, 2_R and 21_R.

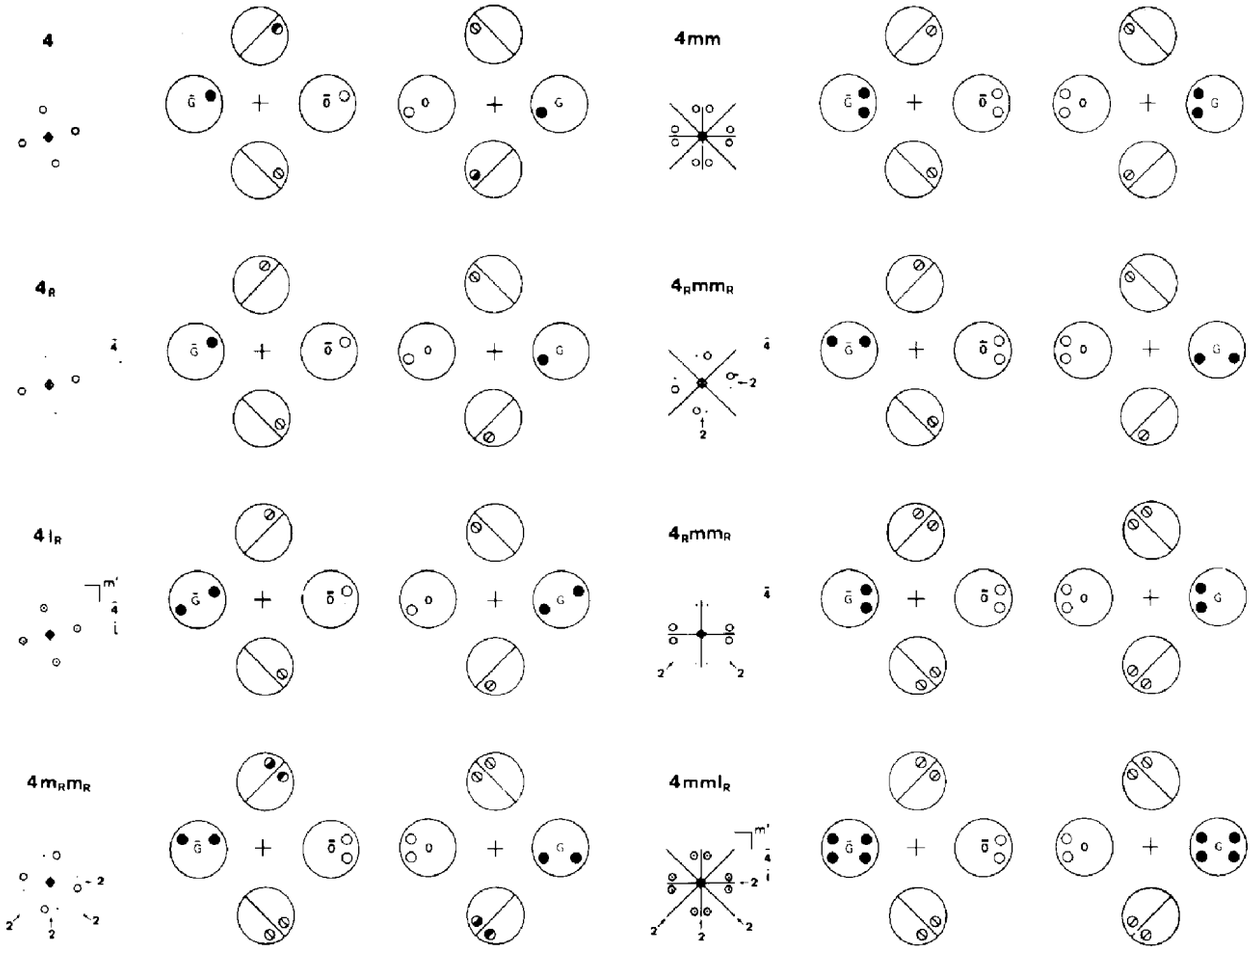

Fig. 2.5.3.7 (*cont.*).

Tables 2.5.3.5, 2.5.3.6 and 2.5.3.7 express the symmetries illustrated in Fig. 2.5.3.7 with the symmetry symbols for the hexagonal six-beam case, square four-beam case and rectangular four-beam case, respectively. In the fourth rows of the tables the symmetries of zone-axis patterns (BP and WP) are listed because combined use of the zone-axis pattern and the SMB pattern is efficient for symmetry determination. In the fifth row, the symmetries of the SMB pattern are listed. In the following rows, the symmetries appearing between the two SMB patterns are listed because the SMB symmetries appear not only in an SMB pattern but also in the pairs of SMB patterns. That is, for each diffraction group, all the possible SMB symmetries appearing in a pair of symmetric six-beam patterns, two pairs AB and AC of the square four-beam patterns and three pairs AB, AC and AD of the rectangular four-beam patterns are listed, though such pairs are not always needed for the determination of the diffraction groups. It is noted that the symmetries in parentheses are the symmetries which add no new symmetries, even if they are present. In the last row, the point groups which cause the diffraction groups listed in the first row are given.

By referring to Tables 2.5.3.5, 2.5.3.6 and 2.5.3.7, the characteristic features of the SMB method are seen to be as follows. CBED symmetry m_2 due to a horizontal twofold rotation axis can appear in every disc of an SMB pattern. Symmetry 1_R due to a horizontal mirror plane, however, appears only in disc G or H of an SMB pattern. In the hexagonal six-beam case, an inversion centre i produces CBED symmetry 6_R between discs S and S' due to the combination of an inversion centre and a vertical threefold rotation axis (and/or of a horizontal mirror plane and a vertical sixfold rotation axis). This indicates that one hexagonal six-beam pattern can reveal whether a specimen has an inversion centre or not, while the method of Buxton *et al.* (1976) requires two photographs for the inversion test. All the diffraction groups in Table 2.5.3.5 can be identified from one six-beam pattern except groups 3 and 6. Diffraction groups 3 and 6 cannot be distinguished from the hexagonal six-beam pattern because it is insensitive to the vertical axis. In the square four-beam case, fourfold rotary inversion $\bar{4}$ produces CBED symmetry 4_R between discs F and F' in one SMB pattern, while Buxton *et al.*'s method requires four photographs to identify fourfold rotary inversion. Although an inversion centre itself does not exhibit any symmetry in the square four-beam pattern, it causes symmetry 1_R due to the horizontal mirror plane produced by the combination of an inversion centre and the twofold rotation axis. Thus, symmetry 1_R is an indication of the existence of an inversion centre in the square four-beam case. All of the seven diffraction groups in Table 2.5.3.6 can be identified from one square four-beam pattern. One rectangular four-beam pattern can distinguish all the diffraction groups in Table 2.5.3.7 except the groups m and $2mm$. It is emphasized again that the inversion test can be carried out using one six-beam pattern or one square four-beam pattern.

Fig. 2.5.3.8 shows CBED patterns taken from a [111] pyrite (FeS_2) plate with an accelerating voltage of 100 kV. The space group of FeS_2 is $P2_1/a\bar{3}$. The diffraction group of the plate is 6_R due to a threefold rotation axis and an inversion centre. The zone-axis pattern of Fig. 2.5.3.8(a) shows threefold rotation symmetry in the BP and WP. The hexagonal six-beam pattern of Fig. 2.5.3.8(b) shows no symmetry higher than 1 in discs O, G, F and S but shows symmetry 6_R between discs S and S', which

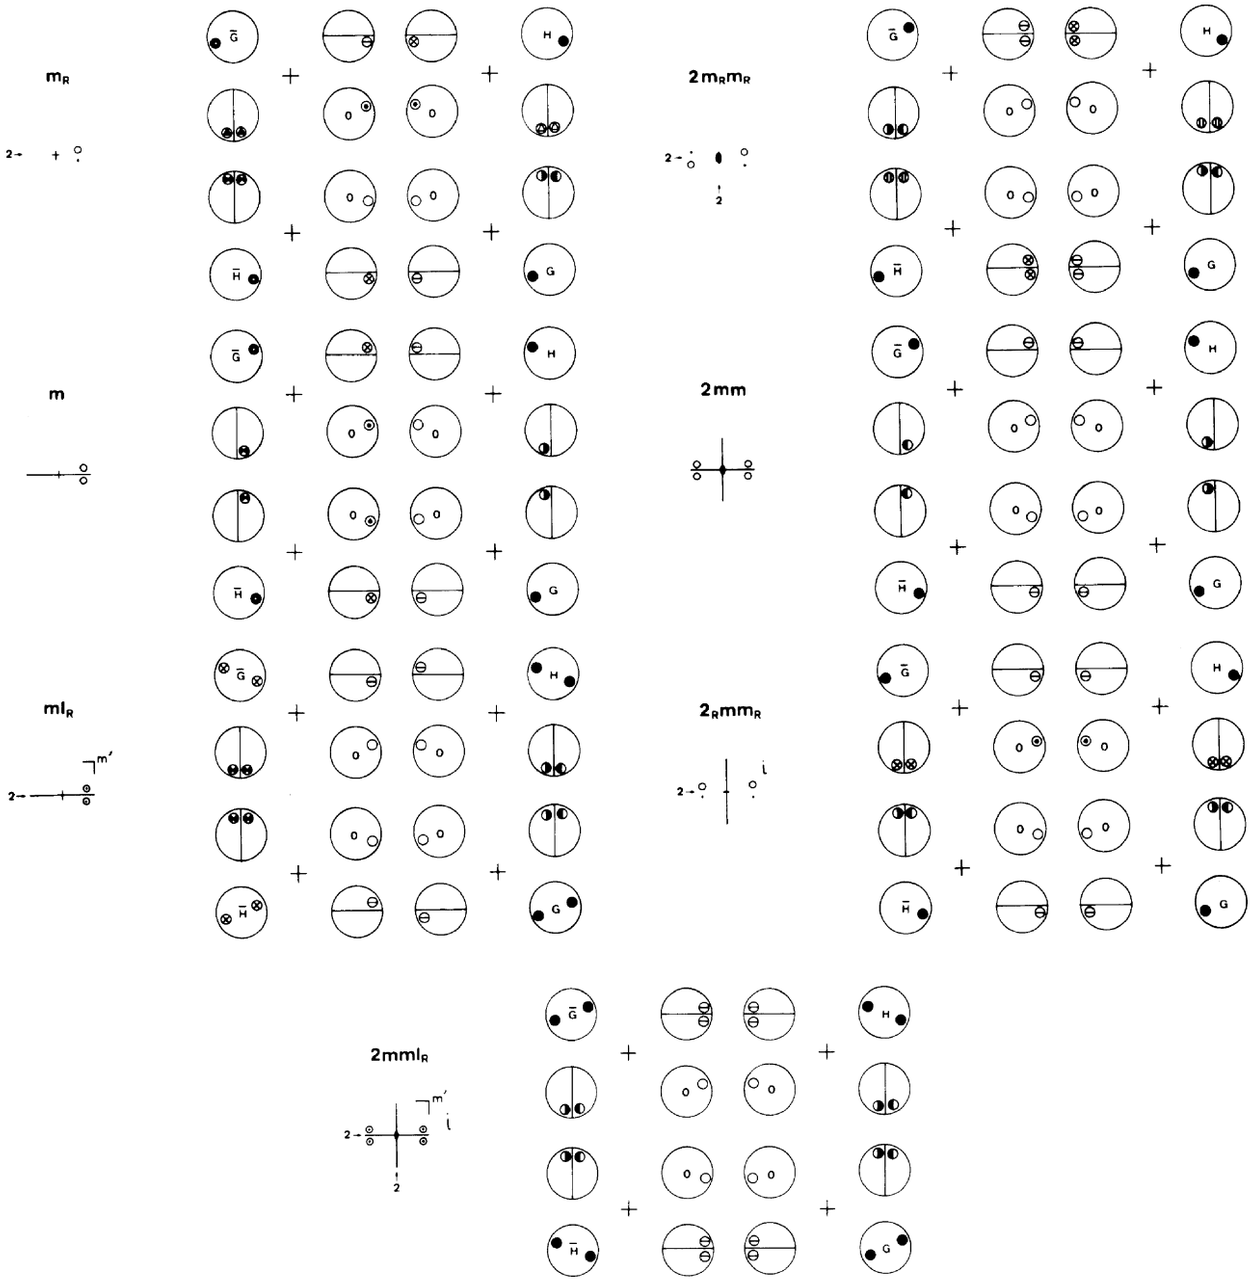

Fig. 2.5.3.7 (*cont.*).

proves the existence of a threefold rotation axis and an inversion centre. The same symmetries are also seen in Fig. 2.5.3.8(*c*), where reflections $\bar{O}$, $\bar{G}$, $\bar{F}$, $\bar{S}$, $\bar{F}'$ and $\bar{S}'$ are excited. Table 2.5.3.5 indicates that diffraction group 6_R can be identified from only one hexagonal six-beam pattern, because no other diffraction groups give rise to the same symmetries in the six discs. When Buxton *et al.*'s method is used, three photographs or four patterns are necessary to identify diffraction group 6_R (see Table 2.5.3.3). In addition, if the symmetries between Figs. 2.5.3.8(*b*) and (*c*) are examined, symmetry 2_R between discs G and $\bar{G}$ and symmetry 6_R between discs F and $\bar{F}$ are found. All the experimental results agree exactly with the theoretical results given in Fig. 2.5.3.7 and Table 2.5.3.5.

Fig. 2.5.3.9 shows CBED patterns taken from a [110] V_3Si plate with an accelerating voltage of 80 kV. The space group of V_3Si is $Pm3n$. The diffraction group of the plate is $2mm1_R$ due to two vertical mirror planes and a horizontal mirror plane, a twofold rotation axis being produced at the intersection line of two perpendicular mirror planes. The zone-axis pattern of Fig. 2.5.3.9(*a*) shows symmetry $2mm$ in the BP and WP. The rectangular four-beam pattern of Fig. 2.5.3.9(*b*) shows symmetry 1_R in disc H due to the horizontal mirror plane and symmetry m_2 in both discs $\bar{S}$ and F' due to the twofold rotation axes in the [001] and [110] directions, respectively. The same symmetries are also seen in Fig. 2.5.3.9(*c*), where reflections $\bar{H}$, S' and $\bar{F}$ are excited. Table 2.5.3.7 implies that the diffraction group $2mm1_R$ can be identified from only one rectangular four-beam pattern, because no other diffraction groups give rise to the same symmetries in the four discs. When Buxton *et al.*'s method is used, two photographs or three patterns are necessary to identify diffraction group $2mm1_R$ (see Table 2.5.3.3). One can confirm the theoretically predicted symmetries between Fig. 2.5.3.9(*b*) and Fig. 2.5.3.9(*c*). All the experimental results agree exactly with the theoretical results given in Fig. 2.5.3.7 and Table 2.5.3.7.

These experiments show that the SMB method is quite effective for determining the diffraction group of slabs. Buxton *et al.*'s method identifies two-dimensional symmetry elements in the first place using a zone-axis pattern, and three-dimensional symmetry elements using DPs. On the other hand, the SMB method primarily finds many three-dimensional symmetry elements in an

SMB pattern, and two-dimensional symmetry elements from a pair of SMB patterns, as shown in Tables 2.5.3.5, 2.5.3.6 and 2.5.3.7. Therefore, the use of a ZAP and SMB patterns is the most efficient way to find as many crystal symmetry elements in a specimen as possible.

2.5.3.3. Space-group determination

2.5.3.3.1. Lattice-type determination

When the point group of a specimen crystal is determined, the crystal axes may be found from a spot diffraction pattern recorded at a high-symmetry zone axis, using the orientations of the symmetry elements determined in the course of point-group determination. Integral-number indices are assigned to the spots of the diffraction patterns. The systematic absence of reflections indicates the lattice type of the crystal. It should be noted that reflections forbidden by the lattice type are always absent, even if dynamical diffraction takes place. (This is true for all sample thicknesses and accelerating voltages.) By comparing the experimentally obtained absences and the extinction rules known for the lattice types [P, C (A, B), I, F and R], a lattice type may be identified for the crystal concerned.

2.5.3.3.2. Identification of screw axes and glide planes

There are three space-group symmetry elements of diperiodic plane figures: (1) a horizontal screw axis $2'_1$, (2) a vertical glide plane g with a horizontal glide vector and (3) a horizontal glide plane g'. These are related to the point-group symmetry elements $2'$, m and m' of diperiodic plane figures, respectively. (It is noted that these symmetry elements and ten point-group symmetry elements form 80 space groups.)

The ordinary extinction rules for screw axes and glide planes hold only in the approximation of kinematical diffraction. The kinematically forbidden reflections caused by these symmetry elements appear owing to *Umweganregung* of dynamical diffraction. Extinction of intensity, however, does take place in these reflections at certain crystal orientations with respect to the incident beam (*i.e.* in certain regions within a CBED disc). This dynamical extinction was first predicted by Cowley & Moodie (1959) and was discussed by Miyake *et al.* (1960) and Cowley *et al.* (1961). Goodman & Lehmpfuhl (1964) first observed the dynamical extinction as dark cross lines in kinematically forbidden reflection discs of CBED patterns of CdS. Gjønnes & Moodie

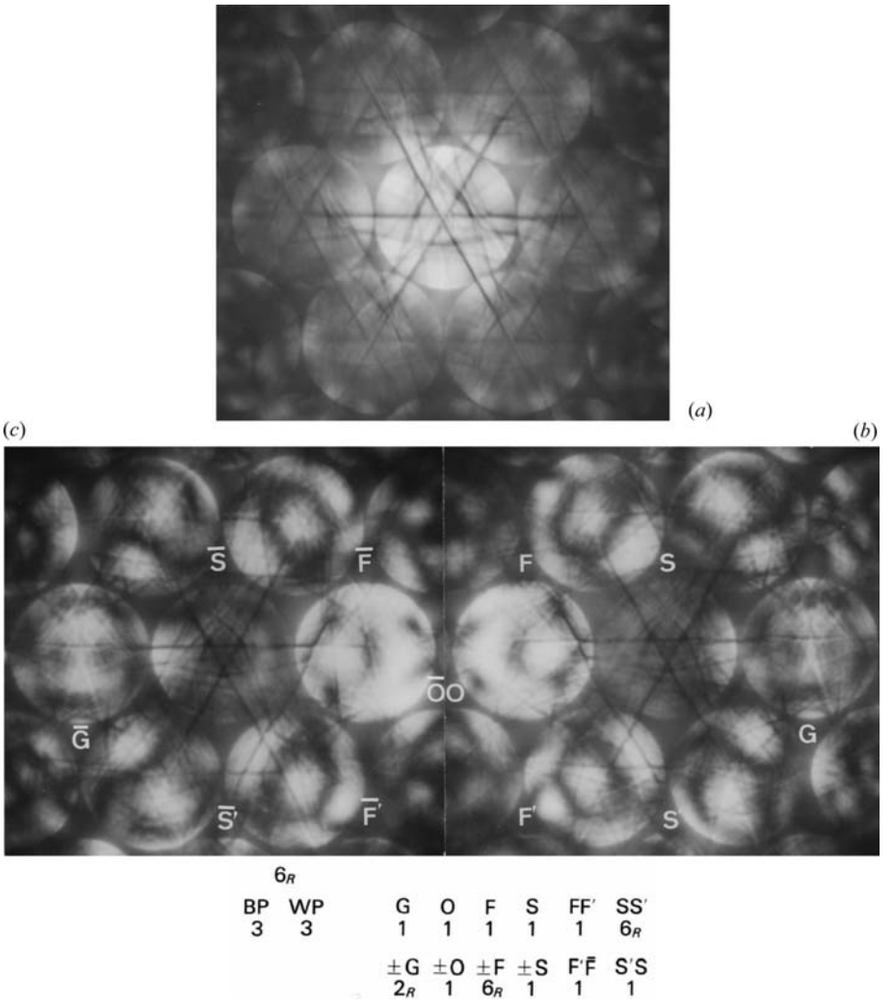

Fig. 2.5.3.8. CBED patterns of FeS_2 taken with the [111] incidence. (*a*) Zone-axis pattern, (*b*) hexagonal six-beam pattern with excitation of reflection $+G$, (*c*) hexagonal six-beam pattern with excitation of reflection $-G$. Symmetry 6_R is noted between discs S and S' and discs $\bar{F}$ and $\bar{F}'$.

(1965) discussed the dynamical extinction in a more general way considering not only ZOLZ reflections but also HOLZ reflections. They completely clarified the dynamical extinction rules by considering the exact cancellation which may occur along certain symmetry-related multiple-scattering paths. Based on the results of Gjønnes & Moodie (1965), Tanaka, Sekii & Nagasawa (1983) tabulated the dynamical extinctions expected at all the possible crystal orientations for all the space groups. These were later tabulated in a better form on pages 162 to 172 of the book by Tanaka & Terauchi (1985).

Fig. 2.5.3.10(*a*) illustrates *Umweganregung* paths to a kinematically forbidden reflection. The $0k0$ (k = odd) reflections are kinematically forbidden because a b-glide plane exists perpendicular to the a axis and/or a 2_1 screw axis exists in the b direction. Let us consider an *Umweganregung* path a in the zeroth-order Laue zone to the 010 forbidden reflection and path b which is symmetric to path a with respect to axis k. Owing to the translation of one half of the lattice parameter b caused by the glide plane and/or the 2_1 screw axis, the following relations hold between the crystal structure factors:

$$F(h,k) = F(\bar{h},k) \quad \text{for } k = 2n,$$
$$F(h,k) = -F(\bar{h},k) \quad \text{for } k = 2n+1. \qquad (2.5.3.1)$$

That is, the structure factors of reflections $hk0$ and $\bar{h}k0$ have the same phase for even k but have opposite phases for odd k.

Since an *Umweganregung* path to the kinematically forbidden reflection $0k0$ contains an odd number of reflections with odd k, the following relations hold:

$$F(h_1,k_1)F(h_2,k_2)\ldots F(h_n,k_n) \quad \text{for path } a$$
$$= -F(\bar{h}_1,k_1)F(\bar{h}_2,k_2)\ldots F(\bar{h}_n,k_n) \quad \text{for path } b, \qquad (2.5.3.2)$$

where

$$\sum_{i=1}^{n} h_i = 0, \quad \sum_{i=1}^{n} k_i = k \ (k = \text{odd})$$

and the functions including the excitation errors are omitted because only the cases in which the functions are the same for all the paths are considered. The excitation errors for paths a and b become the same when the projection of the Laue point along the zone axis concerned, L, lies on axis k. Since the two waves passing through paths a and b have the same amplitude but opposite signs, these waves are superposed on the $0k0$ discs (k = odd) and cancel out, resulting in dark lines A in the forbidden discs, as shown in Fig. 2.5.3.10(*b*). The line A runs parallel to axis k passing through the projection point of the zone axis.

In path c, the reflections are arranged in the reverse order to those in path b. When the 010 reflection is exactly excited, two paths a and c are symmetric with respect to the bisector m'–m' of

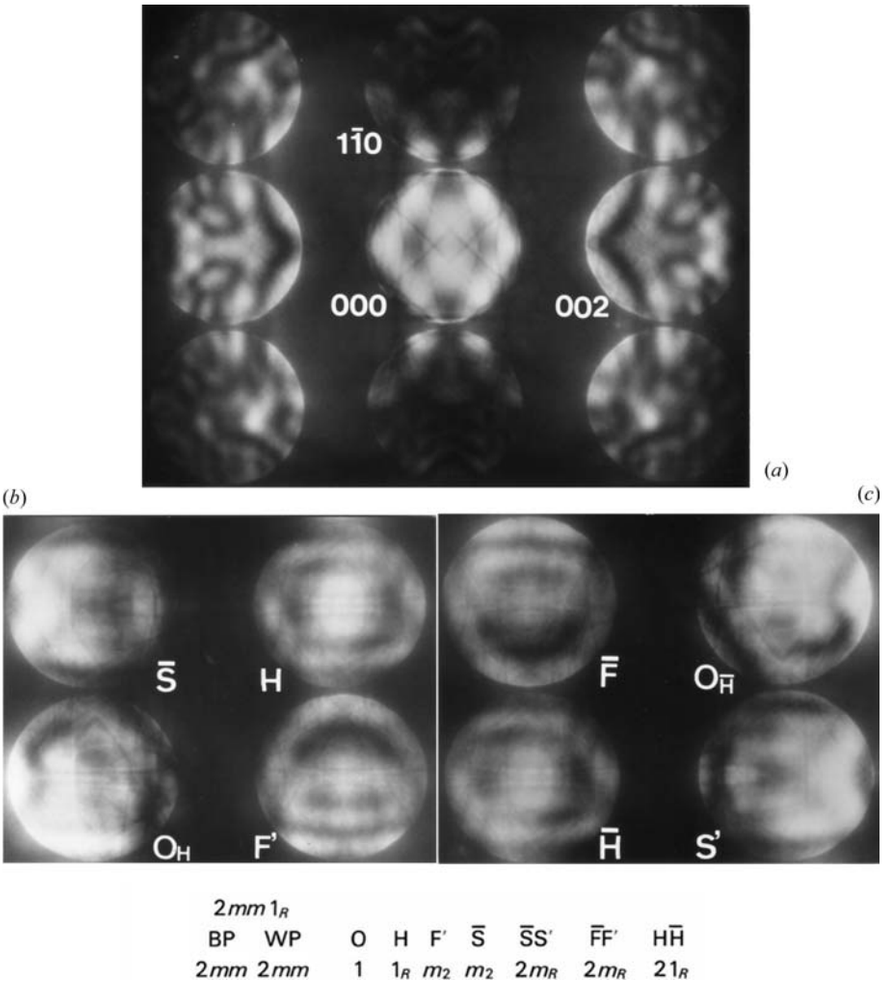

Fig. 2.5.3.9. CBED patterns of V_3Si taken with the [110] incidence. (*a*) Zone-axis pattern, (*b*) rectangular four-beam pattern with excitation of reflections H, $\bar{S}$ and F, (*c*) rectangular four-beam pattern with excitation of reflections $\bar{H}$, S and $\bar{F}$.

the 010 vector having the same excitation errors. The following equation holds:

$$F(h_1, k_1)F(h_2, k_2)\ldots F(h_n, k_n) \quad \text{for path } a$$
$$= -F(\bar{h}_n, k_n)F(\bar{h}_{n-1}, k_{n-1})\ldots F(\bar{h}_1, k_1) \quad \text{for path } c. \tag{2.5.3.3}$$

Since the waves passing through these paths have the same amplitude but opposite signs, these waves are superposed on the 010 discs and cancel out, resulting in dark line B in this disc, as shown in Fig. 2.5.3.10(*b*). Line B appears perpendicular to line A at the exact Bragg positions. When *Umweganregung* paths are present only in the zeroth-order Laue zone, the glide plane and screw axis produce the same dynamical extinction lines A and B. We call these lines A_2 and B_2 lines, subscript 2 indicating that the *Umweganregung* paths lie in the zeroth-order Laue zone.

The dynamical extinction effect is analogous to interference phenomena in the Michelson interferometer. That is, the incident beam is split into two beams by Bragg reflections in a crystal. These beams take different paths, in which they suffer a relative phase shift of π and are finally superposed on a kinematically forbidden reflection to cancel out.

When the paths include higher-order Laue zones, the glide plane produces only extinction lines A but the screw axis causes only extinction lines B. These facts are attributed to the different relations between structure factors for a 2_1 screw axis and a glide plane,

$$F(hkl) = (-1)^k F(\bar{h}k\bar{l}) \quad \text{for a } 2_1 \text{ screw axis in the [010] direction,} \tag{2.5.3.4}$$

$$F(hkl) = (-1)^k F(\bar{h}kl) \quad \text{for a } b \text{ glide in the (100) plane.} \tag{2.5.3.5}$$

In the case of the glide plane, extinction lines A are still formed because two waves passing through paths a and b have opposite signs to each other according to equation (2.5.3.5), but extinction lines B are not produced because equation (2.5.3.4) holds only for the 2_1 screw axis. In the case of the 2_1 screw axis, only the waves passing through paths a and c have opposite signs according to equation (2.5.3.4), forming extinction lines B only. We call these lines A_3 and B_3 dynamical extinction lines, suffix 3 indicating the *Umweganregung* paths being *via* higher-order Laue zones.

It was predicted by Gjønnes & Moodie (1965) that a horizontal glide plane g' gives a dark spot at the crossing point between extinction lines A and B (Fig. 2.5.3.10*b*) due to the cancellation between the waves passing through paths b and c. Tanaka, Terauchi & Sekii (1987) observed this dynamical extinction, though it appeared in a slightly different manner to that predicted by Gjønnes & Moodie (1965). Table 2.5.3.8 summarizes the appearance of the dynamical extinction lines for the glide planes g and g' and the 2_1 screw axis. The three space-group symmetry elements can be identified from the observed extinctions because these three symmetry elements produce different kinds of dynamical extinctions.

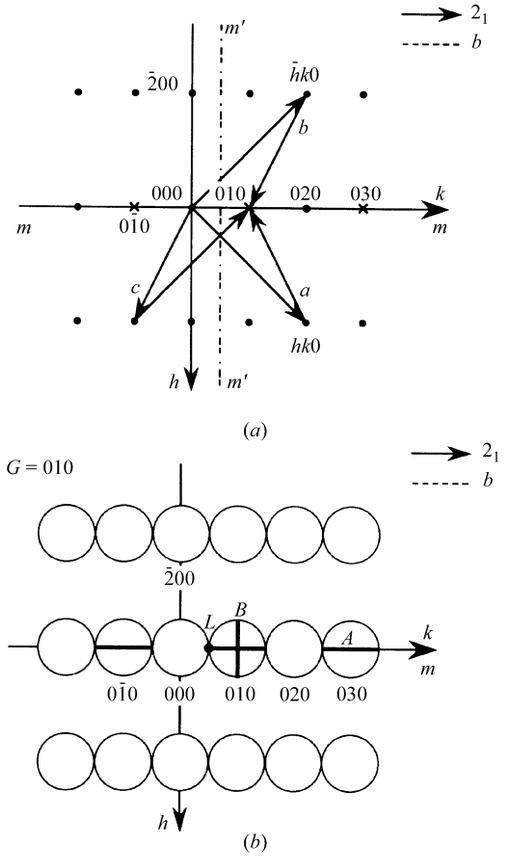

Fig. 2.5.3.10. Illustration of the production of dynamical extinction lines in kinematically forbidden reflections due to a b-glide plane and a 2_1 screw axis. (a) *Umweganregung* paths a, b and c. (b) Dynamical extinction lines A are formed in forbidden reflections $0k0$ (k = odd). Extinction line B perpendicular to the lines A is formed in the exactly excited 010 reflection.

In principle, a horizontal screw axis and a vertical glide plane can be distinguished by observations of the extinction lines A_3 and B_3. It is, however, not easy to observe the extinction lines A_3 and B_3 because broad extinction lines A_2 and B_2 appear at the same time. The presence of the extinction lines A_3 and B_3 can be revealed by inspecting the symmetries of fine defect HOLZ lines appearing in the forbidden reflections instead of by direct observation of the lines A_3 and B_3 (Tanaka, Sekii & Nagasawa, 1983). That is, if HOLZ lines form lines A_3 and B_3, HOLZ lines are symmetric with respect to the extinction lines A_2 and B_2. If HOLZ lines do not form lines A_3 and B_3, HOLZ lines are asymmetric with respect to the extinction lines A_2 and B_2. When the HOLZ lines are symmetric about the extinction lines A_2, the specimen crystal has a glide plane. When the HOLZ lines are symmetric with respect to lines B_2, a 2_1 screw axis exists. It should

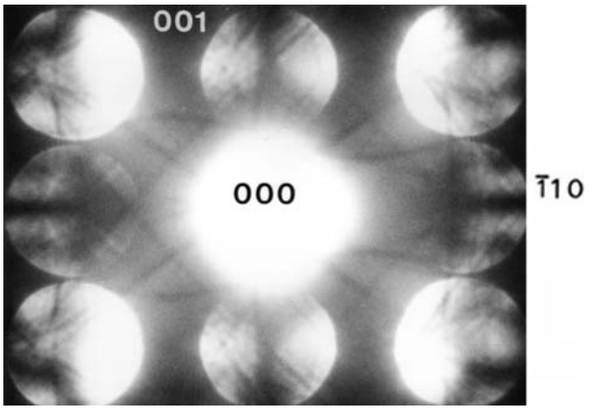

Fig. 2.5.3.12. CBED pattern of FeS_2 taken with the [110] electron-beam incidence. In the 001 and $00\bar{1}$ discs, HOLZ lines are asymmetric with respect to extinction lines A_2, indicating the existence of a 2_1 screw axis parallel to the c axis. In the $\bar{1}10$ and $1\bar{1}0$ discs, HOLZ lines are symmetric with respect to extinction lines A_2, indicating existence of a glide plane perpendicular to the c axis.

be noted that a relatively thick specimen area has to be selected to observe HOLZ lines in ZOLZ reflection discs.

Fig. 2.5.3.11 shows CBED patterns taken from (a) thin and (b) thick areas of FeS_2, whose space group is $P2_1/a\bar{3}$, at the 001 Bragg setting with the [100] electron-beam incidence. In the case of the thin specimen (Fig. 2.5.3.11a), only the broad dynamical extinction lines formed by the interaction of ZOLZ reflections are seen in the odd-order discs. On the other hand, fine HOLZ lines are clearly seen in the thick specimen (Fig. 2.5.3.11b). The HOLZ lines are symmetric with respect to both A_2 and B_2 extinction lines. This fact proves the presence of the extinction lines A_3 and B_3, or both the c glide in the (010) plane and the 2_1 screw axis in the c direction, this fact being confirmed by consulting Table 2.5.3.9. Fig. 2.5.3.12 shows a [110] zone-axis CBED pattern of FeS_2. A_2 extinction lines are seen in both the 001 and $\bar{1}10$ discs. Fine HOLZ lines are symmetric with respect to the A_2 extinction lines in the $\bar{1}10$ disc but asymmetric about the A_2 extinction line in the 001 disc, indicating formation of the A_3 extinction line only in the $\bar{1}10$ disc. This proves the existence of a 2_1 screw axis in the [001] direction and an a glide in the (001) plane. The appearance of HOLZ lines is easily changed by a change of a few hundred volts in the accelerating voltage. Steeds & Evans (1980) demonstrated for spinel changes in the appearance of HOLZ lines in the ZOLZ discs at accelerating voltages around 100 kV.

Another practical method for distinguishing between glide planes and 2_1 screw axes is that reported by Steeds *et al.* (1978). The method is based on the fact that the extinction lines are observable even when a crystal is rotated with a glide plane kept parallel and with a 2_1 screw axis perpendicular to the incident

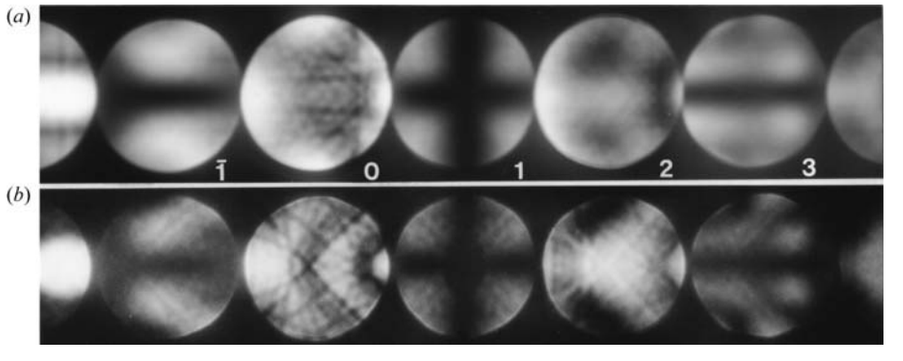

Fig. 2.5.3.11. CBED patterns obtained from (a) thin and (b) thick areas of (001) FeS_2. (a) Dynamical extinction lines A_2 and B_2 are seen. (b) Extinction lines A_3 and B_3 as well as A_2 and B_2 are formed because HOLZ lines are symmetric about lines A_2 and B_2.

Table 2.5.3.8. *Dynamical extinction rules for an infinitely extended parallel-sided specimen*

Symmetry elements of plane-parallel specimen	Orientation to specimen surface	Dynamical extinction lines	
		Two-dimensional (zeroth Laue zone) interaction	Three-dimensional (HOLZ) interaction
Glide planes	perpendicular: g	A_2 and B_2	A_3
	parallel: g'	—	intersection of A_3 and B_3
Twofold screw axis	perpendicular: 2_1	—	—
	parallel: $2_1'$	A_2 and B_2	B_3

beam. With reference to Fig. 2.5.3.10(*a*), extinction lines A_3 produced by a glide plane remain even when the crystal is rotated with respect to axis h but the lines are destroyed by a rotation of the crystal about axis k. Extinction lines B_3 originating from a 2_1 screw axis are not destroyed by a crystal rotation about axis k but the lines are destroyed by a rotation with respect to axis h.

2.5.3.3.3. Space-group determination

We now describe a space-group determination method which uses the dynamical extinction lines caused by the horizontal screw axis $2_1'$ and the vertical glide plane g of an infinitely extended parallel-sided specimen. We do not use the extinction due to the glide plane g' because observation of the extinction requires a laborious experiment. It should be noted that a vertical glide plane with a glide vector not parallel to the specimen surface cannot be a symmetry element of a specimen of finite thickness; however, the component of the glide vector perpendicular to the incident beam acts as a symmetry element g. (Which symmetry elements are observed by CBED is discussed in Section 2.5.3.3.5.) The 2_1, 4_1, 4_3, 6_1, 6_3 and 6_5 screw axes of crystal space groups that are set perpendicular to the incident beam act as a symmetry element $2_1'$ because two or three successive operations of 4_1, 4_3, 6_1, 6_3 and 6_5 screw axes make them equivalent to a 2_1 screw axis: $(4_1)^2 = (4_3)^2 = (6_1)^3 = (6_3)^3 = (6_5)^3 = 2_1$. The 4_2, 3_1, 3_2, 6_2 and 6_4 screw axes that are set perpendicular to the incident beam do not produce dynamical extinction lines because the 4_2 screw axis acts as a twofold rotation axis due to the relation $(4_2)^2 = 2$, the 3_1 and 3_2 screw axes give no specific symmetry in CBED patterns, and the 6_2 and 6_4 screw axes are equivalent to 3_1 and 3_2 screw axes due to the relations $(6_2)^2 = 3_2$ and $(6_4)^2 = 3_1$. Modifications of the dynamical extinction rules were investigated by Tanaka, Sekii & Nagasawa (1983) when more than one crystal symmetry element (that gives rise to dynamical extinction lines) coexists and when the symmetry elements are combined with various lattice types. Using these results, dynamical extinction lines A_2, A_3, B_2 and B_3 expected from all the possible crystal settings for all the space groups were tabulated.

Table 2.5.3.9 shows all the dynamical extinction lines appearing in the kinematically forbidden reflections for all the possible crystal settings of all the space groups. The first column gives space groups. In each of the following pairs of columns, the left-hand column of the pair gives the reflection indices and the symmetry elements causing the extinction lines and the right-hand column gives the types of the extinction lines. The (second) suffixes 1, 2 and 3 of a 2_1 screw axis in each column distinguish the first, the second and the third screw axis of the space group (as in the symbols 2_{11} and 2_{12} of space group $P2_12_12$). The glide symbols in the [001] column for space group $P4/nnc$ have two suffixes (n_{21} and n_{22}). The first suffix 2 denotes the second glide plane of the space group. The second suffixes 1 and 2, which appear in the tetragonal and cubic systems, distinguish two equivalent glide planes which lie in the x and y planes. The equivalent planes are distinguished only for the cases of [100], [010] and [001] electron-beam incidences, for convenience. The c-glide planes of space group $Pcc2$ are distinguished with symbols c_1 and c_2 (the first suffix only), because the equivalent planes do not exist. The glide symbol in the [001] column for space group $P4/mbm$ has only one suffix 1 or 2. The suffix distinguishes the equivalent glide planes lying in the x and y planes. The first suffix to distinguish the first and the second glide planes is not necessary because the space group has only one glide symbol b. When the index of the incident-beam direction is expressed with a symbol like $[h0l]$ for point groups 2, m and $2/m$, the index h or l can take a value of zero. That is, the extinction rules are applicable to the [100] and [001] electron-beam incidences. However, if columns for [100], [010] and [001] incidences are present, as in the case of point group $mm2$, $[hk0]$, $[0kl]$ and $[h0l]$ incidences are only for nonzero h, k and l. The reflections in which the extinction lines appear are always perpendicular to the corresponding incident-beam directions ($0k'l' \perp [0kl]$, $h'k'0 \perp [hk0]$, ...). The indices of the reflections in which extinction lines appear are odd if no remark is given. For c-glide planes of space groups $R3c$ and $R\bar{3}c$ and for d-glide planes, the reflections in which extinction lines appear are specified as $6n + 3$ and $4n + 2$ orders, respectively.

The number of indistinguishable space groups was first counted by Tanaka, Sekii & Nagasawa (1983) but later corrections were made by Eades & Spence (1987). It was found that 177 space groups out of 230 can be identified using the extinction lines (Tanaka *et al.*, 2002). Another reference for space-group determination is due to Eades (1988). The indistinguishable space-group sets using the extinction lines are listed in Table 2.5.3.10. Most of the sets are caused by the fact that CBED cannot identify 4_2, 3_1 (3_2) and 6_2 (6_4) screw axes. However, these sets can be rather easily distinguished in the ordinary way, that is, by observing how the intensities of the reflections which may be kinematically forbidden change when the crystal orientation is varied. If the axis concerned is a screw axis, kinematically forbidden reflections show a sudden decrease in intensity when an orientation change causes the loss of *Umweganregung* paths. If the axis is a rotation axis, the intensities of the reflections do not change conspicuously for such an orientation change. Using this test, each space group in the 23 sets can be identified except the pairs in parentheses and pairs (16) and (17) in Table 2.5.3.10 (see Eades, 1988).

Tsuda *et al.* (2000) showed theoretically that the coherent CBED method can distinguish between space groups ($I23$ and $I2_13$) and between ($I222$ and $I2_12_12_1$), which are indistinguishable pairs (16) and (17), respectively, in Table 2.5.3.10. The coherent CBED pattern is obtained in such a way that the convergence angle of the incident beam is set to a larger value than usual to make adjacent CBED discs overlap (Dowell & Goodman, 1973). When the focus point is displaced from the specimen, or a certain area is illuminated, sinusoidal interference fringes of the lattice spacing corresponding to the adjacent discs are formed in the overlapping regions if the probe size of the incident beam is smaller than the lattice spacing. (If the focus point of the incident beam is on the specimen, each overlapping region of the CBED discs shows uniform intensity.) Formation of the interference fringes was explained in detail first by Spence & Cowley (1978). Vine *et al.* (1992) showed distortion-free interference fringes from 6*H*-SiC and succeeded in observing the fringes with a shift of half a period due to a glide plane. Tsuda *et al.*'s method

distinguishes the difference in the relative arrangements of twofold rotation axes and 2_1 screw axes along the [111] direction between the two space groups by examining the symmetry of intensity pairs appearing in the overlapping discs of a coherent [111] ZOLZ pattern. Saitoh, Tsuda *et al.* (2001) extended the method to distinguish the other ten indistinguishable space-group pairs. The method can distinguish between a space group which is composed of a principal rotation axis and a twofold rotation axis like $P321$ and a space group which is composed of a principal screw axis and a twofold rotation axis like $P3_121$ (or $P3_221$) by investigating the difference in the relative arrangements of the twofold rotation axis with respect to the principal axis. Table 2.5.3.11 shows the 12 space-group pairs which are distinguishable by applying the coherent CBED method.

The pairs in parentheses form left- and right-handed space groups. Handedness or chirality may occur in space groups that do not possess mirror and/or inversion symmetry. The handedness of space groups is identified in such a way that the senses of two crystal axes are determined with the aid of kinematical structure-factor calculations and the sense of the third axis is determined with the aid of dynamical calculations. This method was used for quartz by Goodman & Secomb (1977) and Goodman & Johnson (1977) and for MnSi by Tanaka *et al.* (1985). We also mention that Taftø & Spence (1982) developed a simple but clever method without computation for determining the absolute polarity of the sphalerite structure utilizing multiple-scattering effects on weak beams, which are almost independent of thickness. Because of the importance of structure in the field of semiconductor science, this method is conveniently used nowadays to determine polarity.

It is worth mentioning that space groups that are indistinguishable by CBED (Table 2.5.3.10) do not appear frequently in real inorganic materials. The crystal data collected by Nowacki (1967) on 5572 different inorganic materials shows that the number of materials belonging to space groups among sets (2), (3), (5), (7) and (11) in Table 2.5.3.10 is more than 15 but the number belonging to space groups among the other sets is less than ten. This implies that the probability of finding indistinguishable space groups is very low.

Table 2.5.3.11. *Space-group sets distinguishable by coherent CBED*

The space-group pairs in parentheses can not be distinguished by coherent CBED but can be distinguished by a handedness test. An asterisk (*) indicates the incidence at which the distinction is carried out by many-beam interference (Saitoh, Tsuda *et al.*, 2001).

2.5.3.3.4. Dynamical extinction in HOLZ reflections

Space-group determination as described in the previous sections is carried out using the extinction lines appearing in ZOLZ reflections. Vertical glide planes whose translation vectors are perpendicular to the specimen surface do not cause extinction lines in ZOLZ reflections but cause them in HOLZ reflections. (It is noted that the vertical glide planes with glide translations not parallel to the surface are not the symmetry elements of diperiodic plane figures.) Vertical glide planes whose translation vectors are parallel to the surface cause extinction lines in both ZOLZ and HOLZ reflections. Vertical screw axes are expected to form extinction lines in HOLZ reflections whose vectors are parallel to the screw axes. These reflections, however, cannot be observed by ordinary CBED. Thus, the extinction lines appearing in observable HOLZ reflections are used to identify not screw axes but glide planes. Examination of HOLZ extinction lines together with ZOLZ extinction lines is an efficient way to characterize the glide vectors and determine the space group.

The dynamical extinction lines appearing in HOLZ reflections caused by the glide planes whose glide vectors are not only parallel but also not parallel to the specimen surface were tabulated by Nagasawa (1983) for various incident-beam orientations of all the space groups that have glide planes. The tabulated results appear on pages 214–225 of the book by Tanaka *et al.* (1988). Table 2.5.3.12 shows the results. The meanings of the letters used in the table are explained in Fig. 2.5.3.13. We consider a vertical glide plane with a glide vector perpendicular to the surface as is shown in Fig. 2.5.3.13(*a*). Letter *A* is given for cases in which the Ewald sphere intersects two circled-cross reflections in the first Laue zone as seen in Fig. 2.5.3.13(*b*), where black circles and circled crosses denote allowed reflections and kinematically forbidden but dynamically allowed reflections due to the glide plane, respectively. *A** denotes cases in which the Ewald sphere intersects a circled-cross reflection on one side of the incident beam and a black-circled reflection on the other, as seen in Fig. 2.5.3.13(*c*). This case occurs only in space group $P2_1/a\bar{3}$. A_h denotes cases in which the Ewald sphere intersects a circled-cross reflection on one side but does not intersect on the other, owing to the asymmetric arrangement of reflections with respect to the incident beam.

The first column of Table 2.5.3.12 list the space groups and the following columns show the type of the extinction lines for possible incident-beam directions. In each pair of columns, the left-hand column gives the reflection indices of the extinction line and the symmetry elements causing the extinction and the right-hand column gives the type of extinction. The first suffix 1, 2 or 3 of a glide symbol distinguishes the first, the second or the third glide plane of a space group. The second suffixes 1 and 2, which appear in the tetragonal and cubic systems, distinguish two equivalent glide planes which lie in the *x* and *y* planes. The suffix o of a reflection index implies that the index is odd-order. Figs.

2.5.3.14(*a*) and (*b*) were taken for FeS_2, space group $P2_1/a\bar{3}$, with incident-beam directions of [100] and [110]. Inserts show enlarged HOLZ patterns for ease of viewing. Extinction lines of type *A* are seen in the $h_o k0$ HOLZ reflections in Fig. 2.5.3.14(*a*) due to the *b*-glide plane (equivalent to the *a*-glide plane in the space-group symbol) parallel to the (001) plane. An extinction line *A** is seen in an $h_o k0$ HOLZ reflection in Fig. 2.5.3.14(*b*) due to the same glide plane as that of Fig. 2.5.3.14(*a*). It should be noted that extinction lines in HOLZ reflections are better observed in thinner specimen areas than those suitable for the observation of the extinction lines in ZOLZ reflections, because the profiles of HOLZ reflections are concentrated into small areas of CBED discs in thicker specimens.

In summary, the use of not only ZOLZ, but also HOLZ extinction lines is recommended for space-group determination.

2.5.3.3.5. Symmetry elements observed by CBED

In the above sections, point-group and space-group determination methods were described following the theory of Buxton *et al.* (1976). They assumed that the observable symmetry elements are those of an infinitely extended parallel-sided specimen or of diperiodic plane figures. CBED patterns determine diffraction groups. Crystal point groups are identified by consulting Fig. 2.5.3.4, which gives the relations between diffraction groups and crystal point groups. When the assumption made by Buxton *et al.* (1976) is accepted in a strict sense, CBED symmetry m_2 caused by a twofold rotation axis oblique to the specimen surface, which is not a symmetry element of a diperiodic plane figure, ought not to be observed. However, the symmetry m_2 due to a twofold rotation axis in the $[1\bar{1}0]$ direction of an Si film with [100] surface normal has been clearly observed at [111] electron incidence (Tanaka *et al.*, 1988, p. 33). This indicates that crystal symmetry elements oblique to the specimen surface are observable when the specimen is tilted. An important condition for CBED is that the top and bottom surfaces be parallel over the specimen area illuminated by the incident beam. CBED observes the symmetry elements of a crystal to the extent that the boundary conditions at the specimen surface do not break the symmetries of the CBED patterns. Gjønnes & Gjønnes (1985) reported that the breaking of CBED symmetry due to a surface oblique to the incident beam is practically negligible.

In Section 2.5.3.3 on space-group determination, space-group symmetry elements of crystals which have glide and screw components parallel to the specimen surface were considered to act as space-group symmetry elements of diperiodic plane figures by mitigating the strict application of the assumption of diperiodic plane figures. In fact, vertical glide planes with a glide vector not parallel to the specimen surface, which were dealt in Section 2.5.3.3.4, are not the symmetry elements of diperiodic plane figures. Ishizuka (1982) showed theoretically that a vertical glide plane with a vertical glide vector produces dynamical extinction lines in HOLZ discs if the Laue zones are well separated. Tanaka *et al.* (1988, pp. 214–225) tabulated the extinction lines appearing in HOLZ discs caused by the vertical glide planes whose glide vectors are not only parallel but also not parallel to the specimen surface. Dynamical extinction lines caused by the glide planes with a glide vector not parallel to the surface have been demonstrated using FeS_2 and $MgAl_2O_4$ (Tanaka *et al.*, 1988, pp. 51–61).

Vertical 2_1, 3_1, 3_2, ..., 6_5 screw axes, which are not symmetry elements of diperiodic plane figures, are expected to form dynamical extinction lines in kinematically forbidden reflections that are located in the direction of the screw axes or of the surface normal. The extinction lines, however, are difficult to observe in ordinary CBED. Thus, CBED does not observe all the symmetry elements of the crystal space groups but observes many more symmetry elements than those of the diperiodic plane figures. It is clear now that it makes no sense to construct space groups using actually observable symmetry elements because they do not form a complete set of groups. It is of no importance to give the relation between the 230 space groups of crystals and the 80 space groups of diperiodic plane figures. Buxton *et al.*'s theory, which determines crystal point groups with the help of diperiodic plane figures, is very beautiful and successful. However, it is not correct to state that CBED observes the symmetry elements of the diperiodic plane figures. The use of the groups of diperiodic plane figures should be recognized as a convention for the sake of convenience. As a further example, horizontal screw axes and horizontal glide planes must be located at the middle of a specimen to form symmetry elements of the diperiodic plane figures. However, those screw axes and glide planes which are not located at the middle of a specimen do produce CBED symmetries. Since we now know that CBED does not observe the symmetries of the diperiodic plane figures but observes those of a physical crystalline specimen, we can determine the corresponding infinite crystal symmetries more freely, by using our knowledge of the symmetries of the sample concerned, guided but not restricted by the beautiful theory of Buxton *et al.* (1976).

One point to note, for symmetry determination, is that one has to be aware of spurious symmetries that appear for crystals of certain structure types (Tanaka *et al.*, 1988, pp. 20–32 and 42–45) and destroy the correct determination of the point and space groups. Another point for precise symmetry determination is that one has to be aware of how CBED symmetry is destroyed by a small breakdown of crystal symmetry (Tanaka *et al.*, 1988 pp. 46–47).

2.5.3.3.6. Examples of space-group determination

A simple example of point-group determination has already been given for Si in Section 2.5.3.2.5. In this section, two examples of space-group determination for rutile and samarium selenide are described, in which the point-group determination still accounts for an important part. The examples look to be a little sophisticated but are a good exercise for those who want to acquire experience in CBED space-group determination. The present determination is carried out by assuming the lattice parameters to be known.

Rutile (TiO_2). The space group of rutile is well known to be $P4_2/mnm$. The lattice parameters are $a = b = 0.459$ nm and $c = 0.296$ nm. Fig. 2.5.3.15(*a*) shows a CBED pattern taken with the [001] incidence at an accelerating voltage of 80 kV. Since no fine HOLZ lines appear in all the discs, projection diffraction groups (column VI of Table 2.5.3.3) have to be applied to explain this pattern. The projection (proj.) WP shows symmetry 4*mm*. The projection diffraction group is found to be $4mm1_R$ from Table 2.5.3.3. Thus, possible diffraction groups are $4m_Rm_R$, 4*mm*, 4_Rmm_R and $4mm1_R$. Another CBED pattern at a second crystal orientation needs to be taken because Fig. 2.5.3.15(*a*) shows only projection symmetry. Figs. 2.5.3.15(*b*) and (*c*) show CBED patterns taken with the [101] incidence at an accelerating voltage of 100 kV. In Fig. 2.5.3.15(*b*), which is the central part of Fig. 2.5.3.15(*c*), no HOLZ lines are seen. The symmetries of the projection BP and projection WP are both 2*mm*. The projection diffraction group of the pattern is $2mm1_R$. The WP of Fig. 2.5.3.15*(c)* is seen to have one mirror symmetry *m*. The diffraction groups which satisfy symmetry *m* are *m*, $m1_R$ and 2_Rmm_R. Among these diffraction groups, the diffraction group whose projection becomes $2mm1_R$ is only diffraction group 2_Rmm_R. By consulting Fig. 2.5.3.4, diffraction group 2_Rmm_R obtained from Figs. 2.5.3.15(*b*) and (*c*) and one diffraction group $4mm1_R$ among diffraction groups $4m_Rm_R$, 4*mm*, 4_Rmm_R and $4mm1_R$ obtained from Fig. 2.5.3.15(*a*) commonly satisfy point group 4/*mmm*. Thus, the point group of rutile is determined to be 4/*mmm*.

Fig. 2.5.3.15(*d*) shows an ordinary diffraction pattern taken with the [001] incidence at an accelerating voltage of 80 kV. With the help of the lattice parameters and the camera length, the indices of the reflections are given as shown in the figure. There
